Abstract

The relationships between the catalyst physicochemical properties and its photocatalytic activity have been investigated and elucidated in the photodegradation of the organophosphate insecticide methylparathion. The photocatalytic degradation was investigated by using a sol-gel synthesized Bi³⁺-doped TiO₂ nanocatalyst (using doping concentrations up to 2 wt% Bi³⁺) under UV-A light in aqueous suspension. The prepared photocatalysts were characterized by X-ray diffraction, (environmental) scanning electron microscopy, transmission electron microscopy, energy dispersive X-ray analysis, IR-UV-visible absorption spectra, X-ray photoelectron emission spectroscopy and room- and low- temperature photoluminescence spectra. The photodegradation and mineralization products of methylparathion were analyzed by high performance liquid chromatography, dissolved organic carbon and ion chromatography techniques. The experiments demonstrated that the presence of Bi³⁺ in TiO₂ catalysts substantially enhances the photocatalytic degradation of methylparathion in aqueous suspension. The degradation of methylparathion by these catalysts followed a first-order kinetic model and an optimal dosage between 0.7% and 1.5% Bi³⁺ in TiO₂ achieved the fastest methylparathion degradation under the experimental conditions. This study has also investigated the mineralization of methylparathion in terms of carbon, sulphur and nitrogen conversion during the photocatalytic reaction. The possible mechanisms of photoluminescence quenching and photodegradation are elucidated in the context of donor-acceptor interactions with Bi-O polyhedra acting as electron trapping centres which hinder electron-hole pair recombination.

1. Introduction

Endocrine disrupting chemicals (EDCs) have been shown to produce changes in the endocrine system of organism that may lead to increase in cancers and abnormalities in reproductive structure and function. Recent research has highlighted the existence of hormonally active compounds in sewage and industrial effluents and their potential for recycling back into the environment including drinking water supplied through point and non-point sources. On the other hand, surplus pesticides, even though within their expiration limits, will become a burden when their future use is prohibited by legislation due to toxicological or environmental concerns. Furthermore, the Food and Agricultural Organization of the United Nations (FAO) has estimated that more than 400 kilotonnes of obsolete pesticides are stocked worldwide [1,2]. The disposal of EDCs such as pesticides, fungicides and insecticides can cause serious environmental problems due to the chemical toxicity of the active ingredients in the formulations and sometimes, of their decomposition products.

Methylparathion is one of the most widely-used organophosphate insecticides. Its widespread use has caused environmental concern due to its frequent leakage into surface and ground waters. It is acutely toxic to mammals, for example the oral LD_{50} for rats is in the range 18-50 mg kg^{-1} . It acts by inhibiting the enzyme acetyl cholinesterase in nerve tissue. An ideal treatment method for such pesticide wastes should be non-selective, achieve rapid and complete degradation to inorganic products and be suitable for small-scale wastes. Possible methods include biodegradation, chemical reaction, physical entrainment, and incineration. Entrainment is losing acceptance as a final solution for waste disposal. Incineration is prohibitively expensive for dilute aqueous wastes because of high-energy requirements and transport costs. Biodegradation and chemical reaction, especially oxidative photodegradation, look to be the most promising methods.

Various innovative technologies have been proposed for methylparathion treatment. These include the use of UV radiation and hydrogen peroxide [3,4], ultrasonic irradiation [5], or mercury promoted hydrolysis [6]. The major disadvantage of these technologies is that they are designed for decontamination of aqueous solutions with very low active ingredient contents and are not suitable for degrading higher concentrations of unwanted pesticides. Furthermore, the use of mercury species is to be discouraged. Among various oxide semiconductor photocatalysts, TiO₂ is known as one of the most effective for the degradation of organic pollutants and its photocatalytic behavior has been studied extensively [7,8]. Although TiO₂ catalysts are capable of decomposing a wide variety of organic and inorganic pollutants and toxic materials in both liquid and gas phase systems [9,10], the fast recombination rate of photogenerated electron-hole pairs prevents the commercialization of this technology. For this reason, much attention has been paid to doping the material with transition and noble metals. The presence of heavy metals, such as Pt, Pd, Au and Ag has been demonstrated to enhance the degradation efficiency of photocatalytic reactions [11,12].

The present work focuses on the preparation, characterization and application of Bi³⁺-doped TiO₂ photocatalysts (hereafter referred to as Bi-TiO₂) for the degradation of the environmental EDC methylparathion: (H₃C-O)₂P(=S)-O-C₆H₄NO₂. Not only has the photodegradation efficiency shown an improvement relative to that for the undoped photocatalyst, but some understanding of the mechanisms of photoluminescence and photodegradation have been forthcoming. The experimental details are presented in Section 2. In Section 3 the characterizations of the photocatalysts using different instrumental techniques are described. The results from the photodegradation study are presented in Section 4 and some conclusions are listed in Section 5.

2. Experimental

2.1. Materials

Titanium tetra-n-butoxide (Ti(O-Bu)₄) and bismuth nitrate (both AR analytical grade, Aldrich Chemical Company, USA) were used as titanium and bismuth sources for the preparation of TiO₂ and Bi-TiO₂ photocatalysts. Methylparathion was obtained from the Pesticide Testing Laboratory, Tamil Nadu Agricultural University, India (AR grade) and used

without further purification. Deionised, doubly distilled water was used for the preparation of all solutions. Water and acetonitrile (International Laboratory, USA - HPLC-grade) were used as HPLC eluents.

2.2. Preparation of photocatalysts

The bismuth doped TiO₂ samples (Bi-TiO₂) were prepared by the sol-gel method in which 21 ml of Ti(O-Bu)₄ was dissolved in 80 ml of absolute ethanol, and the resulting solution was stirred vigorously. Then 2 ml of water and 0.5 ml of acetic acid (50%) were added to another 80 ml of ethanol to make an ethanol-water-acetic acid solution. The latter solution was slowly added to the Ti(O-Bu)₄-ethanol solution under vigorous stirring. When the resulting mixture turned to a sol, the bismuth nitrate solution was added drop-by-drop. The resulting transparent colloidal suspension was stirred for 1 h and was aged for 2 d until the formation of a gel. The gel was dried at 70 °C *in vacuo* and then ground. The resulting powder was calcined at 500 °C for 4 h. A TiO₂ sample was also prepared by the above same procedure without the addition of the bismuth nitrate solution, and this is subsequently referred to as *neat* TiO₂. The doping concentrations of Bi³⁺ are expressed as wt%.

2.3. Characterization of photocatalysts

The crystalline phases of the synthesized TiO₂ and Bi-TiO₂ catalysts were analyzed by X-ray powder diffraction using a X-ray diffractometer (XRD Philips PW3020) with Cu K_α radiation ($\lambda = 0.154060$ nm). An accelerating voltage of 40 kV and an emission current of 30 mA were used. The texture and morphology of the prepared samples were measured by (environmental) scanning electron microscopy (ESEM Phillips XL30), fitted with an EDX accessory. The diffraction pattern and interplanar spacings of the neat and doped catalysts were examined by TEM using a JEOL JEM – 2011 microscope operated at 200 keV. The _____

TEM samples were prepared by dispersion in ethanol by sonication and deposition on a carbon film supported on a copper grid. The photoluminescence (PL) emission spectra of the samples were measured at room temperature by two spectrofluorometers (Photon Technology International MD502 and Jobin-Yvon Fluoromax-3) using 325 nm xenon lamp excitation. Low temperature (~10 K) emission spectra of the powder samples of pure TiO₂ and Bi-TiO₂ (1%) were measured at a resolution of 2-4 cm⁻¹ using a Panther optical parametric oscillator system pumped by the second harmonic of a Surelite Nd-YAG laser. The crystals were mounted in an

Oxford Instruments closed cycle cryostat. The emission was collected at 90° and passed through an Acton 0.5 m spectrometer equipped with a charge-coupled device. To study the absorption spectra of the photocatalysts, the diffuse reflectance spectra (DRS) of the samples in the wavelength range 250-700 nm was obtained using a spectrophotometer (Shimadzu UV-2101), with MgO as reference. The transmission absorption spectra of TiO₂-Bi (1%) in a KBr disc (0.63 wt%) was recorded in the infrared (by a Nicolet Avatar 360 FTIR instrument) and ultraviolet (by an Agilent 8453 instrument) regions. X-ray photoelectron spectra (XPS) were recorded by a PHI Quantum ESCA Microprobe system using a MgK_α excitation source. Calibration of the spectra was done at the C 1s peak of surface contamination taken at 1253.6 eV. The fitting of XPS curves was performed using Multipak 6.0A software.

2.4. *Set up of photocatalytic reactor*

Photodegradation studies of methylparathion were carried out in the photocatalytic reactor system shown in Fig. 1, which consists of a cylindrical borosilicate glass reactor vessel with an effective volume of 250 ml, a cooling water jacket, and a 8 W medium-pressure mercury lamp (Institute of Electric Light Source, Beijing) positioned axially at the center as a 365 nm UV-A light source. The reaction temperature was kept at 25 °C by cooling water. A special glass frit as air diffuser was fixed at the bottom of the reactor to uniformly disperse air into the solution.

[Fig. 1]

2.5. *Experimental procedure*

In order to investigate the effects of bismuth doping on the photocatalytic activity of TiO₂, the oxidative photodegradation of methylparathion was carried out in the aerated TiO₂ or Bi-TiO₂ suspension under UV-A irradiation. The reaction suspensions were prepared by adding 0.25 g of catalyst into 250 ml of aqueous methylparathion solution with an initial concentration of 20 mg l⁻¹. Prior to photoreaction, the suspension was magnetically stirred in a dark condition for 30 min to establish an adsorption/desorption equilibrium condition. The aqueous suspension containing methylparathion and photocatalyst was then UV-A irradiated with constant aeration. At the given time intervals, the analytical samples were taken from the suspension and

immediately centrifuged at 4000 rpm for 15 min, then filtered through a 0.45 μm Millipore filter to remove particles. The filtrate was analyzed by HPLC, DOC and IC for the degree of the methylparathion degradation.

2.6. Analytical methods

The methylparathion concentration was analyzed by a HPLC instrument with a UV-VIS detector (Finnigan Mat Spectra System P4000). In the HPLC analysis, a pinnacle II C18 column (5 μm particle size, 250 mm length and 4.6 mm inner diameter) was employed and mobile phase of acetonitrile/water (7:3 v/v) was used with a flow rate of 0.8 ml min^{-1} . An injection volume of 20 μl was used and the UV detector determined the amount of methylparathion. The DOC concentration was determined by a TOC-analyser (Shimadzu 5000A) equipped with an auto sampler (ASI-5000). The concentrations of the photoreaction products nitrate and sulphate were determined by ion chromatography (IC) using a conductivity detector (Alltech ICM-300 Ion Chromatograph). An AllsepTM (100 mm \times 4.6 mm) anion column and mobile phase containing 0.51 mM sodium bicarbonate and 0.54 mM sodium carbonate with a flow rate of 1 ml min^{-1} was used for the determination of nitrate and sulphate.

3. Characterization of photocatalysts

3.1 XRD analysis of TiO_2 and Bi- TiO_2 photocatalysts

The crystalline quality and crystal structure of TiO_2 and Bi- TiO_2 samples were examined by XRD and the diffractograms are shown in Fig. 2. It has been reported by several groups [13,14] that sol-gel samples of TiO_2 undergo a phase transformation from anatase to rutile phase during sintering treatment. In this study all the samples were sintered at 500 $^\circ\text{C}$ for 2 h in a muffle furnace and the diffractograms in Fig. 2 reveal that all the Bi- TiO_2 and pure TiO_2 samples possess the anatase phase. No additional peaks are detected.

[Fig. 2]

Based on the XRD results, the crystallite sizes of the TiO₂ and Bi-TiO₂ powders were calculated using the Scherrer equation [17] and were found to be between 16 and 22 nm. The lattice parameters **a** and **c** [18] were measured as 0.38 nm and 0.95 nm in all samples. The doping of up to 2% Bi³⁺ into the TiO₂ lattice therefore does not give significant changes in the diffractograms. Similar conclusions have previously been made by Xu et al. [19] showing that XRD is not sensitive enough to detect such minor changes to the TiO₂ materials.

3.2 ESEM, TEM and EDX analyses of TiO₂ and Bi-TiO₂ photocatalysts

The texture and morphology of the pure TiO₂ sample in comparison with 1%-doped Bi-TiO₂ were also observed by electron microscopy and the typical ESEM micrographs shown in Fig. 3 reveal that both of these two samples were composed of particles with a similar size about 15 nm. Since no obvious particle agglomeration occurred, the large surface area conveys high adsorption abilities of the catalysts. Fig. 4A shows the TEM bright-field image of TiO₂ particles, with average diameter about 22 nm. The inserted image in this figure is their corresponding diffraction pattern. The first four rings correspond to the interplanar distances (in nm) of 0.346, 0.227, 0.186 and 0.168. They are consistent with (101), (103), (004/112) and (200) diffractions from anatase. Fig. 4B shows the bright-field image of Bi-TiO₂ particles. The average diameter of these particles is about 17 nm. Again, the inserted figure is the corresponding diffraction pattern, which can be also indexed as anatase. However, the calculated interplanar distances are slightly larger than for pure TiO₂, as shown in the following for the corresponding first four diffractions (in nm): 0.357, 0.238, 0.192 and 0.173. The TiO₂ lattice is apparently expanded by Bi³⁺ doping.

[Fig. 3]

[Fig. 4]

EDX analysis was carried out for neat and doped TiO₂ using SEM, TEM and ESEM. Fig. 5A shows results from SEM for TiO₂ where only Ti and O are detected. Fig 5B shows the SEM result for 1% Bi³⁺-doped TiO₂ and the Bi L_α line is observed very weak, and more clearly shown in the inset from TEM-EDX, Fig. 5B. The analytical results from EDX are in reasonable agreement with the nominal wt% of Bi³⁺ doped into TiO₂. EDX elemental maps of samples for

Ti, O and Bi showed homogeneous elemental distributions and no clustering of Bi was detected in the 1%-doped Bi-TiO₂ sample.

[Fig. 5]

3.3 XPS and the valence states of TiO₂ and Bi-TiO₂ photocatalysts

The XPS spectrum shows that there are Ti, O and C on the surface of the neat TiO₂, and there are Ti, O, C and Bi on the surface of bismuth doped TiO₂. The C arises from the organic precursors for the sol-gel method which are not completely removed during heat treatment. According to the high resolution XPS spectra, the transitions involving the Ti 2p, O 1s, and Bi 4f orbitals are observed. For pure TiO₂ and 1% Bi-TiO₂, the Ti 2p peaks are narrow with slight asymmetry and have a binding energy of 458.70 eV (full width at half-maximum, FWHM 1.0 eV), showing the presence of Ti⁴⁺. There was no evidence for the presence of Ti³⁺ in 1% Bi-TiO₂. The O 1s wide peak structure for Bi-TiO₂ at 530.79 eV (FWHM 1.36 eV) is at a similar energy to the O 1s electron binding energy for TiO₂, where the narrow peak has slight asymmetry with a binding energy of 529.81 eV (FWHM 1.15 eV). Finally, the Bi 4f peaks of Bi-TiO₂ consisted of several individual peaks in the region 155-167 eV corresponding to Bi³⁺.

3.4 Optical absorption properties of photocatalysts

The FTIR spectra of the photocatalysts diluted and pressed in KBr discs show a strong, broad feature between 470 and 690 cm⁻¹, due to Ti-O stretching vibration modes. Weak features are observed at ~3430 and 1630 cm⁻¹, due to adsorbed water. These latter two bands are also present in the KBr disc alone. The UV-visible absorption spectra of Bi-TiO₂ samples were measured in the wavelength range 250-800 nm at room temperature using transmission spectra and between 350-500 nm using DRS. The transmission spectrum of a KBr disc of (1%) Bi-TiO₂ exhibits an increasing absorption at wavelengths below 500 nm. A clearer comparison of the doped and neat samples is given by DRS (Fig. 6) where it is evident that increasing the %Bi³⁺ doped into the sample gives rise to longer wavelength absorption. Extending the absorption of TiO₂ further into the visible region is expected to provide enhanced photocatalytic behaviour. A

brief discussion is now given concerning the reasons for the long wavelength tail in the doped photocatalysts.

[Fig. 6]

According to theory [20], semiconductors absorb light below a threshold wavelength λ_g (the fundamental absorption edge). The band gap energy value of anatase (TiO_2) is about 3.2 eV with the threshold wavelength $\lambda_g = 387.5$ nm. It is well known that intrinsic transitions give sharp increases in absorbance whereas impurity or defect state transitions give absorption tails in semiconductors. An impurity atom changes its local lattice environment, but since the $6s^2$ configuration Bi^{3+} ion (ionic radius 103 pm) is unable to directly substitute the $4s^0$ Ti^{4+} ion (ionic radius 61 pm) using a "soft" chemical method of preparation, a new phase is formed. An analogous case has been observed when the lanthanide ion Er^{3+} is doped into $\alpha\text{-Al}_2\text{O}_3$ [21] where the host ion size is also much smaller, so that new compounds are formed, with ErAlO_3 being formed at lower dopant ion concentrations of Er^{3+} , rather than $\text{Er}_3\text{Al}_5\text{O}_{12}$. Several compounds have been well characterized in the $\text{Bi}^{3+}\text{-TiO}_2$ case: $\text{Bi}_2\text{Ti}_2\text{O}_7$ [22], $\text{Bi}_4\text{Ti}_3\text{O}_{12}$ [23,24] and $\text{Bi}_{12}\text{TiO}_{20}$ [25]. The first of these comprises disordered $(\text{Bi}_2\text{O})^{4+}$ tetrahedral nets interpenetrating with corner-sharing $(\text{Ti}_2\text{O}_6)^{4-}$ octahedra [26]; the second consists of three $(\text{Bi}_2\text{Ti}_3\text{O}_{10})^{2-}$ layers sandwiched between two $(\text{Bi}_2\text{O}_2)^{2+}$ layers [19]; whereas the third comprises $(\text{TiO}_4)^{4-}$ tetrahedra and a Bi-O polyhedral network [25]. All compounds exhibit two characteristic features. First, the band gap is reduced from that of TiO_2 , with the energy band assumed to be between the top of the (lone pair) Bi^{3+} 6s band and the bottom of the Ti^{4+} 3d band [25]. Thus the absorption spectra extend to longer wavelengths so that lower energy photons can be absorbed for photoreaction. Second, the positively-charged Bi-O polyhedra can function as electron sinks, which has repercussions for the photoluminescence and photocatalytic properties.

3.5 *PL spectra of the photocatalysts*

The PL spectra are useful to disclose the efficiency of charge carrier trapping, migration and transfer, and to understand the nature of electron-hole pairs in semiconductor particles since PL emission results from the recombination of free carriers. In this study, the 325 nm excited

room temperature PL spectra of all pressed-powder samples were examined in the range of 350-550 nm. The results (not shown here) indicated that the luminescence intensity of neat TiO₂ ($\lambda_{em(max)} \sim 388 \pm 10$ nm; FWHM ~ 75 nm) was substantially quenched by the doping of Bi³⁺. The relative intensity of the 0.3% and 1% Bi³⁺-doped samples was ~ 0.7 of that of undoped samples. No significant band shifts were observed. Thus Bi³⁺ doping of TiO₂ hinders free carrier recombination under irradiation.

The emission spectra of neat TiO₂ and (1.0%) Bi-TiO₂ were also recorded at 10 K under 355 nm laser excitation and the results shown in Fig. 7 differ considerably from those at room temperature. First, the neat TiO₂ emission band is red-shifted to 542 nm (2.3 eV). Furthermore, the quenching of emission by Bi³⁺ is more pronounced and the Bi³⁺-doped sample emits at a slightly longer wavelength. The low energy emission band in the neat TiO₂ sample resembles the ~ 530 nm emission band reported for TiO₂:Er³⁺ under 325 nm excitation at 20 K. The latter has been assigned to the reduction of Ti⁴⁺ to Ti³⁺ after H₂O adsorption [27]. However, this hypothesis requires further confirmation since the emission could otherwise be due to self-trapped exciton states in TiO₂ [28]. It is clear however that Bi³⁺ again acts as a trapping centre.

[Fig. 7]

4. Photocatalytic degradation of methylparathion

4.1 Photocatalyst activity for the degradation of methylparathion

In order to determine the photocatalytic activity of Bi-TiO₂ and find out the optimum content of Bi impurity, a set of experiments for methylparathion degradation under UV-A irradiation was carried out in aqueous suspension with either TiO₂ or different Bi-TiO₂ catalysts with a Bi content between 0.3% and 2%, and the experimental results are shown in Fig. 8. The experiments demonstrated that methylparathion was degraded by more than 95% within 120 min for all catalysts including pure TiO₂. However, the Bi-TiO₂ catalysts attained faster degradation rates than the neat TiO₂ catalyst. For example, the experiment using 1.5% Bi-TiO₂ achieved a complete degradation of methylparathion at 90 min. It was found that pseudo-first-order kinetics was obeyed for the photocatalytic degradation of methylparathion as illustrated in Fig. 8. The

calculated first-order kinetic constants are listed in Table 1 and show maximum values in the range of Bi³⁺ content between 0.7 and 1.5 wt%. It is well-known that the photocatalytic mechanism of TiO₂ involves electron-hole production, with the separated electrons and holes generating reactive radical species such as O^{2·-} and ·OH, respectively. Thus from the kinetic results it is clear that Bi-TiO₂ at intermediate doping concentrations functions more effectively as a separation center. Presumably the reduced efficiency at the highest dopant ion concentration (2%) is due to the formation of Bi³⁺ clusters.

[Fig. 8]

The reactive radicals formed in the photocatalytic process further react with organic and inorganic compounds adsorbed on TiO₂ and oxidize or reduce them. Generally speaking, the photocatalytic activity of TiO₂ mainly depends upon three factors: (1) the electron-hole generation capacity; (2) the separation efficiency of the photogenerated charge pair; and (3) the charge transfer efficiency of holes and electrons to compounds adsorbed on TiO₂. The yield of the photogenerated electron-hole pair first depends upon the intensity of incident photons with energy exceeding or equaling to the TiO₂ band gap energy. Our results indicate that Bi-TiO₂ photocatalyst is superior to neat TiO₂ for methylparathion degradation since the degradation rate is almost doubled. As mentioned above, the most effective photocatalysts are in the regime of 0.7-1.5% Bi³⁺ doping. This efficiency is ascribed to process (2) in which the Bi-O polyhedral centres act as traps for photogenerated electrons and deter the pair recombination process.

4.2 Effect of pH on the degradation of methylparathion

The effect of pH upon the photocatalytic degradation of methylparathion by Bi-TiO₂ was investigated by performing the degradation study in the initial pH range of 2 to 10 for 1% Bi³⁺ doping, with the initial concentrations (C₀) of methylparathion 20 mg l⁻¹ and catalyst 1 g l⁻¹. The experimental results are shown in Fig. 9. A higher degradation rate and adsorption were observed at low pH values, with a monotonic rate constant decrease from pH 2 ($k \sim 5 \times 10^{-2} \text{ min}^{-1}$) to pH 10.0 ($k \sim 3.5 \times 10^{-2} \text{ min}^{-1}$). The amphoteric behaviour of many metal oxides changes the surface charge properties of the catalyst when the pH changes. For Bi-TiO₂, increasing the solution pH diminished the adsorption of methylparathion. The zero-point charge pH_{zpc} is 6.8 for

TiO₂ particles (Degussa) [29]. In the Bi-TiO₂ system, TiO₂ is more positively charged in an acidic medium (pH < 6.8) than in an alkaline medium (pH > 6.8) based upon the zero point charge. Hence, at lower pH methylparathion, which has electronegative centres (N and S), can have enhanced adsorption on the catalyst surface. This effect acts to increase the degradation of methylparathion at lower pH. It was also observed from mass balance experiments performed in the dark that very little methylparathion is actually adsorbed onto the catalyst. The rate of photodegradation therefore has the bottleneck of adsorption. In this study, all the experiments with different initial pH values were conducted without a pH control. It was found that pH decreased during the photocatalytic degradation of methylparathion. For example, the reaction solution with an initial pH 7 was run for 120 min with a final pH 3.6. These results indicate that the products of methylparathion degradation contain a certain amount of acidic compounds: either organic acids such as oxalic acid, acetic acid and formic acid or inorganic acids such as sulphuric acid and nitric acid, according to a pathway of methylparathion degradation proposed by Vlyssides et al. [2].

[Fig. 9]

4.3 Mineralization of methylparathion

To study the mineralization of methylparathion in this photocatalytic reaction, a set of experiments of methylparathion degradation with an initial concentration of 20 mg l⁻¹ (DOC = 7.3 mg l⁻¹) was carried out using different photocatalysts and samples were collected at suitable time intervals for up to 120 min, and then analyzed for DOC concentration. The experimental results are shown in Fig. 10. The DOC removals after 120 min are given in parentheses for the various photocatalysts: neat TiO₂ (21%), 0.3% Bi-TiO₂ (39%), 0.5% Bi-TiO₂ (42%), 0.7%Bi-TiO₂ (53%), 1% Bi-TiO₂ (61%), 1.5% Bi-TiO₂ (58%), and 2.0% Bi-TiO₂ (46%). These results indicate that the doping regime between 0.7% and 1.5% of Bi³⁺ achieved the highest percentage of DOC removal.

[Fig. 10]

In order to elucidate the mineralization pathways for the degradation of methylparathion, a detailed investigation was carried out using 1% Bi-TiO₂ for 180 min. During the reaction, samples were collected and analyzed for concentrations of methylparathion, DOC, nitrate ion, and sulphate ion. The normalized experimental results are shown in Fig. 11. It can be seen that methylparathion almost disappeared at 90 min. However, although the DOC concentration in the solution decreased significantly during the photoreaction from the initial value of 7.3 mg l⁻¹, 47% of the initial DOC still remained. After 120 min, methylparathion was completely degraded, whereas DOC had 38% leftover. It is clear that the disappearance of the reactant was considerably faster than the mineralization process. The experimental results also confirm that the decomposition of methylparathion proceeded by a nitrate and sulphate release pathway. After 180 min, conversion of nitrogen (N) and sulphur (S) from organic forms into inorganic products was achieved by 68% and 84%, respectively, whereas the conversion of carbon (C) was by 74% with 26% of DOC remaining. These results indicate that the conversion of carbon, nitrogen and sulphur was ranked from high to low as S > C > N during this photocatalytic reaction. The pathway proposed by Vlyssides et al. [2] also illustrates the sequencing steps of methylparathion degradation reaction, in which sulphate formation occurs at an earlier stage than nitrate formation.

[Fig. 11]

5. Conclusions

A series of bismuth-deposited titania samples were prepared, well-characterized, and then employed for the photodegradation of methylparathion under UV-A radiation. The photocatalytic degradation of methylparathion in aqueous solutions was further promoted by the Bi-TiO₂ photocatalysts, compared with neat TiO₂ alone. The doped bismuth was shown to be present in the 3+ oxidation state by XPS, and to exist in pores or on the surface of the TiO₂ as regions of positive sites comprising Bi-O polyhedra. The optimal content of Bi³⁺ doping for photocatalysis was in the regime between 0.7 and 1.5%. The ability of the Bi-O sites to act as electron traps was not only illustrated in the photocatalysis experiments but also in the photoluminescence study. In summary, it has been demonstrated that methylparathion was

effectively degraded in aqueous Bi-TiO₂ suspension to an extent of 97% within 120 min, whilst DOC was also converted into CO₂ with the high proportion of up to 62%. This study confirms the potentialities of heterogeneous photocatalysis to decontaminate wastewaters containing organic pollutants, which are often toxic for bacteria in biological treatments. The present findings can be valuable in designing in-situ treatment of pesticide-contaminated water and wastewater.

Table 1.

First-order kinetic constants of methylparathion photodegradation by Bi-TiO₂ (Initial concentration, C₀ = 20 mg l⁻¹)

Photocatalyst	Kinetic constant, k (min ⁻¹)	Coefficient of determination, R^2
Pure TiO ₂	3.8×10^{-2}	0.9571
0.3% Bi-TiO ₂	3.3×10^{-2}	0.9937
0.5% Bi-TiO ₂	3.7×10^{-2}	0.9724
0.7% Bi-TiO ₂	5.3×10^{-2}	0.9953
1.0% Bi-TiO ₂	4.8×10^{-2}	0.9990
1.5% Bi-TiO ₂	5.6×10^{-2}	0.9975
2.0% Bi-TiO ₂	4.1×10^{-2}	0.9914

Figure Captions

- Fig. 1. The schematic diagram of the photoreactor system (1. air; 2. water; 3. UV-A lamp; 4. timer; 5. stirrer; 6. quartz jacket).
- Fig. 2. XRD diffractograms of (a) TiO_2 and (b)-(d) Bi-TiO_2 . The structure corresponds to anatase (A) [15,16].
- Fig. 3. ESEM micrographs of two photocatalysts: (A) TiO_2 and (B) 1% Bi-TiO_2 .
- Fig. 4. TEM micrographs of (A) TiO_2 and (B) 1% Bi-TiO_2 . The inserted figures indicate the diffraction patterns of the anatase phase.
- Fig. 5. SEM-EDX of two photocatalysts (A) TiO_2 and (B) 1% Bi-TiO_2 . The inset in (B) shows the TEM-EDX result for (B) at higher sensitivity.
- Fig. 6. Diffuse reflectance UV-visible spectra of neat and Bi^{3+} -doped TiO_2 at room temperature.
- Fig. 7. The PL spectra of neat TiO_2 and 1% Bi^{3+} -doped TiO_2 photocatalysts in the range of 440-740 nm at 10 K. The breaks in the curves are artifacts due non-overlap of the window edges of the charge-coupled device detector.
- Fig. 8. Kinetic fits for the degradation of methylparathion by TiO_2 and Bi-TiO_2 . (Initial concentration of methylparathion 20 mg l^{-1} ; pH 3.4; catalyst 1 g l^{-1}).
- Fig. 9. Effect of pH on the degradation of methylparathion by Bi-TiO_2 . (Initial concentration of methylparathion 20 mg l^{-1} ; catalyst 1 g l^{-1})
- Fig. 10. DOC removals during methylparathion degradation using different catalysts
- Fig. 11. Time change of normalized concentration of methylparathion, DOC, sulphate and nitrate in the mineralisation of methylparathion. (Initial concentration of methylparathion 20 mg l^{-1} ; catalyst 1 g l^{-1}).
