## 1 ABSTRACT

2

3 Although nutrient enrichment of estuarine and coastal waters is considered a key factor for the  
4 development of green tides, the extent, distribution, and species composition of blooms vary  
5 among systems of similar nutrient loading, which compromises our ability to predict these  
6 events based on information about nutrient status alone. Additional factors may play a role in  
7 the control and development of macroalgal blooms. The identification of relevant scales of  
8 variation is a necessary prerequisite before explanatory models can be proposed and tested. In  
9 this study spatial and temporal patterns of biomass distribution were assessed for two *Ulva*  
10 morphologies in two Irish estuaries heavily affected by green tides (wet biomass >1kg m<sup>-2</sup>  
11 during the peak bloom). Moreover, using genetic markers, the species composition of these  
12 green tides was assessed. Results revealed that these blooms were multi-specific, with *Ulva*  
13 *prolifera*, *U. compressa* and *U.rigida* the most frequent species. The species *U. prolifera* and *U.*  
14 *compressa* usually showed a tubular morphology, while *U. rigida* was mainly laminar. A  
15 seasonal succession common to both estuaries was also identified, with the bloom dominated  
16 by tubular species during spring and early summer, and co-dominated by tubular and laminar  
17 morphologies during late summer and autumn. Moreover, tubular and laminar morphologies  
18 exhibited different distribution patterns, with tubular morphologies varying at bigger spatial  
19 scales and higher biomass than the laminar. As tubular and laminar morphologies exhibited  
20 different distribution patterns, varying tubular morphologies along bigger spatial scales with  
21 higher biomass levels than the laminar. Considering that tubular morphologies were usually  
22 anchored to the sediment, while laminar *Ulva* were usually observed free-floating, these  
23 differences could explain a differential influence by water motion. An important annual and  
24 decadal variability in biomass levels of *Ulva* was observed, in the case of the Tolka estuary a  
25 noticeable increase over the last two decades. These findings should be considered for the  
26 development of management and monitoring strategies since the different habitat of laminar  
27 and tubular morphologies (anchored vs. free-floating) may play an important role in the balance  
28 of nutrients and biomass in the estuary, or determine the response to pollutant exposure.  
29 Furthermore, the presence of different species with different ecological requirements could  
30 favour the duration and extension of the bloom though temporal and spatial successions.

33 Biodiversity.

34

## 1        **1. Introduction**

2  
3        Nutrient enrichment of marine and transitional waters has increased worldwide as  
4 consequence of the growing human population, especially in the coastal zone (Nixon et al.,  
5 1986; Teichberg et al., 2010). In European coastal waters eutrophication has been identified as  
6 a key pressure, and the reduction of nutrient loads as the main restoration measure (Hering et  
7 al., 2010). In transitional water bodies such as coastal lagoons or estuaries, one of the most  
8 evident signs of eutrophication is the accumulation of fast-growing opportunistic macroalgal  
9 species, mainly Ulvoid species (Teichberg et al., 2010). These accumulations of macroalgae, or  
10 so-called “seaweed tides” or “seaweed blooms”, are named according to the colour of the main  
11 species present, either green tides (e.g. *Ulva*, *Cladophora*, *Chaetomorpha* or *Ulvaria*) or golden  
12 tides (e.g. *Sargassum* or *Ectocarpaceae*), and in the case of red macroalgae, red seaweed  
13 tides (e.g. *Gracilaria*) (Smetacek and Zingone, 2013; Thornber et al., 2017). Although  
14 macroalgae causing seaweed tides are not themselves toxic to humans, the blooms can affect  
15 shore-based activities by virtue of their sheer physical mass (e.g. navigation, tourism, fisheries;  
16 Smetacek and Zingone, 2013). More importantly, biomass degradation can cause serious  
17 amenity and public health impacts as a consequence of oxygen depletion and the release of  
18 sulphuric compounds, which can be harmful for humans and wildlife (Valiela et al., 1997; Sfriso  
19 et al., 2003).

20        Although nutrient enrichment of estuarine and coastal waters seems to be a key factor  
21 explaining the development of macroalgal blooms (Valiela et al., 1997; Teichberg et al., 2010;  
22 Smetacek and Zingone, 2013), the extent, distribution, and species composition of blooms vary  
23 strongly among systems of similar nutrient load, which compromises our ability to predict such  
24 events based on information about nutrient status alone (Bonsdorff, 1992; Malta and  
25 Verschuure, 1997; Lotze et al., 2000). Additional factors may play a role in the development of  
26 macroalgal blooms, such as local coastal geomorphology, hydrodynamic conditions, irradiance,  
27 water temperature, grazing or propagule bank size (Lotze et al., 2000; Nelson et al., 2008;  
28 Thornber et al., 2017). In addition, the local pool of species capable of producing a bloom can  
29 also stimulate or prolong the intensity and duration of the bloom, since a temporal and spatial  
30 succession can occur (Lavery et al., 1991; Nelson et al., 2003; Guidone and Thornber, 2013). In  
31 this sense, the arrival of cryptic non-native species could account for the occurrence of  
32 macroalgal tides in places where nutrients conditions have remained more or less constant (e.g.  
33 Yabe et al., 2009; Yoshida et al., 2015). Therefore an understanding of the factors that control  
34 the occurrence and development of seaweeds tides is key for the implementation of effective  
35 management strategies.

36        The genus *Ulva* is notorious for producing green tides (Valiela et al., 1997; Wang et al.,  
37 2015; Thornber et al., 2017). Species belonging to *Ulva* genus have a simple morphology,  
38 consisting either of a monostromatic tubular thallus (formerly *Enteromorpha* genus; Hayden et  
39 al., 2003) or a distromatic laminar thallus. Although in some cases microscopic traits can be  
40 useful for taxonomic identification, the high plasticity and the lack of reliable traits especially in

1 detached specimens forming *Ulva* blooms (e.g. lack of the basal part, intermediate size of cells  
2 or numbers of pyrenoids, etc) confounds accurate identification (Malta et al., 1999; Guidone and  
3 Thornber, 2013). Molecular genetic information is a powerful tool to overcome these challenges.  
4 In this sense, the large subunit of ribulose-1,5-bisphosphate carboxylase/oxygenase (*rbcL*) has  
5 been shown to reliably amplify with published primers and to provide enough variation to  
6 distinguish species within the genus *Ulva* (e.g. Hayden et al., 2003; Heesch et al., 2009; Wan et  
7 al., 2017).

8 The study of spatial and temporal patterns of variation in natural assemblages can be helpful  
9 to identify or infer the processes or factors affecting benthic assemblages (e.g. Benedetti-  
10 Cecchi et al., 2001; Terlizzi et al., 2007; Bermejo et al., 2015). The identification of relevant  
11 scales of spatial and temporal variation is a necessary prerequisite, before explanatory models  
12 can be proposed and tested (Andrew and Mapstone, 1987). Estuaries are highly dynamic and  
13 complex ecosystems subjected to significant fluctuations in physico-chemical conditions due to  
14 natural and anthropogenic processes, which produce an important variability in the structure  
15 and composition of natural assemblages (Nelson et al., 2003; Carvalho et al., 2011). In the case  
16 of green tides formed by *Ulva* spp., significant variations in biomass distribution and abundance  
17 have been observed at different temporal and spatial scales. This has been explained by  
18 diverse biotic and abiotic processes, such as desiccation, time availability for nutrient uptake  
19 and photosynthesis, grazing, salinity gradients, or geomorphological characteristics in relation to  
20 prevailing winds, currents, and tidal dynamics, which favour or preclude the accumulation of drift  
21 seaweeds (Aldridge and Trimmer, 2009; Park et al., 2014; Lanari and Copertino, 2016).

22 The objectives of this study were: i) to infer the most important factors controlling the  
23 development and persistence of green tides, by assessing spatial and temporal patterns of  
24 biomass distribution in two estuaries; and ii) by combining morphological characters and genetic  
25 markers, to assess the species composition of these tides.

## 26 27 **2. Materials and methods**

### 28 29 *2.1. Study sites, experimental design and sample collection*

30  
31 Two estuaries in Ireland (Tolka on the east coast – Irish Sea; and Argideen along the south  
32 coast – Atlantic Ocean; Fig. 1) affected by large green tides were studied over seven sampling  
33 occasions, in order to assess the spatial and temporal patterns of variation in *Ulva* biomass  
34 between June 2016 and August 2017. Both study areas are shallow, nutrient enriched estuaries  
35 with broadly similar physical characteristics. The Argideen is the larger estuary with a surface  
36 area of 9.3 km<sup>2</sup> and a length of 6.49 km vs 3.6 km<sup>2</sup> and 4.58 km for the Tolka. The residence  
37 time in the Argideen is 4 days (Ní Longphuirt *et al.*, 2015) compared to 5.4 in the Tolka estuary  
38 (calculated as per Hartnett *et al.*, 2011). The mean depth was 3.7 m for the Argideen and 2.1 m  
39 for the Tolka. Both estuaries showed a similar tidal range (4.4 m for the Tolka, and 4.3 m for the  
40 Argideen).

1 The Tolka estuary is located in a large urban catchment in the greater Dublin area.  
2 Maximum DIN concentrations are found during winter (28.43  $\mu\text{M}$  in February 2017). In the case  
3 of SRP, the highest concentrations are measured during summer (1.98  $\mu\text{M}$  in June 2017). The  
4 Argideen estuary is dominated by an agricultural landscape with diffuse nutrient inputs. The  
5 highest DIN concentrations are observed during winter (18.13  $\mu\text{M}$  in February 2017). The SRP  
6 do not follow a clear seasonal pattern (Table 1) in this estuary, ranging from 0.20  $\mu\text{M}$  (April  
7 2017) to 0.71 (August 2017). The Tolka was classified as eutrophic and the Argideen as  
8 potentially eutrophic in a recent assessment of water quality (O'Boyle and Tierney, 2018).

9 Both estuaries were sampled within a maximum period of one week on each sampling  
10 occasion, so as to avoid temporal effects that may confound any spatial variation. For logistical  
11 reasons, the first sampling occasion was performed within a period of three weeks. On each  
12 sampling occasion, a hierarchical design was applied to identify relevant scales of spatial  
13 variation, both parallel and perpendicular to the coast (Fig. 1 a and b). The estuaries were  
14 divided into two sections, one close to the open sea ("outer section") and another one kilometre  
15 upstream towards the freshwater-tidal limit ("inner section"). In each section, two sampling sites  
16 separated by one hundred meters were selected. Two random transects perpendicular to the  
17 main channel and separated by 10 meters were sampled per site. The only exception was the  
18 first sampling occasion in Tolka, where only one transect per site was collected in the inner  
19 section of the estuary. Along each transect, three sampling stations were positioned in the upper,  
20 middle and lower part of the intertidal covered by the bloom during their maximum extension,  
21 which usually occurs in June or July in cold-temperate North Eastern Atlantic estuaries (e.g.  
22 Jeffrey et al., 1995; Malta and Verschuure, 1997; Lyngby et al., 1999; Scanlan et al., 2007). The  
23 sampling stations were pre-determined using Google Earth images of blooms from previous  
24 years. The pre-defined sampling stations were located in the field using a Geographical Position  
25 System (GPS; Magellan Triton 400). At each sampling station, three quadrats (25 x 25 cm)  
26 were used to assess the abundance of seaweed. All living material present in each quadrat was  
27 collected, placed in a labelled plastic bag and transported to the laboratory.

## 28 29 *2.2. Sample processing*

30  
31 Seaweed biomass was rinsed with freshwater to remove adherent sedimentary and  
32 particulate material, debris and other organisms. Laminar and tubular morphologies of *Ulva*  
33 were sorted, and their mass was recorded after the removal of the excess water using a  
34 manually operated low-speed centrifuge (i.e. salad spinner). Subsequently, biomass was  
35 standardised to gram per square meter, by multiplying the obtained weight in the 25 x 25 cm  
36 quadrat by 16. Finally, a subsample of morphologically representative specimens of *Ulva* was  
37 collected for further microscopic and molecular identification.

## 38 39 *2.3. Taxonomic identification*

40

1 Based on macroscopic and microscopic traits, representative specimens of *Ulva* were  
2 collected on five sampling occasions (June16; August16; October16; April 17; and June 17). A  
3 part of each specimen was then stored in dry silica gel for genetic analysis, and for specimens  
4 of sufficient size, the remainder was prepared as a herbarium voucher.

5 A plastid-encoded marker was employed to genetically identify the samples, the large  
6 subunit of the Ribulose Biphosphate Carboxylase-Oxygenase (RuBisCO) (*rbcL*). Whole  
7 genomic DNA was extracted from ~5-20 mg of preserved *Ulva* tissue using a commercial kit  
8 [NucleoSpin® Plant II, Macherey-Nagel, Düren, Germany]. The *rbcL* gene region was amplified  
9 in polymerase chain reactions (PCRs), using primers SHF1 and SHR4 at an annealing  
10 temperature of 50°C (Heesch et al., 2009). Protocols for PCR amplification, purification of the  
11 products and sequencing are given in Heesch et al. (2016).

12 Representative sequences from both estuaries were included in an alignment containing 62  
13 sequences in total: 35 published and 19 newly generated in this study of the genus *Ulva*, and an  
14 outgroup comprised of eight sequences, six of the related genus *Umbraulva* and one each of  
15 the genera *Gemina* and *Ulvaria* (see Fig. 2 for GenBank accession numbers and references).  
16 Sequence treatment (quality control and alignment) as well as data analysis under the  
17 Maximum Likelihood (ML) criterion followed methods published in Heesch et al. (2016). The  
18 taxonomical algal nomenclature followed AlgaeBase (Guiry et al., 2014).

## 19 20 2.4. Statistical analyses

### 21 22 2.4.1. Spatial and temporal patterns of variation

23 Statistical analyses were performed using the Vegan package (Oksanen et al., 2012) for R  
24 and PERMANOVA+ add-on PRIMER 6 (Plymouth Routines in Multivariate Ecological  
25 Research) software. In all statistical analyses significance was set at  $p < 0.05$  probability, and  
26 when necessary were based on 1999 permutations. When comparisons with previous studies  
27 were made, dry weights were transformed to fresh weights assuming a 0.12 fresh:dry biomass  
28 ratio following Merceron et al. (2004).

29 In order to identify relevant spatial and temporal scales of distribution in the morphological  
30 composition of the green tides, a multivariate six-way permutational analysis of variance  
31 (PERMANOVA; Anderson et al., 2008) was performed based on the Euclidean distances  
32 between quadrats considering the standardized biomass of both tubular and laminar  
33 morphologies. The six factors considered (three fixed and three random) were: Sampling  
34 occasion (fixed; seven levels: "June 16", "August 16", "October 16", "February 17", "April 17",  
35 "June 17", and "August 17"), Position in the bloom (fixed; three levels: "upper", "middle" and  
36 "lower"), Estuary (fixed; two levels: "Tolka" and "Argideen"), Section (random; two levels nested  
37 in Estuary: "Inner" and "Outer"), Site (random; two levels nested in the interaction between  
38 Section and Sampling occasion), and Sampling station (random; two levels nested in the  
39 interaction between Site and Position). In case of significant effects for a factor, a distance-  
40 based test for homogeneity of multivariate dispersion (PERMDISP; Anderson et al., 2008) and a

1 pairwise PERMANOVA test (Anderson et al., 2008) were performed in order to interpret  
2 patterns.

3 Furthermore, to identify the most relevant scales of variation in biomass for each of the  
4 morphologies in the two estuaries, two univariate PERMANOVA analyses based on Euclidean  
5 distances between quadrats were performed following the six-way model previously described.

#### 7 2.4.2. Correlations between biomass and environmental variables

8  
9 In order to identify the factors that better explain bloom development, Spearman's  
10 correlations among the biomass of both tubular and laminar morphologies, and environmental  
11 variables were measured. To perform these correlations, the median biomass of both tubular  
12 and laminar morphologies for each estuary and sampling occasion were considered. Daily  
13 meteorological information (i.e. rainfall, solar radiation, maximum air temperature and minimum  
14 air temperature) was obtained from the Irish meteorological service (Met Éireann;  
15 <http://www.met.ie/>), or provided by the Environmental Protection Agency from *in-situ*  
16 measurements (i.e. Salinity, DIN and SRP). In the case of the Tolka estuary all the  
17 climatological information was obtained from the meteorological station at Dublin Airport,  
18 located less than 10 km from this estuary. In the case of the Argideen estuary, rainfall data were  
19 taken from the closest pluviometric station (i.e. Ballinspittle, ~11km away). The data for solar  
20 radiation, maximum and minimum air temperature were linearly interpolated considering the  
21 distance from the sampling site to the two closest meteorological stations: Sherkin Island (52  
22 kilometres) and Roche's Point (38 kilometres). In the case of water physico-chemical attributes,  
23 only six of the seven sampling occasions were considered, since data from June 2016 were  
24 missed.

### 26 3. Results

#### 28 3.1. Species composition

29  
30 Seventy-eight *rbcL* sequences were obtained from *Ulva* specimens collected from the Tolka  
31 (42) and the Argideen (36) estuaries, which were between 569 and 1050 bases long. Sequence  
32 comparisons showed that the two blooms studied contained at least seven *Ulva* species (Fig.  
33 2). Four species were found in the Tolka and seven in the Argideen: four were common to both  
34 estuaries (*Ulva compressa* L.; *Ulva procera* (K. Ahlner) Hayden et al.; *Ulva prolifera* O.F. Muller;  
35 and *Ulva rigida* C. Agardh), and three occurred exclusively in the Argideen estuary (*Ulva*  
36 *intestinalis* Linnaeus; *Ulva gigantea* (Kützinger) Bliding; and *Ulva lactuca* L.). The most frequently  
37 encountered species were *U. prolifera* (33 sequences; 32 tubular and one laminar specimens),  
38 *U. compressa* (13 sequences; 13 tubular and no laminar specimens) and *U. rigida* (13  
39 sequences; one tubular and 12 laminar specimens), while the remaining species identified were  
40 less common. These three species were present on all of the sampling occasions assessed.

1 Overall, *U. rigida* exhibited laminar morphology, while *U. prolifera* and *U. compressa* were  
2 tubular.

3 Other species such as *Chaetomorpha linum* (O.F.Müller) Kützing, *Chaetomorpha ligustica*  
4 (Kützing) Kützing, *Gracilaria vermiculophylla* (Ohmi) Papenfuss or different Ectocarpales were  
5 also encountered in the blooms, identified based on morphological traits. Specimens of  
6 *Chaetomorpha* spp. were usually present in samples, reaching measurable biomass densities in  
7 October 2016 in both estuaries.

8

### 9 3.2. Spatial and temporal patterns of variation

10

11 The PERMANOVA analysis regarding the morphological composition of *Ulva* blooms from  
12 the Argideen and Tolka estuaries revealed significant differences between the Estuaries,  
13 Sampling occasions and Positions (Table 2a). Most of the significant interactions included  
14 Sampling occasion (i.e. Estuary x Sampling occasion, Sampling occasion x Section), which  
15 indicated that the distribution and morphological composition of *Ulva* blooms showed an  
16 important seasonal dynamic, with a change in maximum biomass from one section of the  
17 estuary to another (Fig. S1).

18 As evident from Figure 3, Sampling occasion appears to be the factor that best explained  
19 this variance, while differences between Positions were less obvious. The results suggested a  
20 temporal shift from tubular to laminar morphologies throughout the bloom season, which was  
21 common to both estuaries. In February, when no bloom occurred, the biomass for both  
22 morphologies was measured as lower than 0.1 g/m<sup>2</sup>. Subsequently, in April, tubular *Ulva*  
23 exhibited a low biomass, while laminar *Ulva* was either absent or present in only negligible  
24 amounts - most of the variability occurred on the "x" axis representing the biomass of the  
25 tubular *Ulva* (Fig. 3). The peak of biomass for tubular *Ulva* occurs in June, with some variability  
26 evident on the "y" axis during this month as a consequence of the presence of laminar *Ulva* in  
27 measurable biomasses. In the Tolka Estuary from August to October the point cloud is moved  
28 from the bottom-right part of the "xy" coordinate system to the upper-left, showing a decrease in  
29 the biomass of tubular *Ulva* and an increase in the laminar form. In the Argideen Estuary, an  
30 increase in laminar *Ulva* from June to August was observed, with a subsequent decrease from  
31 August to October, while no biomass was present in February.

32 In the case of the position in the bloom, the pairwise PERMANOVA found significant  
33 differences between Middle and Upper positions in both estuaries (Table 2b), existing also  
34 significant differences between middle and lower positions in the Tolka. In the Argideen, the  
35 Upper position showed the lowest data dispersion (PERMDISP test and pairwise comparisons;  
36 p-values <0.01) while in the Tolka, no differences in data dispersion were found among the  
37 different positions (PERMDISP, p-values >0.05), although a similar trend in data dispersion was  
38 observed with minimum dispersion in the Upper position. The lower dispersion at the Upper  
39 positions of the green tide is a consequence of lesser biomass of both morphologies at this

1 shore height, where maximum biomass was lower than that observed at the Middle and Lower  
2 shore positions. These differences were more obvious in the Argideen than in the Tolka (Fig. 3).

3 On the other hand, the significant differences observed between sampling stations, and the  
4 significant interaction between Position and Site, revealed a noticeable variability in the  
5 morphological composition and biomass distribution at spatial scales of meters or tens of  
6 meters. In general terms, the biomass of tubular *Ulva* was higher than the laminar form, even  
7 when the latter reaches peak biomass in late summer or early autumn.

### 8 9 3.2.1. Biomass of the tubular morphology

10  
11 The PERMANOVA results for the biomass of tubular *Ulva* revealed significant differences  
12 between estuaries, sampling occasions and positions (Table 3). Significant interactions were  
13 observed between sampling occasion and most of the spatial scales of variation assessed for  
14 temporal interactions (i.e. Estuary x Sampling occasion, Sampling occasion x Section). The  
15 annual peaks of biomass were detected in June for both estuaries, with significant differences  
16 between June of 2016 and June of 2017 for both estuaries (Fig. 4). In June 2016 the median  
17 values of biomass of tubular *Ulva* were 1193.6 g m<sup>-2</sup> and 3345.6 g m<sup>-2</sup> for the Argideen and the  
18 Tolka respectively. In June 2017 the median values of biomass of tubular *Ulva* were 676.8 g m<sup>-2</sup>  
19 for the Argideen and 1558 g m<sup>-2</sup> for the Tolka. The maximum values for biomass were  
20 measured in June 2016 for both estuaries, reaching 12398.4 g m<sup>-2</sup> in the Tolka estuary, and  
21 7140.8 g m<sup>-2</sup> in the Argideen. Overall, the Tolka has a greater biomass of *Ulva* than the  
22 Argideen, with the exception of April 2017 when the opposite trend was observed. In relation to  
23 shore position of the green tide, significant differences occurred for this morphology between  
24 the upper and middle positions. Overall, a higher biomass was found on the middle shore as  
25 opposed to the upper reaches of the bloom.

26 At smaller spatial scales of variation, significant differences were observed between Sites  
27 (Table 3). Moreover, a significant interaction between Site and Position was identified. No  
28 relevant scales of variation were found at scales of variation smaller than one hundred meters  
29 (i.e. Sampling Stations).

### 30 31 3.2.2. Biomass of the laminar morphology

32  
33 The PERMANOVA results regarding biomass of laminar *Ulva* indicated significant  
34 differences between Sampling occasions, Sections and Sampling stations. Significant  
35 interactions between Sampling occasion and Estuary, and Sampling occasion and Section, and  
36 Position and Site were also identified (Table 3).

37 The annual peaks of biomass for the laminar morphology were observed during August in  
38 the Argideen, and during October in the Tolka (Fig. 5), with median values of 180.0 g m<sup>-2</sup> and  
39 322.4 g m<sup>-2</sup> respectively. No significant differences in the biomass abundance during the peak  
40 bloom were found between both estuaries. The maximum values of biomass abundance were

1 measured in the Tolka during October 2016 (1652.8 g m<sup>-2</sup>) and in the Argideen in August 2017  
2 (2369.6 g m<sup>-2</sup>). During February and April the biomass of laminar *Ulva* was negligible for both  
3 estuaries.

4 On the other hand, the differences between Sections varied through the bloom season.  
5 Before and after the peak bloom of laminar *Ulva*, no differences in biomass densities between  
6 Sections (Tolka: June 16, June 17, and August 17; Argideen: June 16 and June 17), or higher  
7 levels of biomass in the outer part of the estuary (Tolka: August 17; Argideen: October 16) were  
8 observed (Fig. S1). During peak bloom conditions the biomass was significantly higher in the  
9 inner section in both estuaries.

### 11 3.3 Correlations between biomass and environmental variables

13 Significant and direct Spearman correlations were found between maximum (rho = 0.61) and  
14 minimum (rho = 0.54) air temperature, and the biomass of laminar morphologies of *Ulva* (Table  
15 4). In the case, of the tubular *Ulva*, significant and direct correlations were observed with  
16 maximum air temperature (rho = 0.84), and solar radiation (rho = 0.70). Significant and indirect  
17 correlation was observed between the biomass of tubular *Ulva* and DIN (rho = - 0.60),  
18 suggesting an important bio-filtration potential of the green tide.

## 20 4. Discussion

21  
22 This study indicated that tubular morphologies of *Ulva* dominated two of the largest  
23 macroalgal blooms in Ireland. Contrary to what was previously thought (Wan et al., 2017), the  
24 results revealed that the blooms in both these estuaries were multi-specific. Our observations  
25 revealed the presence of at least three species of *Ulva* (*U. prolifera*, *U. compressa* and *U. rigida*)  
26 and members of the genus *Chaetomorpha* in noticeable biomasses at certain times of the year.  
27 A significant spatial and temporal variability of *Ulva* biomass was observed. Regarding temporal  
28 variability, a seasonal succession was identified, with the bloom dominated by tubular species  
29 during spring and early summer, and co-dominated by tubular and laminar morphologies during  
30 late summer and autumn. Although long-term changes in species composition of macroalgal  
31 blooms (Lavery et al., 1991), or differences in spatial distribution between different species has  
32 been previously reported (Hernandez et al., 1997; Nelson et al., 2003; Guidone and Thornber,  
33 2013), this seasonal pattern that is common to both estuaries and both years has not been  
34 previously described in other European estuaries - although in California a relatively similar  
35 temporal succession was observed between *U. intestinalis* and *U. expansa* (Fong et al., 1996).  
36 In addition, the spatial variability of tubular and laminar morphologies exhibited different  
37 distribution patterns suggesting that the mechanism determining the distribution of laminar and  
38 tubular morphologies were different. Considering that tubular morphologies were usually  
39 anchored in the sedimentary substrate due to the burial of their basal part (Schories and Reise,

1993; this study), while laminar *Ulva* were usually observed free-floating or tangled in the tubular canopy, these differences could explain a differential influence by wind and wave action.

#### 4.1. Species composition

Similar to other recent studies concerning the species composition of problematic macroalgal blooms (e.g. Nelson et al., 2003; Guidone and Thornber, 2013), our results revealed that the green tides contained multiple species of *Ulva* (Fig. 2), suggesting *U. prolifera*, *U. compressa* and *U. rigida* as the most frequent and abundant entities in both estuaries. Wan et al. (2017) stated that *Ulva* blooms in seven estuaries in Ireland (from one sampling occasion, including the Tolka and the Argideen) were primarily comprised of *U. rigida*. Although *U. rigida* appears to be the dominant laminar species of *Ulva* in Irish green tides, reaching important biomass densities in late summer and autumn (33% and 24% of total biomass during August and October in the Argideen and Tolka, respectively), the results obtained in the present study showed that the tubular *U. prolifera* and *U. compressa* are more abundant and comprise the main species forming green tides in the Argideen and Tolka Estuaries. This finding is in accordance with reports by Jeffrey et al. (1995), who identified two tubular species, *U. prolifera* and *U. flexuosa*, as the main components of the macroalgal blooms occurring in the Tolka Estuary between June 1989 and September 1990. The differences between the present study and the results obtained by Wan et al. (2017) were due to a sampling bias as that study only collected laminar specimens of *Ulva* for molecular identification on a single sampling occasion.

#### 4.2. Temporal variability

Green tides in both estuaries (Figs. 4 and 5; Jeffrey et al., 1995) started in late March or early April, and persisted until the end of November or early December, showing a slight mismatch in the occurrence of blooms. Algal growth in the southern site (i.e. Argideen) appear to start, peak and finish before the bloom on the east coast (i.e. Tolka), as can be observed in Figures 4 and 5 for both *Ulva* morphologies, suggesting a key role of temperature and light as triggers of bloom development (e.g. Malta and Verschuure, 1997; Gao et al., 2016; Wang et al., 2018). These results also revealed a mismatch between the peaks of biomass of tubular and of laminar morphologies, indicating a temporal succession between species that was common to both estuaries. The studied *Ulva* blooms were dominated by tubular morphologies (i.e. *U. prolifera* and *U. compressa*) in early summer, and co-dominated by laminar (i.e. *U. rigida*) and tubular morphologies (i.e. *U. prolifera* and *U. compressa*) in late summer or early autumn. Additionally, during late summer and autumn, measurable biomasses of *Chaetomorpha* spp. were observed (pers. obs.). The presence of different species of *Ulva* in Irish green tides and the observed sequence of occurrence suggest that the duration and extension of macroalgal blooms in Ireland could be stimulated through spatial and temporal successions between species with different ecological requirements if the biotic interactions between them are weak

1 or negligible (i.e. diversity-stability hypothesis (McCann, 2000)). This hypothesis is also  
2 supported by the occurrence of macroalgal tides as a consequence of the arrival of alien  
3 species in estuaries previously unaffected by such phenomena (Yabe et al., 2009; Yoshida et  
4 al., 2015), or by the changes in dominant species forming green tides due to alterations in  
5 environmental conditions (Lavery et al., 1991), highlighting the importance of knowledge about  
6 the species composition of seaweed blooms and their eco-physiological performance.  
7 Spearman correlations results (Table 4) suggested different eco-physiological responses of the  
8 laminar and tubular morphologies to environmental conditions. Temperature seem to play an  
9 important role in the development of the laminar *Ulva*, while the biomass of the tubular *Ulva*  
10 seems to be explained by temperature and solar radiation. Further studies will be necessary for  
11 a better understanding of the environmental factors controlling bloom development. The  
12 biomass of tubular morphologies and DIN concentration showed a significant and indirect  
13 correlation ( $\rho = -0.60$ ), supporting the idea that these macroalgal blooms and other estuarine  
14 primary producers (e.g. phytoplankton, microbenthos, epiphytes, salt marshes plants,  
15 seagrasses) could accumulate dissolved inorganic nutrients in such quantities that can reduce  
16 nutrient concentration in surrounding seawaters at medium scales (Viaroli et al., 1996; Valiela et  
17 al., 1997).

#### 18 19 20 4.3. Spatial variability 21

22 Our findings support the existence of an important spatial variability in the studied blooms,  
23 suggesting a patchy distribution similar to those observed in other macroalgal blooms  
24 dominated by Ulvoids (e.g. Malta and Verschuure, 1997; Nelson et al., 2003; Thornber et al.,  
25 2017). Marked differences in spatial variability were found between laminar and tubular  
26 morphologies (Table 2), suggesting important differences in the main factors determining  
27 biomass distribution patterns for both morphologies. Interestingly, while tubular morphologies  
28 were usually buried with their basal parts and thus anchored to the sediment (Schories and  
29 Reise, 1993; this study), laminar *Ulva* usually occurred free-floating or tangled in the tubular  
30 canopy. As a consequence, it is expected that wind and wave action are more likely to influence  
31 the transport or movement laminar *Ulva* biomass. In contrast, the tubular species anchored to  
32 the substrate may be less affected by these factors and more susceptible to the effects of local  
33 environmental conditions on their biological performance. Considering that the studied green  
34 tides were thriving in the sedimentary tidal flats of two different estuaries, where the habitat and  
35 environmental heterogeneity was relatively low at small spatial scales, and an important  
36 biomass transport to the open sea is expected due to tidal currents, the observed patterns  
37 partially support this hypothesis. In this case, the biomass of tubular morphologies varies along  
38 bigger spatial scales (i.e. Sites; 100 meters) than the laminar ones (i.e. Sampling Stations; 10  
39 meters), and this morphology was more abundant than the laminar. Our results showed  
40 significant differences between estuaries and the position of the green tide for tubular

1 morphologies. With respect to laminar morphologies, significant differences were observed  
2 between sampling stations and sections, but no significant differences were observed between  
3 shore positions or between estuaries. This suggests that the spatial patterns of tubular  
4 morphologies may be determined by factors affecting the biological performance of the species  
5 such as climatic conditions, desiccation, light and nutrient availability (i.e. factors generating  
6 spatial patterns at scales of estuaries or between positions in the green tide). On the other  
7 hand, the spatial distribution of laminar morphologies might be determined by hydrodynamic  
8 conditions as well as interactions with the substrate morphology and other canopy forming  
9 species, rather than local conditions maximising the biological performance of the species. In  
10 this sense, the anchorage of tubular morphologies to the substrate could favour this  
11 morphological form developing into green tides in areas where the biomass transport due to  
12 tidal currents favours the export of biomass. Moreover, the burial of the basal part of the tubular  
13 morphology could provide access to nutrients from porewaters, which would not be available to  
14 the laminar morphologies (Robertson and Savage, 2018).

#### 16 *4.4. Annual and decadal variability in biomass density*

18 Our results suggest important between-years differences in the levels of biomass present.  
19 These were especially relevant between June 2016 ( $3912.9 \pm 2473.8 \text{ g m}^{-2}$  and  $1193.6 \pm 1665.3 \text{ g}$   
20  $\text{m}^{-2}$  for the Tolka -n=54- and the Argideen -n=72- respectively) and June 2017 ( $1851.5 \pm 1208.1 \text{ g}$   
21  $\text{m}^{-2}$  and  $889.3 \pm 846.4 \text{ g m}^{-2}$  for the Tolka and the Argideen respectively; n=72), when these  
22 blooms seemed to reach maximum biomass. In both cases, higher biomasses were observed in  
23 June 2016 than in June 2017, which could be related to climate factors. It is worth noting that  
24 from January to May the total rainfall in meteorological stations close to both estuaries was  
25 noticeably lower in 2017 than in 2016 (www.met.ie), which may have resulted in suboptimal  
26 conditions during the first stages of bloom development in 2017 (i.e. lower nutrient input and  
27 higher salinity). Significant differences in between-year-variation in macroalgal biomass have  
28 been observed in other green tides (Malta and Verschuure, 1997; Lyngby et al., 1999), leading  
29 to suggestions of a critical role of environmental conditions during the early bloom development  
30 which subsequently determine the total biomass accumulated at peak bloom (Malta and  
31 Verschuure, 1997; Gao et al., 2018). When the mean values of biomass observed in the Tolka  
32 estuary in 2016 and 2017 during the peak of biomass were compared with those obtained by  
33 Jeffrey et al. (1995) in 1989 ( $666\text{--}750 \text{ g m}^{-2}$  of fresh weight considering a 0.12 ratio dry: fresh  
34 weight) and 1990 ( $790\text{--}885 \text{ g m}^{-2}$ ), a noticeable increase in biomass was observed.

#### 36 *4.5. Relevance for environmental management*

38 Maximum values of biomass in the Tolka and Argideen were lower than reported in the  
39 1980's and 1990's for the Venice lagoon and the French coast of Brittany, but similar to other  
40 European estuaries (Table 5). Although the effect of seaweed tides are very much dependent

1 on local environmental conditions, different studies suggest that *Ulva* biomass concentrations  
2 higher than 1000 g FW m<sup>-2</sup> have significant harmful effects on associated biota (Lowthion et al.,  
3 1985; Hull, 1987; Wither, 2003). In the context of the European Water Framework Directive  
4 (WFD), Scanlan et al. (2007) therefore proposed biomass levels as one of the sub metrics to  
5 assess the Ecological Status in transitional water bodies, with 1 kg of wet weight biomass per  
6 square meter during the peak bloom being the threshold between a Good and Moderate  
7 Ecological Status. In the present study the mean values of biomass exceeded this threshold by  
8 five times in the Tolka estuary (June 2016, August 2016, October 2016, June 2017 and August  
9 2017) and three times in the Argideen (June 2016, August 2016, August 2017) (Fig. 6). This  
10 becomes particularly important considering legal implications when a good Ecological Status is  
11 not reached (European Commission 2000), as it necessitates the development of management  
12 actions aimed at reducing the total seaweed biomass in order to reach a good ecological status  
13 complying with obligations under the requirements of the WFD. The different habitats of tubular  
14 and laminar morphologies of *Ulva* (anchored vs. free-floating) may lead to important differences  
15 in the spatial integration of environmental conditions or exposure to pollutants that need to be  
16 considered for the design of monitoring programs using *Ulva* species as bioindicators of  
17 environmental quality and ecological status. Furthermore, as the tubular morphologies might be  
18 more susceptible to biomass burial rather than exportation to sea, this could play an important  
19 role in the balance of nutrients in the estuary, favouring accumulation in pore-waters and  
20 sediments (Corzo et al., 2009). This accumulation of nutrients in sediments could act a reservoir  
21 for further blooms, limiting the impact of management actions such as the reduction in nutrient  
22 loadings.

## 23 24 **Acknowledgements**

25  
26 This research was financed through the 2014-2020 EPA Research Strategy (Environmental  
27 Protection Agency, Ireland), project no: 2015-W-MS-20 (the Sea-MAT Project). The authors are  
28 thankful to A. Mendes, M. Edwards, C. Cara-Ortega, C. Linderhof, N. Keogh, A. Niven and E.  
29 Curley for field assistance. We appreciate the comments and review of the manuscript by  
30 Professor I. Hernández.

1 **Fig. 1.-** Geographical location of the two estuaries monitored in Ireland. Detailed map of the Tolka (A) and the Argideen  
2 (B) estuaries showing a schematic representation of the spatial sampling design.

3  
4 **Fig. 2.** Phylogenetic tree inferred by MaximumLikelihood analysis from partial rbcL sequences of *Ulva* species.  
5 Numbers above lines indicate bootstrap support values (branches without number received less than 60% support).  
6 GenBank/ENA accession numbers are followed by the species name (reflecting current nomenclature; Guiry & Guiry  
7 2018), origin of the sample, and a number indicating the reference: 1- Hayden and Waaland (2002); 2- Hayden and  
8 Waaland (2004); 3- Hayden et al. (2003); 4- Heesch et al. (2009); 5- Hiraoka et al. (2003); 6- Loughnane et al. (2008);  
9 7- Shimada et al. (2003); 8- Saunders and Kucera (2010); 9- Spalding et al. (2016); 10- Sherwood et al. (2000); 11- this  
10 study (sequences set in bold are from the studied estuaries).

11  
12 **Fig. 3.-** Median values of biomass (wet wt.) (n=3) of laminar (y-axis) and tubular (x-axis) morphologies of *Ulva* for each  
13 sampling station in the Tolka and the Argideen over seven different sampling occasions. The dotted diagonal line  
14 represents a 1:1 biomass equivalence of laminar and tubular *Ulva*.

15  
16 **Fig. 4.-** Median values of biomass (wet wt.) of tubular *Ulva* according to Estuary and Sampling occasion. Lower and  
17 Upper error bars represent the 25<sup>th</sup> and 75<sup>th</sup> percentile respectively; n = 72, except for Tolka June 2016 when n = 54.  
18 Letters over the bars represent significant differences.

19  
20 **Fig. 5.-** Median values of biomass (wet wt.) of laminar *Ulva* according to Estuary and Sampling occasion. Lower and  
21 Upper error bars represent the 25<sup>th</sup> and 75<sup>th</sup> percentile respectively; n = 72, except for Tolka June 2016 when n = 54.  
22 Letters over the bars represent significant differences.

23  
24 **Fig. 6.-** Biomass (wet wt.) of *Ulva* according to Estuary and Sampling occasion. Mean  $\pm$  standard deviation; n = 72,  
25 except for Tolka June 2016 when n = 54. The red line represent the biomass level of 1 kg m<sup>-2</sup> established as the  
26 threshold between good and moderate status in the context of the Water Framework Directive (Scanlan et al., 2007).
