Graphical abstract

Highlights

- NR1H4/FXR is highly expressed in stellate cells of human and murine livers.

- NR1H4 binding motifs are highly enriched in stellate cell accessible chromatin.

- The NR1H4 agonist obeticholic acid upholds expression of stellate cell identity genes.

- Stellate cell-confined expression of G_SPCR VIPR1 is attenuated in MASH livers.

- cAMP induces stellate cell expression of homeostatic factor GDF2 *in vitro* and *in vivo.*

Impact and implications

Homeostatic interactions between hepatic cell types and their deterioration in metabolic dysfunction-associated steatohepatitis are poorly characterized. In our current single cell-resolved study of advanced murine metabolic dysfunction-associated steatohepatitis, we identified a quiescence-associated hepatic stellate cell-signaling module with potential to preserve normal sinusoid function. As expression levels of its constituents are conserved in the human liver, stimulation of the identified signaling module is a promising therapeutic strategy to restore sinusoid function in chronic liver disease.

Single cell-resolved study of advanced murine MASH reveals a homeostatic pericyte signaling module

Background & Aims: Metabolic dysfunction-associated steatohepatitis (MASH) is linked to insulin resistance and type 2 diabetes and marked by hepatic inflammation, microvascular dysfunction, and fibrosis, impairing liver function and aggravating metabolic derangements. The liver homeostatic interactions disrupted in MASH are still poorly understood. We aimed to elucidate the plasticity and changing interactions of non-parenchymal cells associated with advanced MASH.
Methods: We characterized a diet-induced mouse model of advanced MASH at single-cell resolution and validated findings by assaying chromatin accessibility, bioimaging murine and human livers, and via functional experiments *in vivo* and *in vitro*.
Results: The fibrogenic activation of hepatic stellate cells (HSCs) led to deterioration of a signaling module consisting of the bile acid receptor NR1H4/FXR and HSC-specific G_S-protein-coupled receptors (G_SPCRs) capable of preserving stellate cell quiescence. Accompanying HSC activation, we further observed the attenuation of HSC *Gdf2* expression, and a MASH-associated expansion of a CD207-positive macrophage population likely derived from both incoming monocytes and Kupffer cells.
Conclusion: We conclude that HSC-expressed NR1H4 and G_SPCRs of the healthy liver integrate postprandial cues, which sustain HSC quiescence and, through paracrine signals, overall sinusoidal health. Hence HSC activation in MASH not only drives fibrogenesis but may desensitize the hepatic sinusoid to liver homeostatic signals.

Introduction

Metabolic dysfunction-associated steatohepatitis (MASH) is the result of years of cycling between insults and inadequate regeneration and presents itself as a state of elevated cellular turnover and net deposition of extracellular matrix (ECM). Function of the MASH liver is compromised by inflammation, microvascular dysfunction, and fibrosis, aggravating the initial metabolic derangements. This deterioration of liver function is attributed to hepatocellular plasticity and shifts in cellular communication. Yet, the progression of MASH is incompletely understood, as studies resolving liver plasticity in advanced MASH are scarce. Comprehensive analysis of human MASH is hindered by the sparsity of patient liver biopsies and by patient differences. Single cell-resolved studies of murine liver fibrosis have provided important insights into early disease development[1–3] but only partially recapitulated established human MASH. A thorough account of hepatocellular dynamics in advanced MASH in the face of prolonged dietary challenge is hence needed to delineate the altered cellular fluxes and information circuits amenable to therapeutic intervention.

Herein, we document the phenotypic redefinition of hepatic cell populations in established MASH in mice fed a Western diet for 52 weeks. We lay out the concept that postprandial cues preserve hepatic stellate cell quiescence and sinusoidal homeostasis, which may guide pharmacological intervention in MASH.

Materials and methods

Animal experiments

MASH was introduced in C57BL/6JBomTac mice by Western diet supplemented with D-fructose (42 g/L) in drinking water for 52 weeks. Age-matched control mice were fed standard chow and pure drinking water. Mice were fasted overnight before sacrifice. The *FLEx-TRAP* knock-in mouse was generated from

the fusion gene *mCherry-Rpl10a*-(IRES)-*FLPo* and the Flip-excision (FLEx)-switch.[4] Gt(ROSA)26Sor^tm1(CAG-Chrm3*/GFP, cAMPRE-luc)Berd (G_SD), Tg(Lrat-cre)1Rshw mice (Lrat-cre) were previously described.[5,6] From 12 weeks of age, G_SD and Lrat-cre:G_SD mice were fed the GAN (Gubra-Amylin MASH) diet for 12 weeks. From 2 days before sacrifice, mice were fasted from zeitgeber time 6 to 12 and given 0.1 mg/kg deschloroclozapine in corn oil by oral gavage. On the third day, mice were sacrificed at zeitgeber time 13.5. All animal experiments were approved by the Danish Animal Experiments Inspectorate (approval #2020-15-0201-00603) and adhered to the ARRIVE guidelines.

Immunohistochemistry and staining of FFPE tissues

Mouse liver lobules were immersion-fixed in 4% para-formaldehyde for 16 h and embedded in paraffin (FFPE). For immunohistochemistry (IHC), sections were probed with indicated antibodies (see supplementary methods and table S2) and incubated with EnVision-HRP-coupled anti-rabbit IgG and AEC+ substrate-chromogen solution. Sections were counter-stained with hematoxylin. Human liver biopsies were performed in patients with severe obesity as part of the PROME-THEUS study (ethics approval S-20160006G) conducted in accordance with the guidelines of the Declaration of Helsinki and the principles of good clinical practice. All subjects gave written informed consent for study participation and a separate biobank consent. Human FFPE liver tissue was stained as described previously with minor modifications.[7] Dual PDGFR and NR1H4 IHC immunoreactivity was visualized using DAB+ and Vector SG chromogens. No counter-staining was performed.

Immunofluorescence and single-molecule fluorescence *in situ* hybridization

Fixed-frozen OCT (optimal cutting temperature) compound-embedded liver tissue was cut, permeabilized, and blocked before probing with antibodies and DAPI. Single-molecule fluorescence *in situ* hybridization (FISH) was conducted on FFPE sections using the RNAscope Multiplex Fluorescent Reagent Kit v2 assay according to the manufacturer's instructions. Slides were mounted with ProLong Diamond Antifade Mountant and DAPI and scanned on a Nikon A1 confocal microscope. Images were passed through the AFid algorithm for autofluorescence mitigation. The same settings were used for all images. Single-molecule FISH image quantification was performed using QuPath (v.0.2.3). Digital cell detection was based on DAPI staining. Data visualization and statistics were performed in R.

Whole liver/bulk RNA purification, sequencing, and analysis

Whole liver RNA was extracted by phenol/chloroform and column purification. Libraries were constructed using the NEBNext Ultra RNA Library Prep Kit for Illumina and paired-end sequenced on the NovaSeq 6000. *STAR* was used for alignment of reads to the mm10 genome. *DESeq2* was used to identify differentially expressed genes. Data visualization and statistics were performed in R. A weighted correlation network analysis (WGCNA) was performed using the *WGCNA* R-package based on 5,000 genes with top loadings across the first four principal components.

Gene expression analysis of *Nr1h4* knockout livers

Nr1h4 knockout animals treated with GSK2324 or vehicle for 3 days, whole liver RNA extraction, cDNA synthesis and qPCR analysis were described previously.[8] Relative expression values for all genes of interest were normalized to *Rplp0* (36B4) expression. Differential expression between conditions (false discovery rate <0.05) was determined by pairwise Wilcoxon Rank Sum tests, Benjamini-Hochberg-adjusted for multiple testing. Primer sequences are provided in Table S1.

Whole liver protein purification and mass spectrometry analysis

For quantitative comparison of the liver proteomes, we prepared peptides essentially as described elsewhere.[9] Equal fractions of peptides from all animals were used to generate a spectral library for liquid chromatography mass spectrometry analysis on a Q Exactive HF-X mass spectrometer and data-independent acquisition. Only proteins identified in ≥3 animals per group were included in the analyses. Differentially expressed proteins were identified using DESeq2. Data analysis and visualizations were performed in R.

Hepatic cell isolation for single-cell sequencing and culture

For single-cell RNA sequencing experiments, retrograde liver perfusion was performed as described.[7] Anti-ASGR1 and anti-CD31-conjugated antibodies were used for partial immuno-depletion and SYTOX Red for dead cell labeling. From each liver, 20,000 live singlets were sorted and loaded onto the 10x Genomics Chromium controller, and Single-Cell 3' v3 libraries were prepared according to the manufacturer's instructions. For stellate cell culture, cells were separated by density centrifugation and sorted by retinoid content and viability and seeded in 24-well plates with 50,000 cells per well.

Single-cell RNA sequencing data analysis

Sequencing data was demultiplexed, aligned against the mm10 reference genome, quantified, and aggregated using the standardized pipeline in the *Cell Ranger* Single-Cell Software Suite. The *Seurat* package was used for data pre-processing, and doublets removed with *DoubletFinder*. Corrected counts were integrated by *Seurat* batch-correction. For clustering, we used the Seurat implementation of the Leiden algorithm. Testing of differential abundance of subpopulations was performed using *miloR*. Identification of transcription factors and putative target genes was performed in pySCENIC. Mononuclear phagocyte transitions were found using *scVelo*. For diffusion maps, trajectory estimations and differential expression, we used *Destiny* in the R-package *Scater*, *Slingshot*, and *tradeSeq*, respectively. For prediction of ligand-receptor interactions we employed *NicheNet*. Human liver single-nuclei data (GSE212837) were processed with *Seurat*. *DecontX* was used for removal of ambient RNA and *DoubletFinder* for doublet removal. Batch integration was performed in Harmony.

Hepatic stellate cells *in vitro* treatments

All treatments started at 40 h post isolation. Obeticholic acid (OCA): hepatic stellate cells (HSCs) were treated with 10 μM OCA or DMSO for 6 h before harvest. Forskolin: HSCs were treated

with 5 μM forskolin or DMSO for 3 h. For acute effects, cells were harvested immediately. For long-term effects, medium was changed, and HSCs were cultured for an additional 21 h before harvest. OCA/vasoactive intestinal peptide (VIP): HSCs were treated with 5 μM OCA or DMSO for 3 h followed by the addition of 0.5 μM VIP for an additional 3 h before harvest. Cells were harvested in TRIzol, and RNA purified as described above.

ATACseq and single-nucleus ATACseq

Nuclei were isolated from Lrat-cre:FLEx-TRAP mouse livers after heart perfusion with 4% PFA followed by dounce homogenization, straining, density centrifugation, and fluorescence-sorting based on DAPI and mCherry (Fig. S5A). Chromatin was tagmented and reverse-crosslinked before column cleanup, PCR amplification, library generation and sequencing. Peak annotation, *de novo* motif-enrichment analyses, and motif scoring were conducted in *HOMER*. For single-nucleus assay for transposase-accessible chromatin-sequencing (ATACseq), liver nuclei were processed using the Chromium Next GEM Single Cell ATAC Library & Gel Bead Kit v1.1 on the 10x Genomics Chromium controller. Barcode-filtering, clustering and peak calling were done using the *ArchR* pipeline. The stellate cell cluster was identified based on chromatin accessibility in *Lrat*, *Dcn*, and *Reln* loci. The HOMER pipeline was used for motif-enrichment analyses.

Additional details are provided in the supplementary data file and the supplementary CTAT table.

Results

Western diet and fructose-feeding features advanced MASH

Advanced MASH was established in male C57BL/6J mice by feeding a Western diet supplemented with D-fructose in the drinking water for 52 weeks (WD; n = 8). Age-matched control mice (chow; n = 9) were fed chow diet and pure drinking water. WD-fed mice gained weight relative to chow-fed mice and exhibited elevated fasting blood glucose and serum alanine aminotransferase levels indicating insulin resistance and liver injury (Fig. 1A). WD-fed mice exhibited hepatic steatosis and prominent pericellular fibrosis (Figs. 1B,C). We further observed expansions of F4/80-positive macrophages and hepatic αSMA+ cells (Fig. S1A) but saw no indication of myofibroblast proliferation. MASH-specific KI67 staining was cytoplasmic and frequently adjacent to crown-like structures (Fig. S1B). *Mki67* RNA mainly localized to *Clec4f+ Trem2+* cells in crown-like structures, independently of *Itgax*, and occasionally to large cells with round nuclei reminiscent of hepatocytes (Figs. S1C-E). No *Mki67+/Dpt+*-activated HSCs (aHSCs) or myofibroblasts were seen (Fig. S1F).

To elucidate molecular changes, we sequenced mRNA from total liver and characterized the proteome. We detected 16,900 transcripts and 5,222 proteins with 4,968 shared features (Fig. 1D). Differences in transcriptomes and proteomes across animals were largely diet-driven (Fig. S1G). Comparing dietary groups, differential expression analyses (*p*.adj. <0.05) revealed 7,230 transcripts and 2,580 proteins (Fig. 1D). In advanced MASH, 434 induced genes and 605 repressed genes showed significant, codirectional changes at the protein level (Spearman rank correlation R = 0.61, *p* <2.2E-16). Differentially expressed genes (DEGs) and proteins (DEPs) belonged to comparable

biological processes and pathways (Figs. 1E, S1H). Induced genes were implicated in regenerative and immune system processes (*up*-DEG, *p*.adj. <0.05; Fig. 1E) whereas WD-repressed genes (*down*-DEG, *p*.adj. <0.05) were linked to glucose, lipid, and bile acid metabolic processes (Fig. 1E).

While the differences *between* diet groups dominated, we leveraged the minor differences *within* our WD-fed group to identify processes that covaried. A WGCNA[10] led to 23 co-expression modules (Fig. S1I). Clustering by adjacencies of the module eigengenes gave us seven clusters of modules across our MASH mice (Fig. 1F). Enriched gene ontology (GO) terms for genes in the clusters showed coupling of processes across cell types (Fig. 1G). Some clusters inversely correlated, such as clusters A & G, clusters B & D, and clusters E & F. Clusters B, E, and G relating to nutrient handling, and clusters A, D, and F reflecting zone-3 detoxification processes, regeneration, and inflammation, respectively. *Within* co-expression modules we found signature genes of aHSCs, macrophages, and endothelial cells, expression of which covaried tightly across our WD-fed mice (Fig. 1G and not shown). Still, all were significantly induced in WD-fed compared to chow-fed mice and likely represent coupled, MASH-associated processes.

Cell type-resolved analysis of MASH-associated shifts in hepatic gene expression

For a single cell-resolved view, we dissociated livers of 52-week WD- and chow-fed mice (n = 6). We limited the input of hepatocytes and endothelial cells through partial anti-ASGR1 and anti-CD31 immunodepletion and sequenced libraries of live cells (Fig. S2A). The 32,282 cells clustered into 22 Leiden clusters, all containing cells from both conditions (Figs. 2A, B and S2B). From marker gene expression, we identified 10 major hepatic cell types and a population of *Birc5+* cycling cells (Figs. 2C–E and S2C). In keeping with histology and bulk data, statistical analysis using miloR[11] showed increased abundances of mononuclear phagocytes (MPs), dendritic cells (DCs), T cells/natural killer (NK) cells, and neutrophils. The same was true for *neighborhoods* of mesenchymal and cholangiocyte-like cells whereas other mesenchymal, endothelial and hepatocyte subpopulations were reduced (Fig. 2E *left*).

We next assigned the annotated cell types to the WGCNA modules from our MASH livers. These assignments confirmed our GO analyses (Fig. S2D) and distilled the inverse relationship between normal parenchymal function, inflammation, and regeneration in MASH.

Expression changes within cell populations were prominent in advanced MASH including the repression of Kupffer cell (KC) genes *Cd163* and *Marco*, hepatocyte *Acot1-4*, and hedgehog-associated *Hhip* and *Disp2* in HSCs (Fig. 2F). Major transcriptional increases included the angiogenesis-associated gene *Esm1*, macrophage *Gpnmb*, hepatocyte serum amyloid genes *Saa1/2*, and fibrosis-associated *Col1a1* and *Dpt* in aHSCs. We attributed discrepancies between bulk and cluster-averaged single-cell expression changes to changes in cell stoichiometry *in situ*. This was most apparent for neutrophils, T cells and B cells leading to increased whole liver *S100a8*, *Cd3g*, and *Ly6d* expression. We further subclustered endothelial cells, cholangiocyte-like cells and hepatocytes, NK cells, T cells, DCs, neutrophils, plasma cells and B cells for increased resolution (Figs. S2E-J).

DEG, differentially expressed gene; DEP, differentially expressed protein; GO, gene ontology; WD, Western diet; WGCNA, weighted correlation network analysis. (This figure appears in color on the web.)

We inferred gene regulatory networks defining these cell populations in advanced MASH, using SCENIC.[12] Clustering of cells according to regulon activity (AUC) scores led to 12 clusters largely aligned with cell types (Figs. 2G and S2K, L). Marker regulons for each cluster and mean AUC scores for cells herein allowed us to infer cell type- and condition-specific transcription factor (TF) activities (Figs. 2H and S2M). Top TFs predicted to lose activity in resident cells in MASH included HSC lineage-determining factors FOXF1,[13] LHX2,[14] and NR1H4 in mesenchymal cells, HOXA5 in endothelial cells, and the xenobiotic receptor NR1I3/CAR in hepatocytes (Fig. 2H). Developmental and regenerative TFs appeared activated in MASH including GATA6, MECOM, and SOX17 in endothelial and mesenchymal cells, as well as FOXJ1, FOXP2, and HNF1B in the cholangiocyte-like cells. MASH-repressed TF activities within immune cell clusters included MAFB, ETV5, NR1H3 in KCs, and a panel of T cell- and NK cell-enriched TFs including EOMES and STAT4 (Fig. S2M). SPI1/PU.1, CEBPE, and IRF5 were among the most activated TFs within myeloid clusters likely reflecting shifts in cluster composition in MASH.

We recapitulated at single-cell resolution the broad transcriptional changes in advanced MASH. We predicted these changes to be rooted in reset TF activities across cell types, aligning well with the shift from nutrient and xenobiotic handling to inflammatory and wound healing programs observed in our bulk studies.

Liver mesenchyme dynamics in advanced MASH

We subclustered the contiguous mesenchymal population into four clusters of *Lrat*^hi^/*Rgs5*+ quiescent HSCs (qHSCs), *Col1a1*+/*Dpt*+ aHSCs, fibroblasts, and *Msln*+/*Gpm6a*+ mesothelial cells (MCs) (Figs. 3A, B). qHSCs of subcluster 1 and 2 mainly came from healthy livers, while aHSCs/fibroblasts of subcluster 3 were derived from MASH livers with the fraction of subcluster-3 cells from chow-fed mice likely representing fibroblasts (Fig. 3C).

We identified subcluster marker genes and tracked their expression across mesenchymal cells and in whole livers from healthy and MASH mice (Figs. 3D and S3A). Markers of aHSCs/fibroblasts related to regeneration and fibrogenesis were induced in MASH livers together with *immediate-early* genes broadly expressed across hepatic cell types. Notably, while expression of qHSC markers were lower in individual aHSCs, several were higher in MASH livers overall (*e.g.*, *Rgs5*, *Reln*, *Lrat*) and others (*e.g.*, *Vipr1* and *Ecm1*) were suppressed. This suggested to us that the expanded population of HSCs was *toned* by the MASH milieu prior to its activation. Expression distributions within subclusters supported this view showing a clear reduction in *Vipr1*^hi^ HSCs among MASH liver-derived subcluster 1-cells whereas *Rgs5* and *Lrat* levels were largely upheld (Fig. 3E). Expression of all HSC markers declined in subcluster-3 and were all but absent in MASH aHSCs. *Dpt* and *Col1a1* expression on the other hand was confined to subcluster 3 and induced in MASH. We confirmed the expansion of HSCs and HSC-derived cells in MASH livers from our *FLEx-TRAP* knock-in mice crossed with the *Lrat-cre* driver line[6] (to express *mCherry-Rpl10a* in HSCs) (Fig. 3F). Despite low recovery of *Acta2*+ cells by single-cell RNA sequencing (scRNAseq), αSMA+/mCherry+ cells were readily seen in MASH livers, indicating an HSC origin of the activated mesenchyme.

We next delineated the HSC activation trajectory in pseudotime (Fig. 3G). We excluded subcluster-4 MCs, which

separated from subclusters 1-3 with only very few cells bridging the two populations (Fig. S3B). A single, unbranched trajectory recapitulated the predicted transition from qHSCs to aHSCs. Focusing on the dominant subclusters 1 and 3, we profiled top highly variable genes (HVGs) over pseudotime (Fig. 3H). This activation trajectory of HSCs in MASH was reminiscent of the HSC trajectory in carbon tetrachloride-induced liver injury, suggesting a common HSC activation mechanism.[2,7]

We applied SCENIC for a focused regulatory network analysis and identification of mesenchymal TFs. AUC-based clustering gave six subclusters (Figs. 3I, *top* and S3C) essentially overlapping our HVG-based clusters (Fig. 3I *bottom left*). Clusters 1 and 2, mainly populated by qHSCs, showed distinctively high activities of LHX2, nuclear receptors NR1H4, NR2F2, NR3C1, RARB, and RXRA as well as ETS1, RELB, NFIB, and SOX5. SCENIC cluster 3 and 4 aHSCs/fibroblasts showed higher activities of SRF, TCF21, HOXB5, KLF9, and HEY1. Yet, TCF21 activity was seen across HSC/fibroblast clusters and decreased in MASH (Figs. 3I and 2H). Cluster 5 MCs were dominated by BHLHE40, WT1, KLF2/4, HLF, DBP, and FOXQ1. High activities of LHX2, NR1H4, NR2F2, NR3C1, and TCF21 regulons yielded to a transient increase in HOXB5 activity and more sustained activity of HEY1 in HVG cluster-1 and -3 cells over pseudotime (Fig. S3E).

Expression of many qHSC signature genes was repressed along the HSC activation trajectory but elevated in whole MASH livers, reflecting an overall increase in MASH-*toned* HSCs. Shifts in TF usage away from nuclear receptors could have driven this transition in response to WD-induced metabolic stress, tissue damage, and altered immune cell activities.

Steady-state dynamics of mononuclear phagocytes

Stellate cell activation co-occurs with profoundly changing macrophage function.[15] By investigating these changes, we expanded on recent reports[16–19] and added important new observations. We subclustered the MP population into nine clusters, capturing its diversity (Fig. 4A). Most MPs recovered from the MASH livers, including monocyte and macrophage subpopulations, rarely found in healthy livers (Fig. 4B). The abundance of embryonically derived *Timd4*+ Kupffer cells (emKCs) declined in advanced MASH while *neighborhoods* of *Clec4f*+/*Timd4*−/*Cd163*−/*Marco*− KCs increased (Figs. 4C–E and S4A). This was consistent with impaired emKC self-renewal[17,18] and replacement by monocyte-derived macrophages (MdMs) and KC-like cells (moKCs), but also with emKC re-specification in MASH. The MASH-associated *Clec4f*+/*Timd4*− KC population had increased expression of *Clec1b*, *Trem2*, and *Cd63* together with *Cd5l* and *Vsig4*. Notably, also in healthy livers, most *Clec4f*+ KCs lacked expression of *Timd4*, *Cd163*, and *Marco* demonstrating an inherent heterogeneity. We hence perceived the three subclusters (1-3) as a continuum of emKCs and *Clec4f*+ moKCs adapting to the MASH environment. Subcluster-1 KCs showed the most complete expression of KC markers while subcluster-2 and -3 KCs shared elevated expression of macrophage markers *Cd63* and *Trem2* in the MASH setting (Figs. 4D, E and S4A). A fraction of subcluster-2 KCs expressed *Mmp12*, *Gpnmb* and lipid-handling genes *Lpl*, *Cd36*, and *Fabp5* (Figs. 4D and S4A) while subcluster 3 was signified by higher expression of antigen processing and presentation genes. These included *Cd207* (*Langerin*), *Tmem176b* and MHC class II genes in addition to

macrophage markers (Fig. S4A) but not DC markers *Flt3*, *Xcr1* or *Clec10a*. A *Cd207*[hi] population was detectable in the healthy liver but expanded in MASH.

Besides the reconfiguration of em- and moKCs, advanced MASH was associated with increased numbers of *Ly6c2*[hi]/*Chil3*[hi] monocytes, *transitioning* monocytes, and *Spn*[+] *patrolling* monocytes (Figs. 4D, E; subclusters 6-8). In line with previous reports,[16,20] two *Trem2*[hi]/*Cd9*[+]/*Cd63*[+] MdM populations expanded in MASH; subcluster 4 was characterized by *Gpnmb*, *Spp1* (*Osteopontin*) and lipid-handling genes while subcluster 5 retained *Cx3cr1* and *Ccr2* expression and acquired *Mrc1*, *Cd81*, *H2-Ab1*, *H2-Eb1*, and *Tmem176b*. Subcluster-4 MdMs identified as scar-associated macrophages were already present at lower levels in healthy livers. Both MdM subclusters contained *Clec1b-* and *Cd5l*-expressing cells, but the absence of *Clec4f* distinguished these from emKCs and moKCs.

To infer transitions between cell populations in healthy and MASH livers, we applied *scVelo*.[21] MASH liver MPs showed a divergence of the *classical Ly6c2*[hi]/*Ccr2*[hi]/*Chil3*[hi] monocytes into *Spn*[hi] patrolling monocytes and the two *Trem2*[hi] MdM populations through a transient, *Ly6c2*[lo]/*Ccr2*[hi] and MHC class II-positive monocyte state (Fig. 4F). Among scar-associated macrophages, the induced *top-likelihood* genes *Gpnmb*, *Elovl1*, *Fabp5*, *Trem2*, and *Lamp2* pointed towards increased phagocytotic capacities (Figs. 4F and S4B). Meanwhile, specifically *Cx3cr1*[hi]/*Mrc1*[hi]/*Cd81*[hi] MdMs transitioned further into the *Cd207*[hi] population of subcluster 3 predicted as the main, MASH-specific endpoint. During this transition, expression of *Clec4f*, *Cd5l*, and *Vsig4* emerged while that of *Cxc3r1*, *Ccr2,* and *Itgax* was lost.

Importantly, we further predicted the convergence of *Clec4f*[hi] subcluster-1 KCs with this *Cd207*[hi] KC-like subcluster 3 in MASH. Dynamic expression of KC-enriched genes (*Cd5l*, *Clec1b*, *Apoc1*, *Wfdc17*, and *C6*) accompanied their transition in concert with induction of *Apoe*, *Mrc1*, *Nedd8*, and *Vcam1* (Figs. 4F and S4B). A focused delineation of the transition from subcluster 1 to 3 supported *Cd207*[hi] cells being a likely *end-state* in murine MASH (Fig. 4G). In cultured precision-cut liver slices from a healthy human donor undergoing *ex vivo* wound healing, MP transitions were uncoupled from the influx of monocytes yet showed a swift repression of KC signature genes and induction of activation markers including *TREM2* and *GPNMB* (Fig. 4H).

CD207 was previously found to be a marker of capsule macrophages[22] but in advanced murine MASH, CD207[+] cells populated the parenchyma (Figs. 4I, J). While GPNMB[+]/*Trem2*[+] MdMs were frequently observed in hepatic crown-like structures, *Cd207*[hi]/*Trem2*[+] KC-like cells were rarely found in them (not shown). Their high expression of *Slc40a1*, *Igf1*, and immunomodulatory *Irf7*, *Il18bp*, and *Hpgd* could point to inflammation-resolving functions. In the healthy liver, transition of low numbers of *Ly6c2*[hi] monocytes through subclusters 5 and 3 towards *Timd4*[hi] end cells (Fig. 4F) indicated a steady-state monocyte contribution to the hepatic MP population (Fig. 4I, J).

To infer transcriptional drivers, we again turned to SCENIC. Nine AUC score-based subclusters were identified (Figs. 4K, *left*, and S4D-E). SCENIC inferred high activities of NR1H3, MAF, MAFB, TFEC, and SPIC across the KC-rich clusters 1-4 (Figs. 4K and S4F). The broad profile of NR1H3 would fit with dual roles in *Clec4f*[+]/*Timd4*[+] KCs specification and adaptation to injury.[17,23] Glucocorticoid receptor NR3C1 and MEF2A activities were more confined to subcluster-1 KCs from healthy livers, whereas active IRF7 and C/EBPα marked cells of subclusters 2-4 with a larger fraction of KCs from MASH livers. The monocyte-rich subclusters 7-9 were dominated by PU.1 (SPI1), C/EBPβ, C/EBPδ, and NFIL3 whose predicted activities dropped steeply in MdMs.

Inference of the steady-state transitions of MPs in healthy liver and MASH showed the convergence of liver-resident emKCs and MdMs in *Timd4*[hi] and *Cd207*[hi] *end populations*, respectively. Proof of the contribution of both emKCs and monocytes to the latter population in advanced MASH will require lineage tracing.

HSC NR1H4 activity is associated with quiescence

Having seen extensive transcriptional reconfiguration of mesenchymal and MP populations, we next predicted specific interactions between these populations in healthy livers and advanced MASH (Fig. 5A). Among the predicted, mesenchyme-derived ligands with top activities were the BMPs (GDF2/BMP9, BMP5, and BMP10) signaling autocrinally through receptors ALK3 (*Bmpr1a*) and BMPR2 or to KCs/MdMs through ACVR2A and ALK1 (*Acvrl1*). Most mesenchyme-derived ligands were abundantly expressed in qHSCs and repressed in aHSCs/fibroblasts. Strongly qHSC-enriched ligands with predicted effects on MPs further included CXCL12, CDH2, NRXN1, MAPT, IL34, HGF, and NTN1, as supported by visualization of expression patterns across HSC clusters (Fig. 5B). Given the importance of GDF2 in the specification of KCs and liver sinusoidal endothelial cells (LSECs),[24,25] we validated our observations *in situ,* demonstrating reduced per-cell *Gdf2* transcript levels in MASH livers (Fig. 5C). Along with *VIPR1* and other qHSC markers, expression of *GDF2* was also strongly reduced in human precision-cut liver slices as they underwent *ex vivo* wound healing (Fig. 5D).

We revisited predicted target genes in our HSC SCENIC analysis and found *Gdf2* as a putative NR1H4 target gene. The association of NR1H4 with HSC quiescence sparked our interest, as NR1H4 agonists like OCA are antifibrotic in humans and mice.[26,27] We therefore transcriptionally profiled primary murine HSCs treated with OCA for 6 h. Culturing induces HSC activation, but OCA preserved expression of the key quiescence-associated genes *Lhx2*, *Lrat*, *Hhip*, and stimulatory G$_S$-protein-coupled receptors (G$_S$PCRs) in addition to *Gdf2*, *Bmp10*, *Angptl6* and other *stellakines* (Fig. 5E and not shown). aHSC-associated genes *Col1a2*, *Ccn2*, *Alcam*, *Aebp1*, and *Mmp10* were repressed. OCA hence had quiescence-preserving activity

directly on HSCs beyond what was previously reported. Direct NR1H4 transactivation would reflect in accessible NR1H4 IR1 binding motifs in HSC chromatin. To test this, we isolated *mCherry*-tagged nuclei from livers of our *FLEx-TRAP* mouse line and performed ATACseq. The NR1H4 motif was strongly enriched (p = 1E^{-214}) in HSC ATACseq peaks found in intronic, intergenic, and promoter-proximal genomic regions (Figs. 5F and S5B). Among the most enriched motifs were also motifs for the HSC lineage-associated ETS-family, CREB, FOXF1, and NRF. Within peaks near (+/-25 kb) transcriptional start sites of OCA-induced genes, the NR1H4 IR1 motif was the top enriched motif (p <1E^{-41}, Fig. S5C) and with higher log-odds motif scores relative to randomly sampled peaks elsewhere (Fig. 5G). Consistent with direct regulation, peaks with NR1H4 binding motifs were found in the vicinity of the OCA-induced qHSC genes *Vipr1*, *Pth1r*, *Lhx2*, and *Des*. Co-enrichment of the ETS-family binding motif in NR1H4 motif-containing peaks (not shown) could explain the HSC-selective effects of OCA. We corroborated our findings from genetically labeled HSCs by single-nuclei ATACseq analysis of mesenchymal nuclei. Again, the NR1H4 IR1 motif was highly enriched within HSC peaks (p = 1E^{-67}) and topped the list of enriched motifs in peaks near OCA-induced genes (p <1E^{-20}) (Figs. S5D-E).

We confirmed HSC-specific co-expression of *Nr1h4* and *Vipr1* in our scRNAseq dataset (Fig. 5H) and validated this in human liver (NAFLD activity score [NAS] 2) *in situ* (Fig. 5I). Here, *VIPR1*-expressing cells co-expressed *NR1H4* and *GDF2* whereas *NR1H4*$^+$/*VIPR1*$^-$ cells had large, round nuclei distinctive of hepatocytes. *NR1H4* and *VIPR1* were co-expressed with *LUM*, further indicating that *NR1H4*$^+$/*VIPR1*$^+$ cells were HSCs (Fig. S5F). *NR1H4* and *VIPR1* more abundant in healthy liver (NAS 0) while *LUM* levels increased in MASH (NAS 7). Human snRNAseq data (GSE212837)[28] corroborated HSC *LUM* expression in both healthy and MASH livers (Fig. S5G). Importantly, the NR1H4 protein was also particularly abundant in PDGFR$^+$ mesenchymal cells (likely HSCs) lining the human liver sinusoids (Fig. 5J).

In vivo stimulation of HSC NR1H4 by OCA in mice has proven difficult. Either due to high levels of endogenous ligands or because of modification rendering it refractory to OCA activation.[29] We instead quantified gene expression in livers of wild-type or *Nr1h4* null mice acutely treated with the selective NR1H4 agonist GSK2324 or vehicle.[8] Like OCA, GSK2324 had no acute effect on qHSC-expressed *Ecm1*, *Vipr1*, *Pth1r*, nor *Col1a1* *in vivo* (Fig. 5K). *Mafg*, expressed by both HSCs and hepatocytes, was readily induced, and *Nr1h4* was repressed as seen in HSCs *in vitro*. Nevertheless, loss of NR1H4 significantly reduced expression of *Ecm1*, *Vipr1*, and *Pth1r*, while *Col1a1* expression was elevated. These findings were consistent with our scRNAseq studies and with NR1H4 upholding HSC quiescence *in vivo*. We found comparable albeit less pronounced changes in our analysis of liver microarray data from *Nr1h4* null mice bred independently elsewhere (Fig. S5H).[30]

The HSC as a sinusoidal signaling nexus

G$_S$PCR genes *Vipr1* and *Pth1r* were repressed in aHSCs along with other GPCRs and auxiliary factors *in vivo* and *in vitro* (Fig. 6A, not shown). This together with the OCA-induced increase in *Vipr1* and *Pth1r* expression prompted us to examine HSC cAMP signaling at the transcriptomic level. To profile the cAMP response independently of receptor levels we treated

murine HSCs with forskolin (5 μM, 3 h). Besides induction of canonical CREB targets and repression of hippo pathway-regulated genes, cAMP increased expression of defining genes for qHSC function including *Foxf1*, *S1pr3*, *Hhip*, *Gdf2*, and *Hgf* (Fig. S6A). We next investigated the sustained effects of cAMP signaling in HSCs 24 h after the 3 h stimulation with forskolin. Consistent with phenotype-preserving effects of cAMP signaling, qHSC gene expression was upheld while activation-associated genes were suppressed (Fig. 6B). This is reflected in the enriched GO categories including differentiation processes and immunomodulation (Figs. 6C and S6B). Accordingly, cAMP-induced genes were abundantly expressed in qHSC subclusters 1 and 2 compared to aHSCs/fibroblasts of subcluster 3 where cAMP-repressed genes were prominent (Fig. 6D). Bile acids and VIP are both elevated in portal circulation postprandially. Having seen OCA-induced G$_S$PCR expression, we stimulated primary HSCs with OCA prior to VIP to potentiate its effects. In keeping with this notion, pre-stimulation with OCA enhanced the stimulatory effects of VIP on qHSC genes and repression of HSC activation genes (Fig. 6E).

Systemic effects of VIP complicate targeting of HSC-specific VIPR1 *in vivo*. We therefore applied a chemogenetic strategy expressing the eGPF-tagged *G$_S$-coupled designer receptor exclusively activated by designer drugs* (G$_S$D)[5] in HSCs for ligand-induced cAMP signaling with the otherwise biologically inert ligand DCZ (deschlorocIozapIne). We confirmed the eGFP signal specifically in *Des*$^+$ HSCs of *Lrat-cre*:G$_S$D but not in cre-negative littermates (Fig. S6C). We next fed these mice (n = 3) the GAN diet for 12 weeks to invoke obesity and massive hepatic steatosis (Fig. S6D). No differences between genotypes were seen. After 3 days with daily oral doses of DCZ (0.1 mg/kg), we found *Gdf2* and *Nr4a1* cre-dependently induced in *Lrat*$^+$ HSCs recapitulating our findings from isolated HSCs *in vivo* in the context of steatotic liver disease (Figs. 6F and S6E). Longer term studies will show if HSC-specific cAMP signaling has sinusoid-preserving and antifibrotic effects *in vivo*.

Combined, our findings feature HSCs as integrators and conveyors of postprandial signals. Further, they point to the phenotypic preservation of qHSCs as a possible direct antifibrotic effect of NR1H4 activation and to the therapeutic potential of HSC-directed treatment to preserve liver sinusoidal health.

Discussion

In the current study, we fed mice a Western diet supplemented with fructose for 52 weeks to recapitulate human MASH. Steatosis, hepatocyte damage, massive expansion of the F4/80^{hi} macrophage population, and extensive pericellular fibrosis were accompanied by major alterations in gene and protein expression revealing process-coupling across hepatic cell populations. Resolving individual cell populations by scRNAseq allowed us to further explore transitions of cell types and crosstalk between them. This led us not only to the elucidation of novel cellular dynamics in both MASH and in healthy livers, but also to the discovery of a NR1H4-G$_S$PCR-GDF2 signaling module that may be exploited therapeutically.

In MASH, HSCs, the main cell type implicated in ECM production, underwent repression of nuclear receptor gene programs conferring pericyte identity including GPCR expression. One of these nuclear receptors, NR1H4, is a promising target for
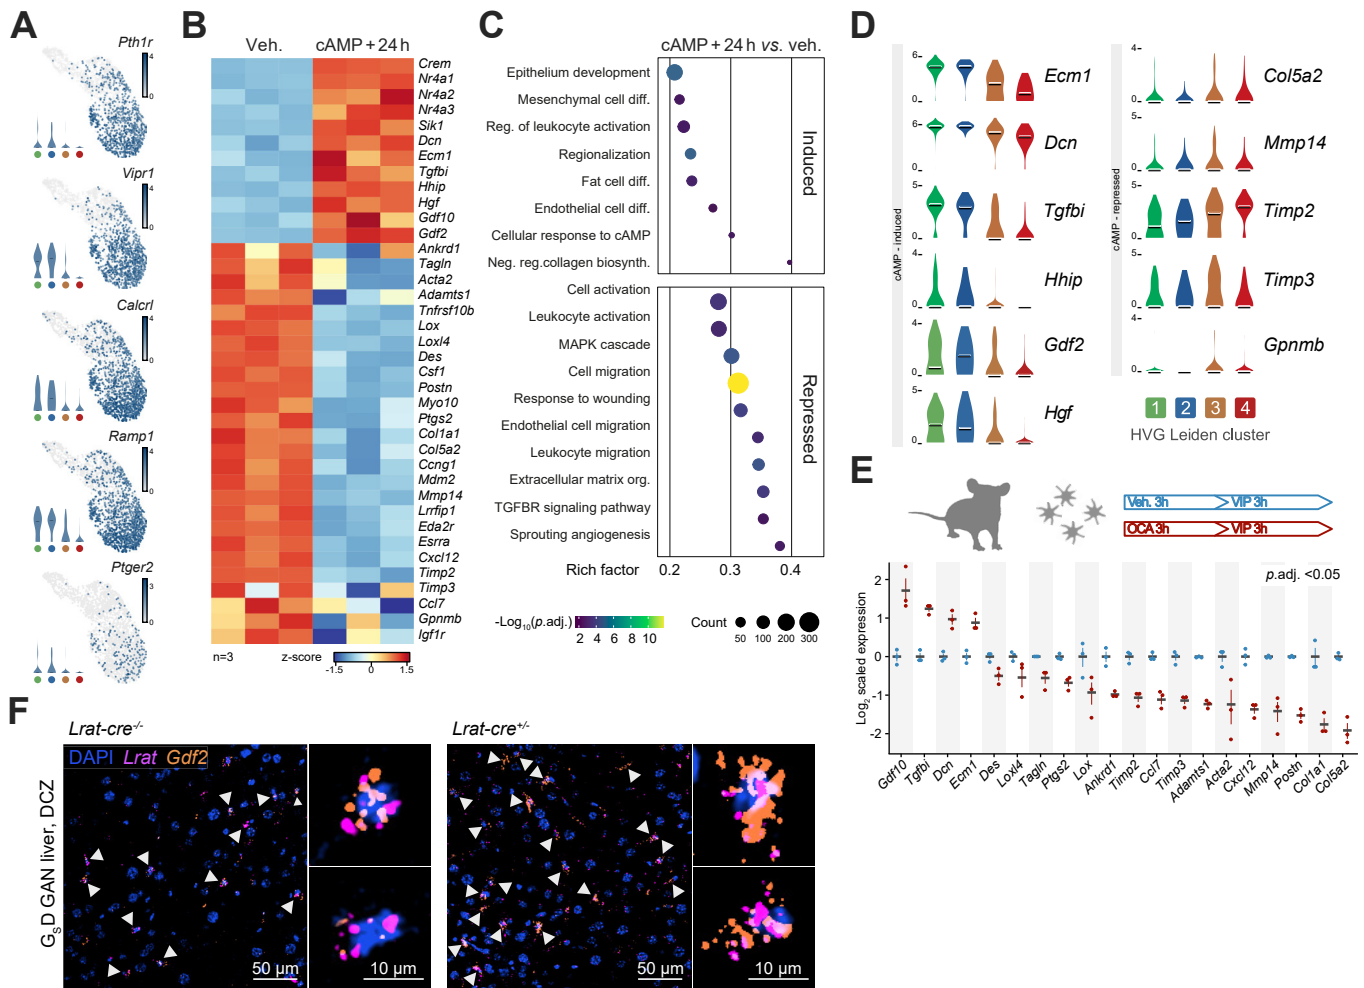

Fig. 6. Hepatic stellate cells as sinusoidal signaling hub. (A) Log$_{1P}$ gene expression and distribution across mes. subclusters. (B) Scaled mean expression of selected DEGs (*p*.adj. <0.05, Wald test, Benjamini-Hochberg-corrected) in primary murine HSCs 24 h after acute cAMP-stimulation (5 μM forskolin, 3 h) or DMSO (Veh.). (C) Selected GO terms enriched among OCA-induced and repressed DEGs. Rich factors, -log$_{10}$(*p*.adj.), and DEG counts within categories are shown. (D) Log$_{1P}$-expression of selected DEGs across mes. subclusters. Medians shown. (E) Log$_2$-normalized, scaled expression of selected DEGs (*p*.adj. <0.05, Wald test, Benjamini-Hochberg-corrected) in primary murine HSCs treated with VIP (500 nM, 3 h) after pretreatment with OCA (5 μM, 3 h) or DMSO. Dotplot vertical bars show standard deviations and horizontal bars means. (F) *Lrat* and *Gdf2* mRNA in livers of G$_S$D and Lrat-cre:G$_S$D mice (n = 3) fed GAN diet for 12 weeks and treated for three days with DCZ (0.1 mg/kg). antifibrotic therapy.[26,31] NR1H4 agonists may directly oppose HSC activation[29,32] but the expression and function of NR1H4 in HSCs have been questioned.[33–35] We found NR1H4 highly expressed in human and murine qHSCs as the sole non-parenchymal cell type and inferred high NR1H4 activity in qHSCs by ATACseq and SCENIC analyses. Paralleling *Foxf1* and *Lhx2*, the expression and inferred activity of *Nr1h4* in HSCs were diminished in MASH, whereas OCA induced qHSC markers and *stellakines* including *Gdf2*, *Angptl6*, and *Bmp10*. OCA also induced the expression of G$_S$PCR genes *Vipr1* and *Pth1r* thereby priming HSCs for cAMP signaling. Why treatment with NR1H4 agonists *in vivo* fails to further stimulate qHSC markers despite high NR1H4 expression is unclear. It is possible that NR1H4, unliganded or activated by endogenous ligands, upholds qHSC gene expression in the healthy liver via cooperation with, for example, ETS1 and FOXF1. Posttranslational modifications could also modulate NR1H4 activities *in vivo*.[29] Refined studies are needed to understand HSC-specific NR1H4 activation in appropriate disease contexts.

Intriguingly, *Nr1h4* null mice are protected against bile duct ligation (BDL)-induced hypercholemia and fibrosis.[33] Similarly, mice lacking *Nr1h4* in HSCs show less BDL-induced fibrosis and a tendency towards lower circulating alanine aminotransferase and bile acid levels,[36] arguing that either HSC NR1H4 links si-nusoidal bile acid accumulation to HSC activation or itself con-tributes to cholestasis. Disease context and dosage of NR1H4 ligands may explain the contrast to the HSC quiescence-preserving effects of NR1H4 in our current study. Further, BDL-associated fibrosis in mice is generally attributed to the activation of portal fibroblasts expressing neither *Nr1h4* nor *Lrat*.[37,38] Constitutive ablation of *Nr1h4* in HSCs could hence impact other mesenchymal populations, the interplay of which is incompletely understood. Notably, *Nr1h4* null mice are not pro-tected against carbon tetrachloride- nor Schistosoma-induced liver fibrosis.[33,39]

OCA has not previously been demonstrated to phenotypically preserve HSC identity and sensitize towards G$_S$PCR agonism. Curiously, NR1H4 does induce *Vipr1* in gallbladder epithelium

where VIP promotes choleresis through increased electrogenic bicarbonate secretion.[40] While the function of HSC-expressed solute carriers is underexplored, the regulatory similarity raises the interesting possibility that HSC-specific VIPR1, by augmenting sinusoidal blood flow, also affects peribiliary vascular drainage and postprandial bile acid transport from the liver.

G$_S$PCRs like VIPR1 are abundant in HSCs and promote their postprandial relaxation. Ablation of NR1H4 or development of MASH led to striking repression of *Vipr1*. To test if VIPR1-induced cAMP signaling was linked to HSC quiescence, we induced cAMP production in isolated HSCs and recorded effects on gene expression. Acute stimulation increased expression of quiescence markers including *Hhip*, *Gdf2*, *Hgf*, *S1pr3*, and *Foxf1*. Sustained effects of transient cAMP-elevation included repression of ECM genes and myofibroblast markers in addition to preservation of the qHSC program. Follow-up experiments will determine if these effects depend on FOXF1 and if selective elevation of cAMP in HSCs *in vivo* can blunt or even reverse their activation. Transient, chemogenetic elevation of cAMP in HSCs *in vivo* markedly elevated *Gdf2* expression, confirming the signaling module revealed by our scRNAseq and *in vitro* studies. An anti-inflammatory and antifibrotic outcome of cAMP signaling in HSCs would be in line with effects in other pathologies.[41–43]

Transcriptional regulators we predicted lose activity upon HSC activation also include nuclear receptors NR2F2, NR3C1, RARB, and RXRA as well as ETS1, IRF1, and SOX5. NR2F2 is abundant in HSCs and LSECs and instrumental for retinoic acid signaling during development[44] but has also been implicated in the liver injury response.[45] ETS1 and IRF1 were recently proposed as HSC lineage-determining factors,[46] whereas SOX5 is critical for neurogenesis and chondrocyte specification.[47,48] Given its putative role in chondrocyte collagen expression, we speculate that SOX5 and possibly NR2F2 maintain accessible chromatin around both quiescence- and repair-associated genes to ensure HSC plasticity and immediate response to injury. We previously proposed a similar role for ETS1.[7]

The steady-state fluxes of MPs of embryonic and monocyte origin expanded and rerouted in advanced MASH. Different environments clearly guided MdMs as they transitioned towards moKCs in healthy and MASH livers. In advanced MASH, *activated* emKCs and *Cx3cr1^hi* MdMs appeared to converge towards *Cd207^hi*/*Trem2^hi* KC-like cells. Activation of emKCs in advanced MASH involved loss of *Timd4*, *Cd163*, and *Marco* expression also seen at earlier disease stages.[17] We did not experimentally validate the mixed emKC and MdM origin of the *Cd207^hi* population, and a contribution from emKCs contrasts with recent reports that *Trem2^+* KC-like cells in less advanced, murine MASH are entirely monocyte derived.[18,20] CCR2 is critical for monocyte extravasation at sites of inflammation. In elegant studies of mice fed a fibrogenic diet, Daemen *et al.*[20] observed little reduction in the TIM4^lo KC population in *Ccr2^-/-* mice despite steep declines in liver Ly6C^hi monocytes and CX3CR1^hi MdMs. Notably, the *Ccr2^-/-* mice showing near-normal levels of TIM4^lo KCs all had markedly lower levels of TIM4^hi KCs. Whether accelerated loss of resident TIM4^hi emKCs in these mice had opened the niche to *Ccr2^-/-* monocytes escaping the recruitment block, or if reduced monocyte infiltration led more activated emKCs to contribute to the TIM4^lo population remains unclear. The repression of HSC *Gdf2* and *Bmp10* in MASH presented here may contribute to sinusoidal phenotypic transition. GDF2-ALK1 and GDF2-BMPR2 signaling is crucial for KC and LSEC specification, respectively,[24,25,49] and missing input from HSCs may accelerate deterioration of the sinusoidal niche.[19] Such a shift from qHSCs upholding sinusoidal specialization to fibrogenic aHSCs is reminiscent of their transition from HGF-producing suppressors of hepatocarcinogenesis to tumor-promoting myofibroblasts[50] upon activation. This highlights the wider prospects of therapeutic preservation of HSC quiescence in chronic liver disease.

Our study establishes a conceptual framework where signals preparing the liver sinusoid for the postprandial state concurrently promote its phenotypic stability through transcriptional networks and paracrine mediators. Within this framework, HSCs emerge as a nexus for the integration and transmission of physiological signals sustaining sinusoidal homeostasis. In advanced MASH, ongoing parenchymal damage, inflammation, and HSC activation may drive sinusoidal deterioration both through fibrogenesis and by desensitization to these physiological cues. Therapeutic utilization of this pericyte signaling module may on the other hand restore liver sinusoidal homeostasis.
