KEYWORDS hybrid perovskites, resonant metasurfaces, plasmonic luminescence enhancement, Purcell effect

ABSTRACT Metal-halide perovskites are rapidly emerging as solution-processable optical materials for light emitting applications. Here we adopt a plasmonic metamaterial approach to enhance photoluminescence emission and extraction of methylammonium lead iodide (MAPbI₃) thin films, based on the Purcell effect. We show that hybridization of the active metal-halide film with resonant nanoscale sized slits carved into a gold film can yield more than one order of magnitude enhancement of luminescence intensity, and nearly threefold reduction of luminescence lifetime, corresponding to a Purcell enhancement factor of more than 300. These results show the effectiveness of resonant nanostructures in controlling metal-halide perovskite light emission properties over a tunable spectral range, a viable approach toward highly efficient perovskite light emitting devices and single-photon emitters.

TEXT Efficient nanoscale light sources are key elements for the development of advanced nanophotonic circuits and integrated thin-film optoelectronic devices. Thanks to their exceptional optoelectronic properties, hybrid organic-inorganic perovskites are gaining prominence for solid-state lighting and displays.^{1,2,3,4} Limiting factors to the adoption of perovskites in photonic applications are stability⁵ and low luminescence yield (low efficiency and relatively slow rate of spontaneous emission), which so far hindered the realization of perovskite-based high-speed light-emitting devices.^{6,7} A number of approaches have been adopted to overcome the luminescence yield limitation, ranging from micro-/nano-structuring of the perovskite materials^{8,9,10,11,12,13} to distributed feedback and microring lasing cavities.^{14,15,16,17,18,19} Thanks to their ability of trapping, confining and enhancing the optical fields in nanoscale volumes, plasmonic and dielectric metamaterials have proven to be an excellent platform for the enhancement of both linear and non-

linear properties of media,^{14,20} and have been used with great success for multifold enhancement of luminescence in variety of active materials like quantum dots, quantum wells and dyes and ultimately enabling both lasing and spasing.^{21,22,23,24,25,26} Here we exploit the design flexibility of plasmonic metamaterials to alter the luminescence of archetypical MAPbI₃ perovskite films hybridized with planar resonant nanoslits tailored to match their emission peak around 760 nm. We control the degree of photoluminescence enhancement by shifting the metamaterial resonance across the MAPbI₃ emission line and obtain more than one order of magnitude increase in light radiation from the perovskite film – correspondingly we observe a significant narrowing of the luminescence linewidth and almost three-fold reduction of the lifetime. These findings prove that hybridization of metal-halide perovskites with metamaterials could lead to the realization of more efficient and faster nanoscale integrated light emitting devices and lasers, as well as to the improvement of intrinsic radiative properties of perovskite compounds through the control of light-matter interactions at the nanoscale.

We selected a basic metamaterial design, a periodic array of nanoscale slits carved onto a continuous metallic film, which supports dipolar resonances in the visible spectral range whose wavelength is determined by the slit length. Six metamaterial nanoslit arrays (30 x 30 μm² squares) were fabricated by Focused Ion Beam (FIB) milling of a $h_{Au} \approx 30$ nm thin gold layer, evaporated over a glass substrate. The arrays feature an increasing slit length L , ranging from 100 nm to 150 nm, in steps of 10 nm, a constant slit width $W \approx 35$ nm, and a square lattice periodicity of $P = 2L$. Figure 1a-c show secondary electron images of three arrays with slits length $L = 100$ nm (1a), 120 nm (1b) and 140 nm (1c), captured over a $\sim 750 \times 750$ nm² field of view: they are presented side by side to produce a distinct perception of the increase in length and periodicity.

Figure 1: a-c) Secondary electrons images of slit metamaterials with slit length of, respectively, 100, 120 and 140 nm, carved by Focused Ion Beam (FIB) milling of a 30nm Au + 5nm SiO₂ film on glass substrate; d) secondary electrons image of a 150 nm slit metamaterial coated with 65nm thick MAPbI₃ perovskite film; scale bar is 100 nm e-f) top-view and cross-section maps of the electric field maps at resonance for a 120 nm long slit illuminated by 760nm light polarized along y, showing local field enhancement inside and in the vicinity of the slit, scale bar is 50 nm.

The MAPbI₃ precursor solution was spin-coated over the entire nanostructured sample, resulting in a $h_{MAPbI_3} \approx 65$ nm thin film with typical roughness of < 10nm, covering both the metamaterials (Figure 1d), the flat gold and a nearby patch exposing the glass substrate, to ensure as uniform as possible coating conditions for the arrays and the reference areas (see Fig S1 and S2 of Supporting Information). To avoid direct contact between gold and the perovskite film, thus preventing luminescence quenching and the possibility of gold diffusion into the perovskite,²⁷ a ~5 nm SiO₂ layer was thermally evaporated onto the sample before spin-coating the MAPbI₃ solution. Three-

dimensional full-wave electromagnetic simulations confirm the dipolar nature of the resonant field trapped inside the nanoslits and the enhancement of the field intensity and local density of states (LDOS), as shown in Figure 1e and 1f, respectively.

The photoluminescence spectrum of the MAPbI₃ perovskite film peaks around the optical bandgap energy of ~1.62 eV, with relatively narrow full-width-half-maximum (FWHM) of ~50 nm. Figures 2a and 2b show the simulated and experimentally measured optical absorption spectra of the different nanoslit metamaterials arrays fabricated, for normally incident light with polarization perpendicular to the slits (TM), before spin-coating the perovskite film. The bare metamaterial spectra feature well pronounced absorption resonances at progressively longer wavelengths with increasing slit length and crossing over the MAPbI₃ photoluminescence spectrum at 760 nm (Figure 2b).

The experimental optical spectra of the metamaterials were measured under normal incidence illumination, using a microphotospectrometer with a circular collection aperture of 25 μm diameter, which allowed removing edge effects from the metamaterial arrays. The simulated spectra were obtained by three-dimensional full-wave electromagnetic simulations using standard literature data for gold²⁸ and glass²⁹. It should be noted that, in this spectral interval, optical absorption of gold is low (4.5%), therefore the optical fields are mostly trapped within the slits or within the air/glass in its vicinity (Figures 1e-f), thus allowing strong interaction with the overlying perovskite film.

Figure 2: a) Simulated optical absorption resonance spectra for slit metamaterials with length varying from 100 nm to 150 nm, in 10 nm steps, (magenta to blue lines); b) experimental optical absorption resonance spectra for slit metamaterials with length varying from 100 nm to 150 nm, in 10 nm steps, overlaid with photoluminescence emission spectrum of a 65 nm thick MAPbI₃ perovskite film on glass (dashed black line)

The effect of the nanoslit gold metamaterials on the light emission properties of MAPbI₃ perovskite films was evaluated by measuring both steady-state and transient photoluminescence in three configurations: MAPbI₃ film on glass, MAPbI₃ film on gold (with ~5 nm SiO₂ spacer) and MAPbI₃ film on each of the six nanoslits metamaterial arrays (with ~5 nm SiO₂ spacer). In the steady-state measurements, we excited the perovskite film using a ps pulsed diode laser and measured the emitted light with a scanning monochromator spectrometer, while time resolved measurements were performed using a ~100 fs optical parametric oscillator (OPA) as pump and a streak-camera to record the photoluminescence. We have chosen an excitation wavelength of $\lambda=405$ nm, detuned from the metamaterials' resonance, and focused the laser beam to a spot size of about 15 μm to avoid any direct effect of the pump on the interaction between MAPbI₃ emission and nanoslits's resonances. All samples were pumped through the MAPbI₃ perovskite

film, with photoluminescence collected from the same side. In the case of metamaterials, observation from the opposite side would yield greater enhancement²²; however we opted for a measuring configuration that is more representative of the enhancement expected in multilayered electroluminescent devices, with light emitted across the film thickness and collected from the transparent bottom contacts.

The steady-state results indicate that the photoluminescence of the MAPbI₃ perovskite film is strongly enhanced by the interaction with the metamaterials and that the degree of enhancement can be controlled by the design of the nanoslits resonators. The measurements were performed selecting the polarization of the emitted light, whereas the polarization of the pump light was left unchanged since both the gold metamaterial and the perovskite film are polarization independent at this wavelength.

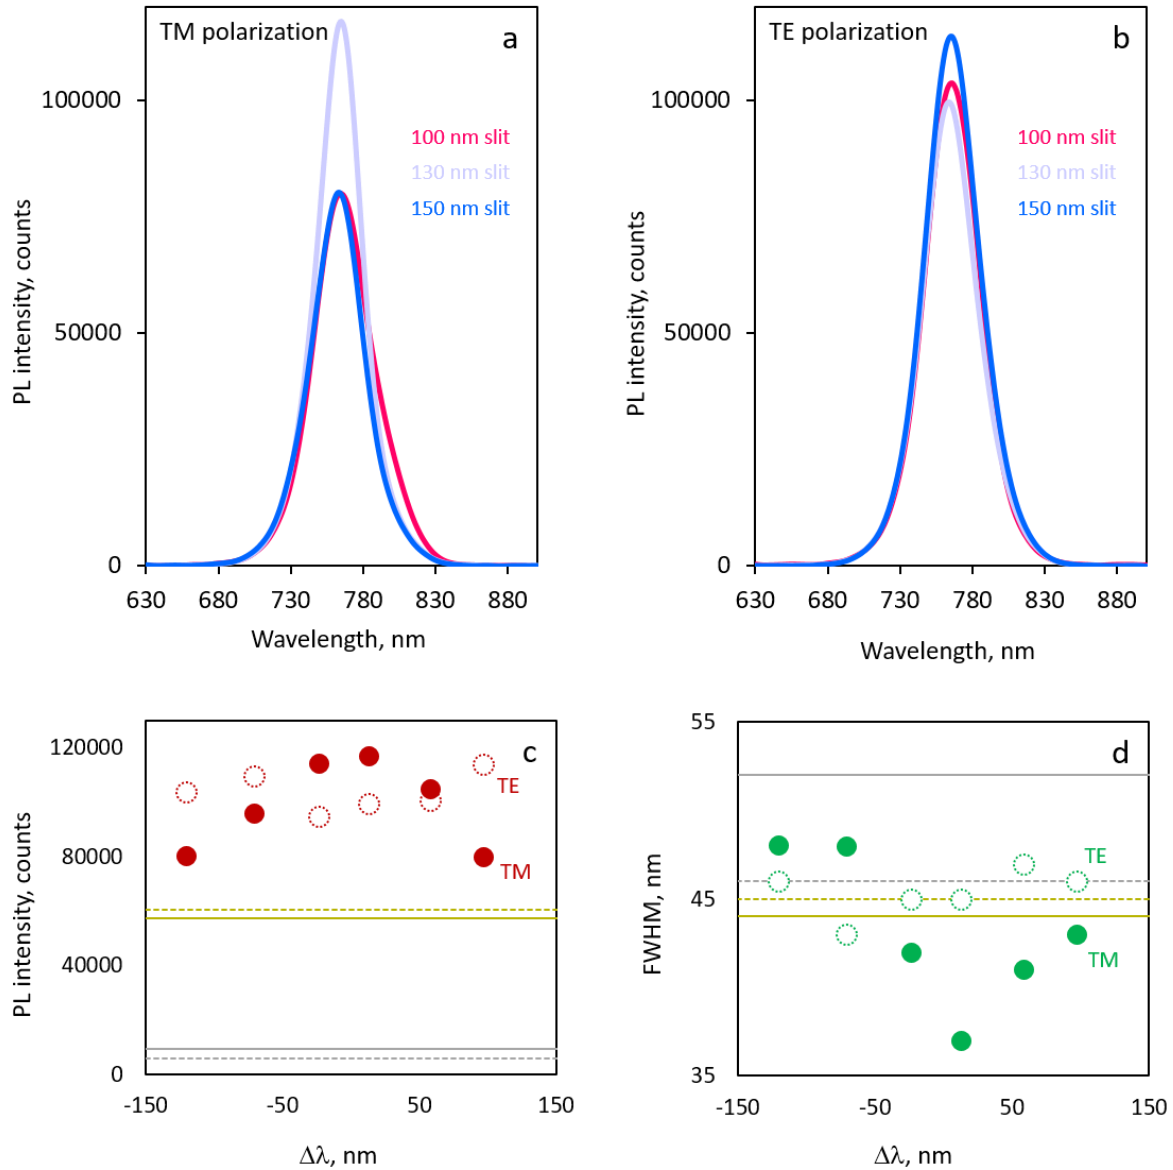

Figure 3: TM (a) and (b) TE (b) polarized spectra of a 65nm thick MAPbI₃ perovskite film on metamaterials with slit lengths of 100 nm (magenta), 130 nm (lilac) and 150 nm (blue); MAPbI₃ intensity (c) and linewidth (d) dependence as function of the wavelength mismatch between the metamaterial optical absorption resonance and the perovskite emission peak for both TM (full markers) and TE (dashed markers) polarizations [as reference, the horizontal lines indicate the intensities in TM (full lines) and TE (dashed lines) polarizations for the MAPbI₃ film on glass (grey), on gold (gold yellow)].

Figures 3a and 3b show the photoluminescence intensity of the perovskite film on metamaterials, for arrays whose resonance is blue-shifted (100 nm slit, magenta curve), centred (130 nm slit, lilac

curve), and red-shifted (150 nm slit, blue curve) with respect to the MAPbI₃ emission peak, in TM (perpendicular to slits) and TE (parallel to slits) polarizations, respectively. It is quite evident that, in TM polarization, the photoluminescence intensity is highest when the metamaterial resonance and the perovskite emission peaks match, while in TE polarization there is no clear dependence on the metamaterial resonance wavelength. To visualize how the photoluminescence intensity depends on the wavelength mismatch ($\Delta\lambda$) between the nanoslits resonance and the MAPbI₃ emission, we plot in Figure 3c the photoluminescence peak intensity for i) the MAPbI₃ film on glass (black horizontal lines), ii) the MAPbI₃ film on gold/SiO₂ (yellow horizontal lines) and iii) the MAPbI₃ film on all the six nanoslit metamaterial arrays (red circles), in both TM (full circles) and TE polarization (dashed circles). The following observations can be made: i) The MAPbI₃ photoluminescence intensity increases (~6x) when the film is placed in the vicinity of gold; ii) The MAPbI₃ photoluminescence intensity is further enhanced, by more than one order of magnitude (~12x), when the film is placed on the metamaterial slits; iii) TM polarized photoluminescence shows a clear dependence on $\Delta\lambda$, while TE polarized photoluminescence is unaffected by the mismatch between the metamaterial optical absorption resonance and the perovskite emission peak wavelengths. This indicates that resonant nanoslits cause a Purcell enhancement of the photoluminescence by confining the electrical field in a nanometric volume when they are excited with polarization perpendicular to the long axis of the slit²¹. Further evidence of the effect induced on the MAPbI₃ photoluminescence by the photonic mode's volume confinement is provided by the linewidth of the TM polarized photoluminescence emission, which decreases proportionally to $\Delta\lambda$, as shown in Figure 3d. The fact that photoluminescence enhancement is comparable for TM and TE polarizations shall be attributed to the non-conformal coverage of the nanoslit volume by

the perovskite films, as explained in Figure S3 (Supporting Information). This also suggests that the values reported here are only a lower bound for achievable enhancement factors³⁰.

A direct manifestation of the enhancement of radiative emission rates by the Purcell effect is the reduction of photoluminescence lifetimes.^{31,32} The photoluminescence decay traces for the MAPbI₃ perovskite film on metamaterial arrays with nanoslits of increasing length are plotted in Figure 4a, together with the fitting curves overlaid to the corresponding spectra (the spectra are vertically shifted for ease of visualization). The peak intensities of the decay traces show a clear dependence on $\Delta\lambda$ (Figure 4b), in good agreement with the behaviour of steady-state spectra. The photoluminescence of MAPbI₃ films on glass shows a double-exponential decay with characteristic lifetimes of $\tau_1 \approx 0.29$ ns and $\tau_2 \approx 4.8$ ns, which are in good agreement with previous assignments to Auger recombination (τ_1) and charge carrier relaxation through band-edge emission (τ_2)¹.

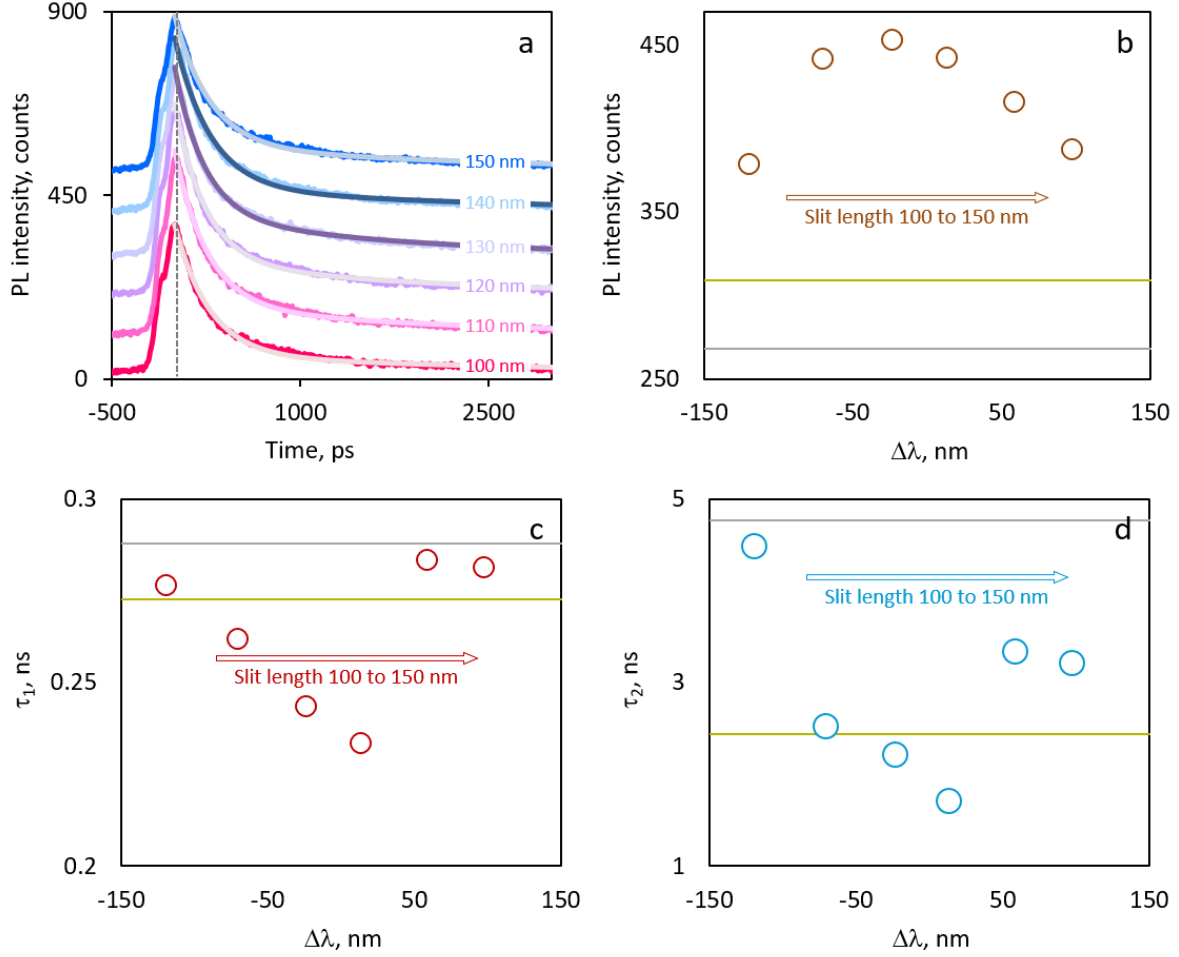

Figure 4: a) Time resolved photoluminescence of a 65nm thick MAPbI₃ perovskite film on metamaterials with slit lengths varying from 100 nm to 160nm, and fitting curves overlaid, (spectra are vertically shifted for ease of visualization); Time resolved photoluminescence peak intensity (b) and 2-exponential fitting time dependence (c & d) of MAPbI₃ on metamaterials as function of the detuning of the metamaterial resonance from the perovskite emission peak [as reference, the horizontal lines indicate the PL intensities for the MAPbI₃ film on glass (grey), on gold (gold yellow)].

The hybridization of the MAPbI₃ film with the nanoslit metamaterials induces a significant reduction of both τ_1 and τ_2 (Figures 4c and 4d, respectively), consistent with the dependence of photoluminescence intensity and linewidth on $\Delta\lambda$. The three-fold shortening of radiative lifetime τ_2 achieved at maximum overlap ($\Delta\lambda \sim 0$, when the metamaterial resonance wavelength matches the MAPbI₃ emission peak) corresponds to a Purcell factor of nearly 3. We also observe a slight reduction ($\sim 20\%$) of the Auger recombination lifetimes, τ_1 , correlated with the metamaterials

resonances, which may be attributed to plasmon-induced hot carrier generation³³. The Auger recombination in MAPbI₃ is usually very efficient compared to spontaneous emission because of the long-range electron-hole diffusion length: the hybridization of MAPbI₃ with metamaterials reduces the τ_2/τ_1 ratio from ~ 17 to ~ 7 , which suggests shortening of the carrier build-up time for population inversion in amplified processes (SE provides seed photons for photon cascade and the avalanche in amplified spontaneous emission, ASE), out-competing Auger processes in thin films. Therefore, the Purcell factor reported here shall be considered as a lower bound. If we consider the environment created by the metamaterial equivalent to a nanocavity, we can adopt the conventional definition of the Purcell Factor as $F = \frac{3}{4\pi} \left(\frac{\lambda}{n}\right)^3 \frac{Q}{V}$, where Q and V are the quality factor of the absorption resonance and mode volume for the 130 nm slit metamaterial. With $\lambda = 760$ nm, $n = 2.4$ for MAPbI₃, $Q = 5.6$ and $V = L \cdot W \cdot h_{Au}$, we estimate the Purcell enhancement factor to be $F = 317$. This is of the same order of magnitude of the enhancement of photoluminescence, $F = 12$, observed in experiments, which corrected for the fraction of MAPbI₃ inside the 130nm slits, $f = V/P^2 h_{MAPbI_3}$, corresponds to a factor $F = \mu/f = 386$. It should also be noted that time-resolved data were acquired for unpolarised emission, while steady-state measurements indicate that nanoslit cavities affect almost exclusively TM polarized photoluminescence. Moreover, all measurements were performed at room temperature, therefore a further increase in radiative rates could be expected at lower temperatures. Thus, the improvements in luminescence properties of perovskite films coupled to resonant metamaterial structures registered so far (enhancement of photoluminescence intensity, narrowing of steady-state linewidths and shortening of SE lifetimes) could arguably lead to a reduction of amplified spontaneous emission (ASE) and lasing thresholds, an important step towards integrated perovskites light emitting devices.

In summary, inspired by the proven ability of metamaterials to manipulate radiation, promote light-matter interaction and facilitate emission at any wavelength and across numerous types of media, we hybridized a metal-halide perovskite film with nanoslits gold metamaterials to control and enhance its optical emission. We demonstrated a substantial increase of the intrinsic photoluminescence intensity by more than one order of magnitude when the metamaterial resonance was tuned to the perovskite intrinsic emission peak. This increase in photoluminescence intensity is accompanied by a significant reduction in the spontaneous emission lifetimes, clearly indicating that the enhancement is radiative in nature. Improved performance and additional functionalities can be foreseen by optimization of the metamaterial structures and their coupling to the perovskite films (e.g., better permeation of the perovskite precursors into the nanostructured scaffold before conversion and crystallization). Similar design principles could also be adopted in the layout of electrodes³⁴. Thus, our strategy hints potential reductions of amplified spontaneous emission (ASE) and lasing thresholds, paving the way towards on-chip integrated perovskite photonic components with wide spectral tunability from UV to NIR, and could potentially constitute a viable architecture for perovskite-based integrated light emitting devices, both optically and electrically pumped.
