3  
4 **Objective:** To describe shoulder-related injury rates, types, severity, mechanisms, and  
5  
6 risk factors in youth ice hockey players during games and practices.  
7  
8  
9

10 **Study Design:** Secondary analysis of data from a 5-year prospective cohort study Safe-  
11  
12 to-Play (2013-2018).  
13  
14

15 **Subjects:** Overall, 4419 individual players (representing 6585 player-seasons; 3806  
16  
17 males: 613 females) participated. During this period, 118 primary shoulder-related game  
18  
19 injuries and 12 practice injuries were reported.  
20  
21  
22  
23

24 **Outcome Measures:** Injury surveillance data was collected from 2013-2018 (time-loss  
25  
26 or medical attention injuries). Descriptive statistics were calculated, and injury rates with  
27  
28 95% CI were estimated using Poisson regression. An exploratory multivariable mixed-  
29  
30 effects Poisson regression model (clustering by team and offset by exposure hours)  
31  
32 examined risk factors.  
33  
34  
35  
36  
37

38 **Results:** The shoulder injury rate was 0.70 injuries/1000 game-hours (95% CI 0.37-1.33)  
39  
40 and 0.07 injuries/1000 practice-hours (95% CI 0.04-0.12). Two-thirds of game injuries  
41  
42 (n=79, 69%) resulted in >8 days of time-loss, and more than one-third (n=44, 39%)  
43  
44 resulted in >28 days of time-loss. An 82% lower rate of shoulder injury was associated  
45  
46 with policy prohibiting body checking compared to leagues allowing body checking  
47  
48 [IRR=0.18 (95% CI 0.10-0.32)]. A higher shoulder injury rate was seen for those who  
49  
50 reported any injury in the last 12-months compared to those with no history [IRR=2.32  
51  
52 (95% CI 1.57-3.41)].

## Introduction

Ice hockey is a collision sport commonly played by youth across Canada. As of 2020, more than 600 000 Canadian youth (ages 5-17 years) were registered to participate through Hockey Canada (1). Participation in sport has vast benefits for youth including improved physical, social, and mental well-being (2-5). On the other hand, participation in ice hockey carries a risk of injury and high injury rates have been reported (6). Further, these injuries may lead to substantial negative consequences for youth such as functional impairment, decreased quality of life, as well as social and/or emotional stress (7-9). Overall, injury rates in youth ice hockey in Canada have been reported to be between 2.16 to 7.98 injuries/1000 game-hours (depending on age of cohort and body checking policy) (10-12). Ice hockey injuries are also known to account for the highest proportion (16%) of youth emergency department visits related to collision sport (12).

Being a collision sport, a common mechanism of injury in ice hockey is body checking, which is a direct, immediate contact (in an opposite or perpendicular direction) with another player (13). In ice hockey, the intention of body checking is to ‘separate an individual from the puck’ and ‘create space’ (14). Injuries however, are a known and unfortunate consequence (11, 15-17). In 2013, body checking policy changes were introduced by Hockey Canada to prohibit body checking nationally in the younger age groups (under-13) as well as regionally in sub-elite divisions of play in the following years (under-15, under-18), with a target to reduce the burden of injury. Even when considering the inherent risks for intentional or unintentional contact associated with the fast-paced and collision nature of ice hockey, shoulder-related injuries have been reported as a common injury across various youth age groups and skill levels. Shoulder injuries

1  
2  
3  
4 are of specific research interest as the shoulder is the most common point of contact for  
5  
6 both the player delivering and the player receiving a body check. Emery et al (2020)  
7  
8 reported a shoulder injury rate (IR) of 0.74 injuries/1000 game-hours (95% CI 0.00-2.20)  
9  
10 among under-15 Canadian players in a body-checking league, which accounted for 9% of  
11  
12 all injuries (n = 12/129) (10). Notably, no shoulder injuries were observed when body  
13  
14 checking was prohibited from game play in the under-15 age group (n = 0/31 injuries)  
15  
16 (10). More recently in 2022, a shoulder IR of 2.31 injuries/1000 game-hours (95% CI  
17  
18 1.64-3.17) was observed in an under-18 body checking league (n = 38/213) and 0.26  
19  
20 injuries/1000 game-hours (95% CI 0.03-0.93) in a non-body checking league (18). In  
21  
22 game play permitting body checking, shoulder injuries accounted for the second highest  
23  
24 proportion (17.8%) of all injury locations (following the head/face) (19). To date,  
25  
26 however, shoulder-specific research in the context of youth ice hockey remains sparse,  
27  
28 and without unified validated surveillance methods or injury definitions being used  
29  
30 broadly across shoulder-specific research. A comprehensive understanding of the  
31  
32 etiology, potential risk factors, and mechanisms for injury from robust, high-quality ice  
33  
34 hockey studies is needed. This currently represents a knowledge gap, as research  
35  
36 attention has previously focused on concussion and injuries of the lower extremity. As  
37  
38 such, the primary objective of this study was to describe shoulder injury rates, locations,  
39  
40 types, severity, and mechanisms in youth female and male ice hockey players ages 10-17  
41  
42 during games and practices. An exploratory objective was to explore potential risk factors  
43  
44 (including body checking policy, injury history, biological sex, playing position, and  
45  
46 player size) on shoulder injury occurrence in youth female and male ice hockey players.

## Methods

### Study Design

This is a secondary analysis of a prospective longitudinal cohort study (10,11,15,16,18). Injury surveillance was implemented across four major Canadian cities from 2013 to 2018. Ethical approval was obtained from the local Research Ethics Board (████████████████████).

### Participants

Study participants included youth in the under-13 (U13; ages 11-12), under-15 (U15; ages 13-14), and under-18 (U18; ages 15-17) age groups. Inclusion criteria for eligible participants were: (1) participation on a team of female and/or male ice hockey players; (2) aged 10-17 years old at baseline; (3) completed both informed parental consent and player assent; (4) the team was registered to participate through their local regulatory body; (5) the teams' head coach agreed to participate; and (6) a team designate or the individual athlete agreed to collect/record relevant injury and participation data.

### Procedures

Validated injury surveillance methodology was conducted (13, 19). Study measures included Injury Report Forms (IRFs), a Preseason Baseline Questionnaire (PBQ), and a Weekly Exposure Sheet (WES).

### Preseason Baseline Questionnaires (PBQs)

Preseason Baseline Questionnaires (PBQs) were completed by participating athletes yearly and included demographics (e.g., age, biological sex), injury history [i.e.,

1  
2  
3  
4 injuries from any activity (including outside of sport) with more than 1 day of time-loss  
5  
6 from activity in the previous 12 months or need for medical attention], and medical  
7  
8 history (e.g., current medications, presence of systemic or chronic diseases/disorders, any  
9  
10 known psychological diagnoses).  
11  
12  
13  
14

### 15 16 **Subject Characteristics** 17

18 Athlete height (cm) and weight (kg) were collected yearly during baseline  
19  
20 assessments by trained research assistants according to a universal study protocol (RA's)  
21  
22 or self-reported in the PBQ.  
23  
24

### 25 26 **Weekly Exposure Sheet (WES) and Injury Report Forms (IRFs)** 27

28 Following reports of an injury, an Athletic Therapist or Physiotherapist followed  
29  
30 up with athletes either in-person or over the phone and completed an Injury Report Form  
31  
32 (IRF). The IRF's outlined the nature of the injury sustained, including written  
33  
34 descriptions of the injury mechanisms, and severity (time-loss from ice hockey, if any).  
35  
36 Weekly Exposure Sheets (WES) measured an athlete's participation hours in games and  
37  
38 practices. The WES was collected by a team designate (e.g., athletic therapist, coach,  
39  
40 manager, team administrator, parent, player). Data collected was specific to each athlete.  
41  
42  
43  
44

### 45 46 **Injury Definitions** 47

48 This study used an inclusive injury definition that considered any player who  
49  
50 sought medical attention (any injuries seen by an athletic therapist, physiotherapist or  
51  
52 physician), was unable to continue in a game or practice session or reported time-loss  
53  
54 from hockey. Shoulder related injuries included any clavicular, scapular,  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 acromioclavicular joint, rotator cuff, or shoulder joint, and surrounding tissue  
5  
6 impairment.  
7  
8  
9

### 10 11 12 13 14 **Statistical Analysis**

15  
16 Participant baseline characteristics were stratified by shoulder injury outcome and  
17  
18 biological sex. More specifically, the following categories were considered to describe  
19  
20 the primary outcome variable: those who reported at least one shoulder injury, those who  
21  
22 reported any other injury (i.e., at least one injury that was not related to the shoulder), and  
23  
24 those who did not report an injury during the study period. Shoulder injuries in this  
25  
26 analysis were operationalized to include only an athlete's primary injury related to the  
27  
28 shoulder joint. If an athlete reported a secondary injury (such as a concussion, for  
29  
30 example) in addition to their shoulder injury, this was coded as a shoulder injury. With  
31  
32 respect to the females in the dataset, sex was self-reported at baseline or assumed based  
33  
34 on league participation (i.e., those who participated in a female-only league). Descriptive  
35  
36 statistics, frequencies, and proportions (stratified by biological sex) were calculated.  
37  
38 Shoulder injury rates (IR) were estimated using Poisson regression with clustering by  
39  
40 team and offset by exposure hours (# injuries/1000 game and practice-hours; with the  
41  
42 corresponding 95% CIs). Injury types, severity, timing, and mechanisms were reported as  
43  
44 frequencies, proportion of injuries reported, and injury rates (with 95% CIs) as they were  
45  
46 observed in youth ice hockey. Crude injury rates per 1000 hours of game exposure were  
47  
48 reported in females due to the low sample size. Multiple imputation by chained equations  
49  
50 (MICE) was used to impute all missing covariate data (30 imputations completed). MICE  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 imputation considered height, weight, body checking policy, injury history in the  
5  
6  
7 previous 12 months, playing position, and level of play.  
8

9  
10 An exploratory multivariable Poisson regression model adjusting for body  
11  
12 checking policy (categorical: permitted, not permitted), weight (continuous: kilograms),  
13  
14 biological sex (categorical: male or female), history of previous injury in the past 12  
15  
16 months (binary: yes/no), level of play (binary: elite ~top 30% by division of play, non-  
17  
18 elite ~lower 70% by division of play) accounting for clustering by team and offset by  
19  
20 exposure hours with one mixed-effect at the team level, was used to examine potential  
21  
22 risk factors for game-related shoulder injuries. Statistical significance was considered at  
23  
24 an alpha level of  $p < 0.05$ .  
25  
26  
27

## 28 **Results**

29  
30 Overall, 4419 individual players (representing 6585 player-seasons; 3806 males,  
31  
32 613 females, 137 prefer not to respond/missing) were recruited over the five-year ice  
33  
34 hockey longitudinal cohort study. During this period, 118 primary shoulder-related game  
35  
36 injuries and 12 primary shoulder-related practice injuries were reported. The male  
37  
38 shoulder IR observed was 0.70 injuries/1000 game-hours (95% CI 0.37-1.33) and 0.07  
39  
40 injuries/1000 practice-hours (95% CI 0.04-0.12). Among females, 6 shoulder injuries  
41  
42 were reported across 5 female participants (4 game and 2 practice injuries) during the  
43  
44 study period. No participants that sex was missing or reported as prefer not to respond  
45  
46 reported a shoulder injury.  
47  
48  
49  
50  
51

52  
53 Baseline demographics stratified by shoulder injury, any other injury (concussion  
54  
55 or non-shoulder musculoskeletal), and those who did not report an injury during the study  
56  
57 are presented in Table 1. The frequency of missing covariate data is reported in this table  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 and ranged from 5% to 28%. The most common game injury types for males were  
5  
6 fractures (n=38, 33%), joint swelling/ligament sprain (n=36, 29%), and muscle strain  
7  
8 (n=18; 16%) (Table 2). For females, the most common game injury types were joint  
9  
10 swelling/ligament sprain (n=2, 50%), fracture (n=1, 25%), and dislocation (n=1; 25%)  
11  
12 (Table 2). Sudden onset injuries associated with contact from another player or the  
13  
14 environment was the most common injury mechanism for both males and females (Table  
15  
16 3). Most shoulder injuries occurred during games (114 game vs. 10 practice injuries for  
17  
18 males; 4 game vs. 2 practice injuries for females). Subsequent time-loss from ice hockey  
19  
20 as a result of shoulder-related injury was substantial (Table 4). With respect to the injury  
21  
22 severity, median time-loss from shoulder-related injury was 19 days (IQR 6-46 days) for  
23  
24 males, and 12 days (IQR 3-69 days) for females. Over two-thirds of male game injuries  
25  
26 (n=79, 69%) resulted in more than 8 days of time-loss, and more than one-third (n=44,  
27  
28 39%) resulted in more than 28 days of time-loss from ice hockey.  
29  
30  
31  
32  
33  
34

35  
36 Considering the exploratory multivariable mixed effects Poisson regression model  
37  
38 (Table 5), an 82% lower rate of shoulder injury was associated with policy prohibiting  
39  
40 body checking [IRR=0.18 (95% CI 0.10-0.32)]. A two-fold higher shoulder IR was seen  
41  
42 for those who had reported a history of any musculoskeletal injury or concussion in the  
43  
44 last 12-months [IRR=2.32 (95% CI 1.57-3.41)]. Goaltenders demonstrated a lower  
45  
46 shoulder injury rate relative to forwards [IRR=0.32 (95% CI 0.11-0.87)]. Biological sex,  
47  
48 level of play, and weight were not associated with shoulder IRs (Table 5).

1  
2  
3  
4 This prospective cohort study sought to comprehensively describe the shoulder-  
5  
6 specific injury patterns in Canadian youth ice hockey players over a five-year period. The  
7  
8 primary finding from this study was the high incidence of game shoulder-related injury at  
9  
10 0.70 injuries/1000 game-hours (95% CI 0.37-1.33) among males. Shoulder-related  
11  
12 injuries most commonly occurred as a result of direct contact with another individual, and  
13  
14 these individuals missed substantial time from ice hockey as a result of their shoulder  
15  
16 injury. A striking observation from this study was that policy disallowing body checking  
17  
18 was associated with an 88% lower rate of shoulder injury compared to leagues permitting  
19  
20 body checking. It is therefore important to consider policy concomitantly alongside  
21  
22 potential injury risk factors when considering efforts to reduce the burden of shoulder  
23  
24 injury in youth ice hockey.  
25  
26  
27  
28  
29  
30

31 The observations from this study are consistent with the findings of Emery et al.  
32  
33 (2010) that sought to evaluate the effectiveness of body checking policy permitting body  
34  
35 checking in games, where body checking leagues observed a three-fold increased risk of  
36  
37 game-related injury compared to non-body checking leagues. Emery et al. (2020)  
38  
39 reaffirmed this position following a prospective cohort evaluation where policy changes  
40  
41 prohibiting body checking was associated with a 54% decrease in all injuries in players  
42  
43 13-14 years. These findings are also consistent with multiple systematic reviews and  
44  
45 prospective cohort studies across age groups suggesting that body checking is associated  
46  
47 with both musculoskeletal injury and concussion occurrence (11, 12, 15, 19, 20). As it  
48  
49 appears that participation in a non-body checking leagues conferred a strong protective  
50  
51 effect on shoulder IRs, this signifies the need for further policy implications and  
52

2  
3  
4 prevention strategies to be considered as it may result in both injury reductions and health  
5 care cost-savings for youth ice hockey players (21, 22).  
6  
7

8  
9 An athlete's history of a previous musculoskeletal injury or concussion in the  
10 previous 12 months was identified as a shoulder injury risk factor among ice hockey  
11 players. It may be hypothesized that these players are returning to sport too soon,  
12 potentially placing them at risk for further or subsequent tissue damage. While these  
13 athletes may even be 'clinically' healed or 'cleared for return to play' by a qualified  
14 healthcare practitioner, they may still suffer from lasting or long-term effects from their  
15 injury which persist (such as muscle atrophy or impaired joint proprioception).  
16  
17 Alternatively, these athletes could also be inherently predisposed to injury in general,  
18 based on their individual risk profile rather than a single previous injury. Such  
19 phenomenon as considering previous sport-related injury or concussion as an injury risk  
20 factor has been previously outlined in various papers and a systematic review with  
21 respect to youth sport (23-25). These studies identified that previous injury or concussion  
22 is a risk factor for future injury or subsequent recurrent injury. Future studies considering  
23 return to play timelines following shoulder injury would serve as an asset to fill in gaps in  
24 the literature with respect to shoulder IRs.

45 Game-related shoulder injuries appeared to result in substantial time-loss from  
46 sport for youth ice hockey players. Considering that shoulder injuries have been reported  
47 to be the second most common injury in body checking-permitted ice hockey leagues  
48 (following concussion), the potential lasting effects of a shoulder injury may have real  
49 life impacts on athletes, and this merits further scrutiny in future studies(18).

1  
2  
3  
4 This study serves to describe current shoulder-related injury trends in Canadian  
5 youth ice hockey. Overall, the findings of this study were relatively consistent with what  
6 has been previously observed. In particular, findings related to the timing of injury  
7 aligned with various previously published works where shoulder injuries were more  
8 common in games than practice exposures (10, 11, 15-17, 26, 27). With respect to the  
9 shoulder injury literature, injuries are known to occur with contact, a phenomenon that  
10 was once again observed (12). In contrast however, player size (namely weight) has  
11 typically been known to be associated with higher injury rates in ice hockey (15-17).  
12 Subjectively, players have been known to report more any injury occurrence during  
13 contact with a larger player than them in boy's collision sports (28). Nonetheless,  
14 information gained from this study has the potential to inform the formulation and design  
15 of shoulder injury prevention strategies and future body checking policies that will make  
16 youth sport a safer space for females and males participating in youth ice hockey.

32  
33  
34

35  
36 As missing covariates accounted for nearly a third of some variables (up to 28%),  
37 data imputation was requisite to improve statistical power. Multiple imputation is  
38 considered a reliable method to reduce sources of error and increase precision within a  
39 given dataset (29, 30). Notwithstanding, a small count of shoulder injuries among certain  
40 strata can be noted (in particular those who played goalie and females). It is a limitation  
41 that only 6 shoulder injuries were reported across 5 female participants (4 game and 2  
42 practice injuries) during the study period. Risk factor analysis, specifically, among female  
43 ice hockey players was not possible due to low sample size. This may directly impact the  
44 generalizability of these results to female ice hockey programs, so further study in this  
45 population is needed to identify shoulder injury risk factors. A low number of practice  
46  
47  
48  
49  
50

56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1 injuries were also observed in this cohort (n=12) so a separate analysis was not feasible.  
2  
3  
4  
5  
6  
7 This limits our ability to draw conclusions with respect to risk factors for shoulder  
8  
9 injuries occurring in practice. The use of an exploratory multivariate model to consider  
10  
11 the shoulder-specific observations in this data is a strength, as it likely results in a more  
12  
13 precise estimation (by adjusting for potentially confounding factors within the model and  
14  
15 reducing the standard error of the residuals). As this was a secondary data analysis,  
16  
17 continued follow-up for missing or incomplete data was not possible. Efforts were made  
18  
19 by the study team to minimize missing data through phone calls directly to participants,  
20  
21 and regular check-ins with the assigned team designates at the time of data collection.  
22  
23  
24 Being a secondary analysis, this also limited the selection of variables available for the  
25  
26 risk factor analysis, with most risk factors being non-modifiable and not shoulder-  
27  
28 specific. A potential source of selection bias in the cohort is that more serious injuries  
29  
30 (such as season-ending injuries or those requiring surgical intervention) may have been  
31  
32 more likely to be lost to follow-up if a player left the team or sport. With multiple players  
33  
34 participating in more than one season, it would have been ideal to also cluster by  
35  
36 individual within the multiple model but such crossed-effects models are computationally  
37  
38 intensive and prohibitively time consuming.  
39

41  
42  
43  
44

## 45 **Conclusions**

46  
47  
48 This study demonstrates that shoulder injury has a high injury incidence rate in  
49  
50 youth ice hockey. A striking observation was that most shoulder injuries resulted in more  
51  
52 than one week of time-loss from sport. Risk factors for shoulder injury included  
53  
54 participation in a body-checking league and previous history of any injury in the previous  
55  
56 12 months. Goaltenders were protected relative to forwards. Although body checking  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 policy is known to be associated with all injury rates, further study of policies and  
5  
6 prevention strategies specific to the shoulder merit further consideration and evaluation.

\* Injury incidence rate calculated using Poisson regression (clustering by team and offset by exposure hours). Crude IR reported for females due to low sample size.

**Table 3.** Shoulder injury mechanisms in games, stratified by biological sex.

Injury Mechanism	Male Injury Mechanisms (n=114)		Female Injury Mechanisms (n=4)	
	Frequency (%)	Injury Incidence Rate [injuries/1000 game-hours] (95% CI)	Frequency (%)	Crude Injury Incidence Rate [injuries/1000 game-hours]
Sudden Onset: Contact with another player or the environment	93 (82)	0.58 (0.29-1.47)	3 (75)	0.15
Sudden Onset: No contact with another player or the environment	10 (9)	0.06 (0.02-0.34)	0	0
Gradual Onset: Repetitive Injuries	3 (1)	0.02 (0.01-0.09)	0	0
Missing	8 (7)	0.05 (0.03-0.84)	1 (25)	0.05

\* Injury incidence rate calculated using Poisson regression (clustering by team and offset by exposure hours). Crude IR reported for females due to low sample size.

**Table 4.** Injury severity defined by time-loss from ice hockey following game-shoulder injury, stratified by biological sex.

	Male Injury Severity (n=114)		Female Injury Severity (n=4)	
<b>Injury Severity (time-loss)</b>	<b>Frequency (%)</b>	<b>Injury Incidence Rate [injuries/1000 game-hours] (95% CI)</b>	<b>Frequency (%)</b>	<b>Crude Injury Incidence Rate [injuries/1000 game-hours]</b>
Slight (0-1 days)	7 (6)	0.04 (0.03-0.07)	1 (25)	0.05
Minimal (2-3 days)	11 (10)	0.07 (0.03-0.17)	0	0
Mild (4-7 days)	17 (15)	0.11 (0.03-0.24)	1 (25)	0.05
Moderate (8-28 days)	35 (31)	0.22 (0.13-0.39)	1 (25)	0.05
Severe (>28 days)	44 (39)	0.27 (0.20-0.42)	1 (25)	0.05
Missing	0	-	0	0

\* Injury incidence rate calculated using Poisson regression (clustering by team and offset by exposure hours). Crude IR reported for females due to low sample size.

**Table 5.** Adjusted Injury Incidence Rate Ratios (IRRs) for game-related injuries based on multiple Poisson regression (clustering by team and offset by exposure hours) with one mixed effect at the team level. MICE imputation used.

Potential Risk Factor (n=130)		Injury Incidence Rate Ratio (95% CI)
<b>Body Checking Policy</b>	Permitted	1 (Reference)
	Not Permitted	<b>0.18 (0.10-0.32)</b>
<b>Weight</b>		1.01 (0.99-1.025)
<b>Previous Injury (last 12 months)</b>	No	1 (Reference)
	Yes	<b>2.32 (1.57-3.41)</b>
<b>Level of Play</b>	Elite	1 (Reference)
	Sub-elite	0.83 (0.56-1.22)
<b>Playing Position</b>	Forward	1 (Reference)
	Defense	0.87 (0.59-1.27)
	Goalie	<b>0.32 (0.11-0.87)</b>
<b>Biological Sex</b>	Male	1 (Reference)
	Female	1.12 (0.42-3.00)

\* Incidence Rate Ratios (IRRs) calculated using multiple Poisson regression (clustering by team and offset by exposure hours).
