rDNA loci and heterochromatin positions support a distinct genome type for 'x=9 species' of section Arachis (Arachis, Leguminosae)
Plant Systematics and Evolution

Dear Dra Lavia,

I am pleased to inform you that your manuscript rDNA loci and heterochromatin positions support a distinct genome type for 'x=9 species' of section Arachis (Arachis, Leguminosae) has been accepted for publication in Plant Systematics and Evolution.

Comments from the Editor and Reviewers can be found below.

The manuscript has been forwarded to the publisher and may now be considered to be "in press". You will soon receive the page and plate proofs. Please comply with the instructions and return the corrected proofs to the publisher as quickly as possible, so that your paper can appear in print with minimal delay.

On behalf of Plant Systematics and Evolution, I thank you for sending your work to the journal. I hope you will make use of Plant Systematics and Evolution again for publishing your research findings.

Yours sincerely,

Karl Hammer
Associate Editor
Plant Systematics and Evolution

Comments from the Editors and Reviewers:

The paper can now be accepted.

Plant Systematics and Evolution

rDNA loci and heterochromatin positions support a distinct genome type for 'x=9 species' of section *Arachis* (*Arachis*, Leguminosae)

--Manuscript Draft--

Manuscript Number:	PLSY-D-13-00411R2
Full Title:	rDNA loci and heterochromatin positions support a distinct genome type for 'x=9 species' of section <i>Arachis</i> (<i>Arachis</i> , Leguminosae)
Article Type:	Original Article
Keywords:	Keywords: chromosomes, DAPI+ bands, FISH, genome type, rDNA sites, x=9 species of section <i>Arachis</i>

Abstract:	<p>Most species of the genus <i>Arachis</i> (Leguminosae; 80 spp.) are diploid with $x=10$ and only four species have $x=9$ chromosomes. Three of these $x=9$ species belong to section <i>Arachis</i> and are morphologically and chromosomally similar. To study the homeology of the genomes of $x=9$ species and their relation to other genomes in section <i>Arachis</i> we applied fluorescence in situ hybridization (FISH) of 18S-26S and 5S rDNA and 4', 6-diamidino-2-phenylindole (DAPI) banding. FISH revealed for these three species one pair of 5S rDNA sites interstitially within the short arm of the metacentric pair 6 and one pair of 18S-26S rDNA sites in the proximal region of the long arm of the SAT chromosomes. Conspicuous DAPI+ bands were detected pericentromerically in all nine chromosome pairs of <i>A. decora</i> and <i>A. praecox</i> and in all but one pair of <i>A. palustris</i>. Our results suggest that all three species with $x=9$ of section <i>Arachis</i> share the same genome type and are different from the other genome types A, B, D, F, and K described for this section. Apparently, the $x=9$ species of section <i>Arachis</i> form a monophyletic group characterized by a genome type that we propose to call G genome.</p>

Plant Systematics and Evolution

Dear Dr. Karl Hammer

We are submitting a revised version of the manuscript entitled "Unraveling the genome constitution of $x=9$ species in section *Arachis* (*Arachis*, Leguminosae) using FISH mapping of rDNA loci and heterochromatin detection: a proposal for a new genome type". We have considered all the suggestions made by the reviewers and listed our replies point-by-point below.

Reviewer #2: *"The only suggestion I have to improve the text is to remove from the Discussion the references to figures and table 2, which could be restricted to the Results"*

- The references to figures and table 2 were removed from the Discussion, except in the page 9, Line 252, because we consider it necessary be there.

Reviewer #3: *"First, according to our count the images show at least 19 instead of 18 chromosomes. Second, the 5S rDNA loci are hardly detectable; even worse the extra DAPI+ bands. Why there is only one arrow for this band? These images must be substituted by more clear ones, if they should serve to postulate a separate genome-type. In a new image the species names, the probe names (in the respective color), arrows at homologous positions, and the size of the bar should be included for reader-friendliness. In general, the paper is much too long. It needs conciseness and stylistic improvement. For instance see below our suggestions for title and abstract. To avoid extensive redundancy, Results and Discussion sections should be combined. BTW, this type of study cannot prove, at best suggest, chromosome homeology."*

A. Figure 2.

- The chromosomes number is 18, the extra chromosome (number 19) observed by reviewer 3 corresponds to a satellite. In the new images, the satellite was linked with the chromosomes with dotted lines to avoid confusion with the number of chromosomes.
- The names of species and the scale bar are in the legend, because there was no sufficient space in the figure.
- With respect to the extra band DAPI, has only one arrow, because it is heteromorphic. These arrows were removed in the new images because the extra band DAPI are not characteristic of the genome. We deleted the sentence: "*Arachis palustris* and *A. praecox*, but not *A. decora*, have an additional, weak, interstitial DAPI+ band on chromosome pairs 1 and 6, respectively" from the discussion (page 8).
- The images were replaced with images with different colors of chromosomes (grey) to better highlight the signal 5S rDNA.
- Probe names in the respective colors and arrows indicating homologue positions were added.
- The legend of Figure 2 was modified according to the new included images and references (page 15, lines 434- 438).

B. To avoid extensive redundancy with the introduction, a paragraph (page 10, lines 273 - 278) in the discussion was summarized.

C. The reviewer proposed that "*Results and Discussion sections should be combined*".

We combined these sections, but the resulting text was difficult to read. Therefore we prefer that these sections remain separated as they are more reader-friendly.

D. "*BTW, this type of study cannot prove, at best suggest, chromosome homeology*".

- Page 8, lines 233 - 234, **the sentence** "*The identification of heterochromatic bands and localization of rDNA loci showed that the three x=9 species of section Arachis are highly genomically homeologous*" **was replaced by** "*The identification of heterochromatic bands and localization of rDNA loci showed that the three x=9 species of section Arachis are genomically similar*".
- Page 9, line 251, **the word "propose" is replaced by "suggest"**.

E. Suggestion for title and abstract:

- The proposed title was accepted, therefore the new title is:

"rDNA loci and heterochromatin positions support a distinct genome type for 'x=9 species' of section *Arachis* (*Arachis*, Leguminosae)"

- The suggested abstract was accepted, so the new abstract is:

Most species of the genus *Arachis* (Leguminosae; 80 spp.) are diploid with $x=10$ and only four species have $x=9$ chromosomes. Three of these $x=9$ species belong to section *Arachis* and are morphologically and chromosomally similar. To study the homeology of the genomes of $x=9$ species and their relation to other genomes in section *Arachis* we applied fluorescence *in situ* hybridization (FISH) of 18S-26S and 5S rDNA and 4', 6-diamidino-2-phenylindole (DAPI) banding. FISH revealed for these three species one pair of 5S rDNA sites interstitially within the short arm of the metacentric pair 6 and one pair of 18S-26S rDNA sites in the proximal region of the long arm of the SAT chromosomes. Conspicuous DAPI+ bands were detected pericentromerically in all nine chromosome pairs of *A. decora* and *A. praecox* and in all but one pair of *A. palustris*. Our results suggest that all three species with $x=9$ of section *Arachis* share the same genome type and are different from the other genome types A, B, D, F, and K described for this section. Apparently, the $x=9$ species of section *Arachis* form a monophyletic group characterized by a genome type that we propose to call G genome.

F. Minor points. Agreeing with the reviewer #3 the following sentences have been modified:

- page 7, lines 183 - 185: “*The general karyotype features, distribution and percentage of heterochromatin of the 5S and 18S–26S rDNA loci mapped for the three x=9 Arachis species are listed in Table 2*” **was replaced for**: “*The general karyotype features, and percentage of heterochromatin per chromosome complement and per chromosomes bearing 5S and 18S-26S rDNA for the three x=9 Arachis species are listed in Table 2*”.
- page 8, lines 209 - 212: “*This is probably due to the interstitial band of heterochromatin that this pair carries in A. praecox (Fig. 2 and 3). The total percentage of heterochromatin was highest in A. praecox (24.07%), followed by A. palustris (23.03%) and A. decora (20.70%) (Table 2)*” **was replaced for**: “*The percentages 24.07 and 23.03 are a clear overstatement of the resolution, taken into account the high variability of chromosome condensation and band appearance in such images as shown in Table 2*”. **In the previous paragraph, the word “weak” was included to describe the extra DAPI bands (line 204).**
- page 9, lines 252 - 255: “*Pair 1 that carries 18S-26S rDNA sites corresponds to pair A10 in A genome, and pair 6 with 5S rDNA sites to pair A3 in the same genome*” **was**

replaced for: *“Pair 9 carries the 18S-26S rDNA locus and corresponds to pair A10, and pair 6 with the 5S rDNA locus to pair A3 of the A genome”.*

The legends of Tables were rewritten making it easier to read (Page 15, Lines 426 and 428).

Thank you very much for the reviewers' comments and suggestions.

Sincerely yours,

Graciela Inés Lavia

19 **ABSTRACT**

1
2 20
3
4 21 Most species of the genus *Arachis* (Leguminosae; 80 spp.) are diploid with $x=10$ and
5 22 only four species have $x=9$ chromosomes. Three of these $x=9$ species belong to section
6
7 23 *Arachis* and are morphologically and chromosomally similar. To study the homeology
8
9 24 of the genomes of $x=9$ species and their relation to other genomes in section *Arachis*,
10
11 25 we applied fluorescence in situ hybridization (FISH) of 18S-26S and 5S rDNA and 4',
12
13 26 6-diamidino-2-phenylindole (DAPI) banding. FISH revealed for these three species one
14
15 27 pair of 5S rDNA sites interstitially within the short arm of the metacentric pair 6 and
16
17 28 one pair of 18S-26S rDNA sites in the proximal region of the long arm of the SAT
18
19 29 chromosomes. Conspicuous DAPI+ bands were detected pericentromerically in all nine
20
21 30 chromosome pairs of *A. decora* and *A. praecox* and in all but one pair of *A. palustris*.
22
23 31 Our results suggest that all three species with $x=9$ of section *Arachis* share the same
24
25 32 genome type and are different from the other genome types A, B, D, F, and K described
26
27 33 for this section. Apparently, the $x=9$ species of section *Arachis* form a monophyletic
28
29 34 group characterized by a genome type, that we propose to call G genome.

33 37 of section *Arachis*

39 INTRODUCTION

40
41 The genus *Arachis* (Leguminosae), which is native to South America, has 80
42 formally recognized species, including the economically important peanut species *A.*
43 *hypogea* L. *Arachis* species are divided into nine sections according to morphology,
44 geographic distribution, and cross compatibility (Krapovickas and Gregory 1994; Valls
45 and Simpson 2005). Chromosome numbers are currently known for 76 species (Lavia et
46 al. 2008 and references therein). Most of them (67 spp.) are diploid with $x=10$ ($2n=20$),
47 a few (4 spp.) are diploid with $x=9$ ($2n=18$), and the rest (5 spp.) are tetraploid with
48 $x=10$. Three of the diploid $x=9$ species, *A. decora* Krapov. W. C. Gregory & Valls, *A.*
49 *palustris* Krapov. W. C. Gregory & Valls, and *A. praecox* Krapov. W. C. Gregory &
50 Valls (hereafter called $x=9$ species), belong to section *Arachis*, whereas one species, *A.*
51 *porphyrocalyx* Valls & C. E. Simpson, belongs to section *Erectoides*.

52 The $x=9$ species of section *Arachis* are annual plants from Brazil (Fig 1). *Arachis*
53 *palustris* is found in the northern part of the distribution range, extending on both sides
54 of the Tocantins River in the states of Maranhão and Tocantins between 7°22'S and
55 12°33'S. *Arachis decora* is distributed in the North-East of the state of Goiás and in the
56 South of state of Tocantins, separated from *A. palustris* by approximately 230 km. The
57 two species co-occur in the Tocantins River basin, implying that there is a geographic
58 continuity between the two species. In contrast, the third species, *A. praecox*, is
59 apparently known only from two populations in the state of Mato Grosso, over 1000 km
60 away from the other two species.

61 Morphologically, the three $x=9$ species are highly similar to one another (Veiga et
62 al. 2001). *Arachis praecox* is distinguished by its short main shoot axis, only up to 2-3
63 cm long, whereas *A. decora* and *A. palustris* have a main shoot axis of up to 15 cm
64 long. *Arachis decora* differs from *A. palustris* only in the presence of setae on stipules
65 (Krapovickas and Gregory 1994). Although previous studies of our lab have shown that
66 they share the karyotype formula ($16m+2sm$) with the same SAT chromosome type 3
67 (Lavia 1998), they are still poorly characterized chromosomally, and their genomic
68 constitution has not been assigned to any of the known genomes in section *Arachis*
69 (Robledo et al. 2009; Robledo and Seijo 2010).

70 At least five different genomes, A, B, D, F, and K, have been described in section
71 *Arachis* (Robledo and Seijo 2008, 2010; Robledo et al. 2009). The A genome is

72 characterized by the presence of the A chromosome pair, which is significantly smaller
73 than the rest of the chromosomes of the complement, and the arms display a differential
74 condensation pattern (Husted 1933, 1936; Fernández and Krapovickas 1994). The B
75 genome, traditionally characterized by the absence of the A pair, has recently been split
76 into the three genome types: B s.s., F, and K (Robledo and Seijo 2010). The D genome
77 is unique to *A. glandulifera* and is characterized by an asymmetric karyotype with
78 several subtelocentric chromosomes and the absence of the A pair (Robledo and Seijo
79 2008; Stalker 1991).

80 Analyses of molecular datasets have revealed that the three x=9 species form a
81 clade (Bechara et al. 2010; Friend et al. 2010; Moretzshon et al. 2013), but their
82 relationship with other species of the section is still unclear. For example, analyses of
83 microsatellites (Moretzshon et al. 2004), single-copy gene sequences (Moretzshon et al.
84 2013), trnT-F cpDNA marker (Tallury et al. 2005), and ITS and 5.8S of the nuclear
85 rDNA (Bechara et al. 2010) suggest that these taxa are more closely related to some
86 non-A genome species, whereas RAPD (Creste et al. 2005) and AFLP (Milla et al.
87 2005) analyses suggest that they are genetically more similar to A genome species.

88 Based on current morphological, chromosomal, and molecular evidence, it is
89 difficult to address the genome identity of the three x=9 species. Nevertheless, the fact
90 that these species form a group within section *Arachis* suggests that they may be
91 phylogenetically related. Indeed, we have previously proposed a single origin for these
92 species (Lavia et al. 2008 and references therein). To determine their genomic affiliation
93 and understand their relationship with other species of the section, detailed
94 chromosomal analyses are necessary. Fluorescent *in situ* hybridization (FISH) has been
95 successfully used to analyze homeology of genomes (Jiang and Gill 1994). For instance,
96 4', 6-diamidino-2-phenylindole (DAPI) banding and physical mapping of ribosomal
97 genes by FISH in other *Arachis* species has increased the number of chromosome
98 markers, which has allowed establishing homeologies in a large number of chromosome
99 pairs (Ortiz et al. 2011; Seijo et al. 2004), particularly in species with A and non-A
100 genomes of section *Arachis* (Robledo et al. 2009; Robledo and Seijo 2010).

101 Taking these antecedents into consideration, the goals of the present work were (i)
102 to describe chromosomal markers that contribute to the genomic identification of the
103 x=9 species, (ii) to provide information about the homeology of genomes within section
104 *Arachis*, and (iii) to discuss the implications of our results to increase our understanding

105 of relationships with other species of section *Arachis*. To this end, we analyzed
106 distribution patterns of heterochromatin using DAPI and the mapping of the ribosomal
107 gene loci using FISH.

108

109 MATERIALS AND METHODS

110

111 *Plant material*

112 Seeds of the *Arachis* species used in this study were obtained from the peanut
113 germplasm collections of the Instituto de Botánica del Nordeste (IBONE) Corrientes,
114 Argentina. The voucher material is deposited in the herbaria CTES and CEN. Origin
115 and collection information of voucher specimens is listed in Table 1.

116

117 *Chromosome preparations*

118 Actively growing root-tips (10–15 mm long) from germinating seeds were
119 pretreated with 2 mM 8-hydroxyquinoline for 3 h at room temperature (Fernández and
120 Krapovickas 1994) and then fixed in 3:1 absolute ethanol:glacial acetic acid for a
121 minimum of 12 h at 4°C. Somatic chromosome spreads were prepared according to
122 Schwarzacher et al. (1980). Root apices were digested in 1% (w/v) cellulose (from
123 *Trichoderma viridae*, Onozuka R-10; Serva, Heidelberg, Germany) plus 10% (v/v)
124 pectinase dissolved in 40% glycerol (from *Aspergillus niger*; Sigma-Aldrich, St. Louis,
125 MO, USA) in 0.01 M/L citrate buffer, pH 4.8, at 37°C for 1 h. Subsequently,
126 Meristematic cells were removed from the root tips, squashed in 45% acetic acid on a
127 slide, and covered with a coverslip. After removal of the coverslip with carbon dioxide,
128 the slides were air-dried for 1-2 days at room temperature and then stored at -20°C until
129 use.

130

131 *Probe labeling and fluorescent in situ hybridization*

132 The 5S and 18S-26S rDNA loci were localized using probes pA5S, pA18S and
133 pA26S isolated from genomic DNA of *A. hypogaea* (Robledo and Seijo 2008) and
134 labeled by nick translation with digoxigenin-11-dUTP (Roche Diagnostics, Mannheim,
135 Germany) or biotin-11-dUTP (Sigma-Aldrich). Pretreatment of slides, chromosome and
136 probe denaturation, conditions for the in situ hybridization (hybridization mixes
137 contained DNA probes at a concentration of 2.5–3.5 ng/μL, with a stringency to allow

138 sequences with 80–85% identity to remain hybridized), post-hybridization washing,
139 blocking, and indirect detection with fluorochrome-conjugated antibodies were
140 performed according to Moscone et al. (1996). The first set of antibodies consisted of
141 anti-biotin produced in goat (Sigma-Aldrich) and monoclonal anti-digoxigenin
142 conjugated to fluorescein isothiocyanate (FITC) produced in mouse (Sigma- Aldrich).
143 The second set consisted of anti-goat conjugated to tetramethyl-rodamine isothiocyanate
144 (TRITC) produced in rabbit (Sigma-Aldrich) and anti-mouse conjugated to FITC
145 produced in sheep (Sigma-Aldrich). Preparations were counterstained by mounting
146 them with Vectashield medium (Vector Laboratories, USA) containing 2 mg/mL of 4',
147 6-diamidino-2-phenylindole (DAPI). Counterstaining with DAPI reveals a C- banding –
148 like pattern with major heterochromatic bands fluorescing more intensely in *Arachis*
149 species (Seijo et al. 2004).

150 151 *Fluorescence microscopy and image acquisition*

152 Chromosomes were viewed with a Leica DMRX fluorescence microscope (Leica,
153 Heerbrugg, Switzerland) and digitally photographed with a computer-assisted Leica DC
154 350 digital camera system. Red, green, and blue images were captured in black and
155 white using the respective filters for TRITC, FITC, and DAPI excitations. Digital
156 images were processed with Photoshop, version 7.0 (Adobe, San Jose, California,
157 USA).

158 159 *Karyotype analysis and loci mapping*

160 For karyotype determination, we used three to six individuals per species and four
161 metaphase plates per individual. Chromosome measurements were made using the
162 computer application MicroMeasure version 3.3 (Reeves and Tear 2000). Karyotype
163 description is based on the nomenclature by Levan et al. (1964). Chromosomes were
164 classified in two categories according to the centromeric index ($CI = \text{short arm} \times 100 /$
165 total length of chromosome): metacentric (m) when $CI = 50$ to 37.5 , and submetacentric
166 (sm) when $CI = 37.5$ to 25 . SAT chromosomes were classified on the basis of the
167 satellite relative size and position of the centromere (Fernández and Krapovickas 1994).
168 The total chromosome length (TCL) was obtained by summing the average length of
169 each chromosome in the four metaphase samples. Chromosome mean length was

170 calculated by dividing the TCL by the number of chromosomes of the species. The
171 karyotype asymmetry indices were estimated using the intrachromosomal (A1) and
172 interchromosomal (A2) indexes by Romero Zarco (1986).

173 Data from homeologous chromosomes were combined for each species to obtain
174 mean values of different pairs of chromosomes in the same metaphases, and,
175 subsequently, of the same chromosome pair in different metaphases. Mean values of
176 each species were represented as haploid complements in the ideograms. Chromosomes
177 were ordered first by morphology and then by decreasing size. Based on the analysis of
178 results of the FISH experiments with the 18S-26S and 5S ribosomal genes and of the
179 DAPI staining, we constructed consensus ideograms for each of the x=9 species studied.

181 RESULTS

182
183 The general karyotype features, and percentage of heterochromatin per
184 chromosome complement and per chromosomes bearing 5S and 18S-26S rDNA for the
185 three x=9 *Arachis* species are listed in Table 2. Representative somatic metaphases are
186 shown in Fig. 2, and the consensus ideograms for each species are illustrated in Fig. 3.

188 *General karyotype features*

189 In all species, karyotypes consisted mainly of metacentric chromosomes, reflected
190 in their karyotype formula $16\ m + 2\ sm$ (Fig. 3). The mean chromosome length ranged
191 between 2.65 μm (*A. decora*) and 3.32 μm (*A. praecox*), and the total karyotype length
192 between 47.70 (*A. decora*) and 59.76 μm (*A. praecox*) (Table 2). A1 ranged from 0.21
193 (*A. decora*) to 0.25 μm (*A. praecox*), while A2 ranged between 0.11 (*A. praecox*) and
194 0.14 (*A. decora*). The A1 values indicate a slight variation between the length of the
195 short and long chromosome arms in each species, whereas the A2 values indicate high
196 similarity in chromosome sizes in each species. In other words, the two asymmetry
197 indexes indicate that the karyotypes of the three species are symmetric (Table 2).

199 *Heterochromatin distribution*

200 The counterstaining with DAPI revealed a C-banding-like pattern. Conspicuous
201 DAPI+ pericentromeric bands were present in all chromosome pairs in *A. praecox* and
202 *A. decora*, whereas they were present in all but one pair (pair 5) in *A. palustris* (Fig. 3).

203 Furthermore, in *A. praecox* and *A. palustris*, we observed a chromosome pair with one
204 additional **weak** heterochromatin band in interstitial position. In *A. praecox*, this band
205 was 0.4 μm and was located on the long arm of pair 6, whereas in *A. palustris*, the band
206 was shorter (0.29 μm) and was located on the long arm of pair 1.

207 The percentage of heterochromatin in relation to chromosome length in pair SAT
208 was similar the pair with 5S rDNA signal was significantly higher in *A. praecox*
209 (30.01%) than in *A. palustris* (23.03%) and *A. decora* (23.01%) (Table 2). **The total**
210 **percentages of heterochromatin 24.07 and 23.03 are a clear overstatement of the**
211 **resolution, taken into account the high variability of chromosome condensation and**
212 **band appearance in such images as shown in Table 2.**

213 214 *Chromosome mapping of the 5S and 18S–26S rRNA genes by FISH*

215 All species had only one pair of 18S-26S rDNA sites localized in the proximal
216 region of the long arm of SAT chromosomes. This pair is a SAT chromosome type 3
217 and the longest of the complements in the three species. It is submetacentric, except in
218 *A. praecox* where it is metacentric (Fig. 3).

219 One pair of 5S rDNA sites was observed in interstitial position of the short arm in
220 pair 6 in the three species. We also observed a DAPI+ interstitial band on the long arm
221 of chromosome pair with 5S rDNA sites in *A. praecox* (Fig. 2 and 3).

222 223 DISCUSSION

224
225 The present work is the first to analyze the distribution of heterochromatin and
226 location of ribosomal sites in three *Arachis* species of section *Arachis* characterized by
227 $x=9$, unusual in the genus. We used results to identify homeologous chromosomes,
228 define the genome type of these species, and discuss possible relationships of the $x=9$
229 species with closely related $x=10$ species with known genome types A, B, F, D, or K
230 (Robledo et al. 2009; Robledo and Seijo 2010).

231 232 *Chromosomal patterns of heterochromatin and 5S and 18S–26S rDNA loci*

233 **The identification of heterochromatic bands and localization of rDNA loci showed**
234 **that the three $x=9$ species of section *Arachis* are genomically similar.** First, they all lack
235 the small A chromosome pair, which supports findings from a previous work that also

236 suggest the absence of such chromosome pair (Lavia 1998). Second, all species have
237 pericentromeric DAPI+ bands with the same brightness, position, and size in all
238 chromosome pairs, except *A. palustris*, which lacks these bands in one chromosome pair
239 (pair 5). Third, the three species have only one pair of 18S-26S rDNA sites in the SAT
240 chromosomes, and one pair of 5S rDNA sites in chromosome pair 6.

241 The homeology observed among chromosomes supports the hypothesis that the x=9
242 species derive from the same common ancestor, as previously suggested (Creste et al.
243 2005; Lavia et al. 2008; Friend et al. 2010). On the other hand, some results as the
244 length of chromosomes, the percentage of heterochromatin in the chromosome pair with
245 5S rDNA, and the similarity in external morphology and the geographic distribution of
246 the plants suggest that *A. decora* and *A. palustris* are more similar to each other than to
247 *A. praecox*. Such relationship pattern agrees with results from molecular studies by
248 Creste et al. (2005), in which the x=9 species form a cluster, and, within this, *A. praecox*
249 is sister to a cluster comprising *A. decora* and *A. palustris*.

250 Based on the number and localization of rDNA sites and the heterochromatic
251 pattern of chromosome pairs carrying the landmarks analyzed, we suggest the following
252 homeologies between x=9 species and the other *Arachis* species (Fig. 3). **Pair 9 carries**
253 **the 18S-26S rDNA locus and corresponds to pair A10, and pair 6 with the 5S rDNA**
254 **locus to pair A3 of the A genome (Seijo et al. 2004; Robledo et al. 2009; Robledo and**
255 **Seijo 2010).**

256

257 *Relationships with other species of section Arachis and genomic assignment*

258 Relationships among x=9 and x=10 species of section *Arachis* have been studied
259 using different approaches, ranging from crossing experiments (in which obtaining
260 viable or non-fertile interspecific hybrids is a test of the degree of relationship between
261 the parent species), to molecular phylogenetic analyses, and the comparative
262 chromosome analysis presented here.

263 In their crossing experiments, Stalker et al. (1991) reported viable hybrids between
264 *A. palustris* (x=9) and *A. duranensis* (x=10, A genome), but recent crosses by Tallury et
265 al. (2005) and Custodio (2009) between x=9 species and x=10 species with A, K or B
266 s.s. genome produced non-fertile hybrids.

267 After analyzing the results obtained by Stalker et al. (1991), we consider that their
268 conclusions are doubtful, because their reported mean of bivalents (II = 9.89) is higher

269 than expected in a hybrid with $2n=19$. The most likely explanation for their results is
270 that the siblings they analyzed resulted from selfing of the female progenitor *A.*
271 *duranensis* with $2n=20$. Therefore, the absence of viable hybrids between $x=9$ species
272 and other species of section *Arachis* suggests that $x=9$ species are reproductively.

273 The molecular phylogenetic relationships of the $x=9$ species with the rest of the
274 section are still unclear, in some studies the $x=9$ species are more closely related to non-
275 A genome species, whereas in others they are more genetically similar to A genome
276 specie. To provide new insights into such relationships, in the present study, we
277 compared the new identified genome characteristics of $x=9$ species with previously
278 published characteristics of the A, B, D, F, and K genomes of section *Arachis*.

279 A genome species have the same DAPI banding pattern as $x=9$ species, a single
280 pair of 5S rDNA sites in interstitial position, and an inter-chromosomal asymmetry
281 index similar to that of $x=9$ species (Robledo et al. 2009). However, the
282 heterochromatic bands in $x=9$ species are more conspicuous and are of very similar size
283 among chromosomes than those in A genome species. In addition, $x=9$ species have
284 only one pair of 18S–26S rDNA sites, while A genome species have two (*A. correntina*,
285 *A. duranensis*, *A. schininii* and *A. villosa*) or four (*A. cardenasii*) (Robledo et al. 2009).
286 Finally, and most importantly, $x=9$ species lack the "A" chromosomes characteristic of
287 the A genome species.

288 The B genome detected in five species (*A. ipaensis*, *A. magna*, *A. gregoryi*, *A.*
289 *valida* and *A. williamsii*) is characterized by the absence of DAPI heterochromatic
290 bands in all chromosomes of the complement (Robledo and Seijo 2010), while $x=9$
291 species have heterochromatic bands in all chromosomes, indicating that they do not
292 share the genome type.

293 The D genome occurs only in *A. glandulifera* and is characterized by an
294 asymmetric karyotype (Stalker 1991; Fernández and Krapovickas 1994), only seven
295 chromosomes with DAPI+ pericentromeric bands, and five pairs of 18S–26S rDNA
296 sites (Robledo and Seijo 2008). The genome of $x=9$ species displays none of these
297 characteristics, since all $x=9$ species have a symmetric karyotype (mainly composed of
298 metacentric chromosomes), almost all or all chromosomes with DAPI+ pericentromeric
299 bands, and only one pair of 18S–26S rDNA sites.

300 Species characterized by the F genome, *A. trinitensis* and *A. benensis* (Robledo and
301 Seijo 2010), have one pair of each ribosomal site, as the $x=9$ species. However, their

8
9
10
11
12
13
14
15
302 small and faint centromeric bands occur in seven or eight of ten chromosome pairs,
303 whereas in $x=9$ species the bands are conspicuous and occur in all or almost all
304 chromosomes.

305 Finally, the K genome characterizes three *Arachis* species: *A. batizocoi*, *A.*
306 *cruziana*, and *A. krapovickasii* (Robledo and Seijo 2010). Similarly to $x=9$ species, K
307 genome species have conspicuous centromeric DAPI+ bands in nine of ten chromosome
308 pairs, but differ in the number and position of the ribosomal sites. K genome species
309 have in fact three chromosome pairs with interstitial sites of 5S rDNA, one of which co-
310 localizes with an 18S-26S rDNA site (Robledo and Seijo 2010).

311 Our comparative analyses indicate that $x=9$ species are chromosomally most
312 closely related to A genome species, because of their similarities in centromeric
313 heterochromatic bands, the interchromosomal asymmetry index and the same number
314 and position of 5S rDNA sites. Yet, the observed genome characteristics of $x=9$ species
315 are different from any known genome type, since the basic chromosome number is
316 different. Therefore, the three $x=9$ species of section *Arachis* seem to have their own
317 genome type, which we here propose as the G genome.

318 In conclusion, the morphological similarities, the incompatibility with other species
319 of section *Arachis*, the reduced basic number (different from the rest of the section), and
320 our results on the uniformity of DAPI bands and the ribosomal signals in the three $x=9$
321 species of section *Arachis* suggest that these species form a monophyletic group
322 characterized by its own G genome. It has been proposed that $x=9$ *Arachis* species
323 originated from non-A genome species of section *Arachis* (Bechara et al. 2010).
324 However, our cytogenetic evidences suggest that it is possible that these species derived
325 from an ancestor with $x=10$ and an A genome through some cytogenetic mechanism yet
326 to determine.

327
