Abstract

Acute venous thromboembolism (VTE) is a common worldwide disease admitted to emergency departments (ED), usually presenting as pulmonary embolism or lower limb deep vein thrombosis (DVT). Due to the lack of typical clinical and biomarker diagnostic features of unprovoked VTE, early identification is challenging and has direct consequences on correct treatment delay. Longitudinal, prospective, observational study. Patients admitted to ED with a suspicion of unprovoked acute VTE between October 2020 and January 2021 were included. Clinical and laboratorial variables were compared between VTE positive and negative diagnoses. Red cell distribution width (RDW) cut point was determinate through a receiver operating characteristic analysis. RDW accuracy, sensitivity, and specificity were calculated. Fifty-eight patients were analyzed. And 82.8% of suspected patients with VTE were diagnosed with an acute thrombotic event confirmed by imaging examination. In patients with VTE, RDW at admission in ED was higher than with other diagnosis, respectively, 14.3% (13.2-15.1) and 13.5% (13.0-13.8). Platelet count was the only additional characteristic that revealed difference between the 2 groups ($264 \times 10^9/L$ for VTE and $209 \times 10^9/L$ for non-VTE). Logistic regression models showed good discriminatory values for $RDW \geq 14\%$, with an area under the curve (AUC) = 0.685 (95% confidence interval, 0.535-0.834). These findings were more pronounced in isolated DVT, with a sensitivity of 76.9%, specificity 100%, and accuracy 85.7%. Our study demonstrated a significant association between an early high RDW and the diagnosis of acute unprovoked DVT. $RDW \geq 14\%$ has an independent predictor of unprovoked VTE in adult patients.

Date received: 28 May 2023; revised: 3 July 2023; accepted: 24 July 2023.

Introduction

Pulmonary embolism (PE) and lower limb deep vein thrombosis (DVT) are the most frequent clinical expressions of acute venous thromboembolism (VTE), resulting in an annual incidence equal to that of stroke.¹ Acute VTE episodes have a significant and constant impact on health resources, accounting for 1 million emergency visits in the United States, being half of them admitted to hospital.² VTE episodes occurring out-of-hospital, compared to those acquired in hospitals, are about 40 times less frequent but have a wide range of related risk factors and morbidities.³ Due to the heterogeneity of these demographic and clinical characteristics, particularly in PE cases, and the absence of specific and sensitive biomarkers, VTE diagnosis in the emergency departments (ED) is a high challenge to physicians. No single clinical symptoms

are predictive or exclude PE, although the lack of dyspnea slightly reduces the probability of PE.⁴ The clinical presentation of VTE is unspecific,⁵ particularly for unprovoked cases, characterized by the absence of any transient or persistent environmental risk factor.⁶ When patients are admitted to the ED, the risk of VTE is assessed by clinical gestalt or clinical scores according to symptoms and existing risk factors.⁷ This risk assessment is the first diagnostic step after suspicion of VTE and it is usually followed by D-dimer measurements to determine whether further investigations are required. Small or intermediate clinical probabilities and negative D-dimers can exclude PE⁸⁻¹⁰ and DVT,¹¹ but the results of positive D-dimers have a low-positive predictive value and are not useful for VTE diagnosis.¹²⁻¹⁴ The key to diagnosis of PE and DVT is still to perform imaging examinations, computed tomography (CT) angiogram, and Doppler ultrasound, respectively. Accessibility, radiation exposure, time-to-exam and high costs are some of the critical aspects that are due to the need of such examinations. The absence of alternative diagnostic biomarkers for VTE has a direct impact on the percentage of 60% undiagnosed cases among all VTE-attributable deaths.¹⁵

Efforts have been made to increase the knowledge on the diagnostic and prognostic importance of red cell indices of cardiovascular diseases. Red blood cell distribution width (RDW) is a measurement of size heterogeneity of circulating erythrocytes,¹⁶ which has been studied as a prediction tool for cardiovascular and thrombotic diseases, including PE,¹⁷⁻¹⁹ although some conflicting results have prevented it from being used in everyday practice. The diagnostic role of RDW for acute VTE is even less well understood. A previous retrospective study on VTE found an association between high RDW at admission to ED and acute VTE, and determined a cutoff of 14.6%, with an Negative Predictive Value (NPV) of 0.85 for DVT and 0.91 for PE, suggesting that RDW could supplement clinical preliminary examinations to exclude acute VTE attacks.²⁰ This study, even considering some limitations, has set a possible threshold of RDW > 14% at admission for distinguishing VTE from non-VTE patients in acute care setting.

In response to the same questions, we decided to investigate the early RDW values in patients admitted to the ED for suspected acute unprovoked VTE episodes and compare clinical characteristics and biomarkers of patients with confirmed and excluded VTE diagnosis.

Methods

Study Design and Settings

We conducted a prospective longitudinal, observational study aiming to describe and compare clinical and laboratory parameters of patients admitted in an ED with suspected VTE, including PE and DVT, from October 2020 to January 2021.

Participants

The study included patients admitted in the ED who were clinically suspected of an acute VTE and referred, according to usual clinical practice, for imaging examinations for diagnosis confirmation.

Inclusion criteria were individuals aged ≥ 18 years with unprovoked suspected acute VTE cases (DVT or PE) admitted in the ED, or transferred to the ED (eg, from an outpatient clinic or other hospital) with a diagnosis of suspected acute VTE <24 h. Patients were excluded if there was VTE suspicion more than 24 h before admission to the ED, life expectancy of <3 months, active neoplasia, pregnancy or breastfeeding, COVID-19 diagnosis, and fever at admission.

Ethical Considerations

The study was conducted in accordance with current International Council for Harmonisation Good Clinical Practice guidelines, and according to Declaration of Helsinki principles. The study protocol was approved by Hospital Beatriz Angelo Ethical Committee and Board. Written informed consent was obtained from all enrolled subjects.

Procedures and Data Collection

Data were collected from patients' medical records. All patients were screened for the presence of VTE and depending on the clinical suspicion thoracic angiotomography for PE and/or lower limb venous Doppler ultrasound for DVT were performed according to usual clinical practice.

The VTE diagnosis was ruled out, if the imaging examinations were negative for the initial suspicion, and another diagnosis was established.

Clinical, Biochemical Parameters, and Imaging Examinations

Collected data included: demographic data (sex and age), present and past medical history, previous medication, physical examination, vital signs, peripheral oxygen saturation, and laboratory parameters such as red blood cells, hemoglobin, hematocrit, RDW, platelets, total leukocyte count, creatinine, D-dimer, and C-reactive protein. All patients performed an imaging examination in the first 24 h after admission to the ED, according to physician's dispositions. The imaging considered to include patients in the analysis consisted of thoracic CT angiography for PE-suspected cases and lower limb Doppler ultrasound for DVT suspicions. Patients were allowed to perform both examinations in the same period.

Statistical Analysis

Continuous data were presented as median and interquartile ranges, mean and standard deviation (SD), maximum and minimum. Discreet variables were presented as absolute and relative frequencies. The normality of the data was assessed using the Shapiro-Wilk test.

Between-group (VTE vs non-VTE) comparisons of continuous variables were performed using Mann-Whitney U tests. Categorical variables were compared using Fisher's exact test.

A receiver operating characteristic curve analysis was used to evaluate the diagnostic value and to define the diagnostic cutoff value of RDW concentrations. Using the cutoff point defined, the RDW were compared between VTE versus non-VTE by the Fisher's exact test.

A logistic regression model was implemented to interrogate the significance of the association of RDW in patients with VTE, considering demographic and other clinical variables.

A significant level of 0.05 was considered for all the analysis. SPSS 26.0 statistical software was used to analyze the data.

Results

Patients' Characteristics and VTE Diagnosis

A total of 59 participants were initially enrolled. One patient abandoned ED without any imaging examination and was excluded. Of the 58 patients included in the analysis, 44 completed thoracic CT angiography and 33 lower limb Doppler ultrasound with diagnostic results of adequate quality, with 19 patients carrying out both examinations. The characteristics of 58 patients are summarized in Table 1. There was a total of 48 patients (82.8%) with an acute VTE diagnosis and the remaining 10 patients received an alternative diagnosis. There was no significant difference between patients with

VTE and without VTE diagnosis in terms of clinical presentation. Considering 44 patients who completed a thoracic CT angiography, 35 (80%) presented features of acute PE, as shown in Table 2. Of those patients who performed a lower limb Doppler ultrasound, 70% (25 cases) presented were diagnosed with acute DVT. According to the imaging examinations, 21% (10 cases) of patients with VTE were diagnosed with both acute PE and acute DVT.

In terms of laboratory investigation, there were significant differences on platelet count and RDW between VTE and non-VTE patients. There were no differences in hemoglobin, hematocrit, leukocytes, and D-dimer. Since RDW was the variable showing the strongest association with acute VTE in the univariate analysis, we focused on RDW for further analyses.

All patients were discharged from the hospital.

Diagnostic Performance of RDW $\geq 14\%$

The diagnostic accuracy of RDW $\geq 14\%$ for determining an acute VTE, as quantified by the area under the curve, was 0.685 (95% CI, 0.535-0.834; Figure 1). At a threshold of $\geq 14\%$, RDW ruled in 47% of individuals, with a sensitivity of 55.6%, specificity 100%, and accuracy 79.0% (95% CI, 65.6%-89.0%). For isolated PE RDW $\geq 14\%$ had a sensitivity

VTE. We evaluated the diagnostic value of clinical and laboratory findings at the time of ED presentation, keeping in mind the need for urgent recognition of acute VTE in this setting, for the emergent initiation of anticoagulation and, in the catastrophic situations, fibrinolytics therapy.²¹⁻²³ Our findings showed that RDW value and platelet count were the only variables with a significant association with acute DVT. A high RDW (\geq 14.0%) at admission to ED was significantly associated with the presence of acute DVT, independent of other clinical and laboratory variables, including D-dimer. These findings are consistent with those of previous general population studies or retrospective series,²⁴⁻³⁰ that utilized healthy controls for comparison. RDW was demonstrated to be higher than normal cutoffs in such diverse conditions as cardiac stent thrombosis,³¹ heart failure,³² inflammatory diseases,³³ or acute exacerbation of chronic obstructive pulmonary disease.³⁴ One of the studies²⁴ described the association of an RDW $>$ 14% to acute deep and superficial vein thrombosis at an ED at the admission, but it mixed unprovoked and provoked VTE—by cancer, trauma, infection, surgery, and other causes—which can be very different populations in terms of RDW. More so, it used outpatients on routine follow ups as controls, expected to present normal RDW, thus not completely reliable as a comparator if we consider that RDW is higher in many of the diseases presenting to the ED. To the best of our knowledge, this is the first study to document that high RDW is associated with the presence of VTE among acutely ill patients who present clinical features suspicious of acute unprovoked VTE, thus distinguishing confirmed from excluded VTE cases. The detailed analysis of RDW $>$ 14% confirmed its high specificity and positive predictive value for distinguishing between acute VTE and other alternative acute diseases, in line with the aforementioned results. We could also observe that all patients admitted to the ED who were diagnosed non-VTE conditions had higher than normal RDW measurements, but RDW value was always inferior to 14%. In the light of these data, we propose that RDW $>$ 14% could be tested as an early biomarker to predict acute VTE among acutely ill patients.

For unprovoked VTE attacks, which make up to a half of all acute VTE episodes³⁵ and present a much higher risk of recurrence compared to patients with VTE provoked by a major transient risk factor,^{36,37} baseline risk assessment of patients with suspected VTE on ED admission may be particularly difficult. The lack of typical clinical characteristics, which our study also found, increases the risk of unprovoked VTE being missed. The use of a high D-dimer should be discouraged to differentiate acute VTE in situations of acute medical or surgical illnesses, even with cutoff adjustments.³⁸⁻⁴⁰ Considering the high prevalence of high D-dimer values in these circumstances, ordering costly, often unavailable, and potentially harmful, contrasted imaging tests for exclusion of VTE is necessary. Our study found that an RDW > 14% alone, for both PE and DVT, had a significant positive predictive value, which is comparable to the association of clinical assessment and D-dimer for low-risk patients. We have arguments to suggest that this diagnostic parameter should be further studied, along with clinical characteristics and risk factors, to augment both the specificity and sensitivity of scores in the early diagnosis of acute VTE. The low specificity demonstrated by D-dimer for both PE and DVT,^{12,41} and that contrasts with its significant negative predictive value, limits its usefulness among acute ED patients. By contrary, further evidence on a high positive predictive value of RDW > 14% in the first hours of acute VTE, particularly in DVT that showed more consistent results when we analyzed separate subgroups of venous thrombosis, may add some value to the existing algorithms. In fact, the combination of both D-dimer and RDW measurements may, eventually, contribute to a higher predictive value of clinical and easily ready blood tests to the diagnosis before imaging examinations. Being this confirmed, we could expect a strong impact in clinical settings where imaging examinations are not immediately accessible and the decision making for beginning anticoagulation is needed.

Our study had several limitations. The first one is directly related to COVID-19 pandemics. During COVID-19 pandemics, worldwide ED were re-arranged to handle patients with potential or confirmed SARS-CoV-2. There was a modification of accessibility to EDs during COVID-19 pandemics, overloaded with COVID-19 cases that consumed most healthcare resources, preventing patients from receiving clinical care. ED visits declined 44%,⁴² and clinical assessment of all incoming patients were likely altered from the "usual" procedures. Furthermore, disorders like PE and DVT, which require extensive workups, may have been significantly affected by the reduction in one-third of the diagnostic examinations. Although in Portugal 48% reduction in ED visits did not impact the mix case of visiting patient,⁴³ little is known about the use of diagnostic imaging tests in the ED. In the light of these details, we could advise against extrapolating the findings to a population not affected by the COVID-19 pandemic. The same caution should be applied due to our small-sized and single-center population. Although we collected data on concomitant diagnosis (ICD-10), we were not exhaustive and lack data on nutritional status, shown to modify RDW among unhealthy populations.²⁰ Finally, we would like

to address the dearth of information regarding patient outcomes. Aside from the mortality outcome, we lacked information on the clinical evolution during the in-hospital stay and after hospital discharge. The analysis of those variables could provide some insight into the potential prognostic significance of RDW over the course of the illness.

In summary, we have demonstrated that high RDW and platelet count, 2 parameters that are inexpensive and easily obtainable, were independently associated with an increased risk of venous thrombosis. Further research is necessary to determine whether this association is causative. Future studies should target the evaluation of these variables as predictors of a recurrent event, which could assist in future decisions regarding anticoagulation and prophylaxis.

Acknowledgments

Our sincere gratitude to Ana Sofia Corredoura, M.D. and Andreia Carlos from the Department of Emergency Department, Hospital Beatriz Ângelo, Loures, Portugal for their contribution and to all colleagues who supported us in patient recruitment. We also acknowledge the participants and their family for contributing by enrolling in the study.

Authorship

Conception, study design, and analyses were conducted by CF and AM. Data collection was conducted by CF, VS, and FF. The first draft of the article was written by CF. All authors critically reviewed and revised multiple drafts of the article and approved the final article before submission.

Declaration of Conflicting Interests

The authors declared no potential conflicts of interest with respect to the research, authorship, and/or publication of this article.
