63 **Main text:**

64 Many emerging and re-emerging pathogens originate from wildlife, but nearly all wild species are  
65 unreachable using conventional vaccination, which requires capture of and vaccine administration  
66 to individual animals. By enabling immunization at scales sufficient to interrupt pathogen  
67 transmission, transmissible vaccines (TVs) that spread themselves through wildlife populations by  
68 infectious processes could potentially transform management of otherwise intractable challenges  
69 to public health, wildlife conservation, and animal welfare. However, generating TVs likely  
70 requires modifying viruses that would be intended to spread in nature, raising concerns ranging  
71 from technical feasibility, to safety and security risks, to regulatory uncertainties (1, 2). We  
72 propose a series of commitments and strategies for vaccine development, beginning with *a priori*  
73 decisions on vaccine design and continuing through to stakeholder co-development (see the box),  
74 that we believe increase the likelihood that the potential risks of vaccine transmission are  
75 outweighed by benefits to conservation, animal welfare, and zoonosis prevention.

76 The inability to control emerging pathogens at their source translates into mitigation strategies  
77 focused on direct protection of humans or domestic animals, an approach that fails to curb the risks  
78 and costs of recurring transmission between species (hereafter, spillover). Diseases threatening  
79 wildlife health, either through recurrent spillover (e.g., Ebola in great apes) or following host shifts  
80 and/or pathogen translocations (e.g., white nose syndrome [WNS] in bats), remain similarly  
81 uncontrollable by conventional approaches. Mass distribution of oral vaccines via baits has shown  
82 that scalable vaccination of wildlife can protect human health and animal welfare; however, bait  
83 delivery systems are incompatible with many wild species (3).

84 TVs have been proposed as a scalable, low-cost option to interrupt transmission within and to  
85 otherwise unreachable wildlife (4). However, risks of vaccine transmission are well recognized  
86 from theory and have been substantiated in conventional vaccines that transmit inadvertently  
87 (Figure 1). Most notoriously, sustained transmission of the live attenuated oral polio vaccine  
88 enabled reversion to its ancestral polio-causing phenotype. Although deliberate vaccine  
89 transmission has only rarely been tested, a vaccine against rabbit hemorrhagic disease (RHD) did  
90 explore the possibility using an attenuated myxomavirus-based vaccine (5). Although no ill effects  
91 were reported prior to natural vaccine extinction, the myxomavirus used was not host specific and  
92 had only a brief co-evolutionary history with the target rabbit species, making its long-term  
93 evolutionary trajectory uncertain. Recent interest in TVs has been revitalized by accumulating

94 evidence that it may be possible to design vaccines that mitigate foreseeable risks while preserving  
95 efficacy. Such TVs are currently being advanced in laboratories, but to our knowledge, none have  
96 been released in any natural population.

97 The relative lack of substantive public discourse involving both proponents and critics of TVs  
98 has created a scientific landscape with conflicting definitions and immaterial evidence that is  
99 unhelpful for policymakers, funders, and the organizations charged with oversight of the research  
100 and development process. As a group of bioethicists, disease ecologists, evolutionary biologists,  
101 immunologists, sociologists, and virologists, including both proponents and critics of TVs, we  
102 appraised the potential ecological and societal risks arising from transmission of an engineered  
103 viral vaccine (see supplementary materials). The commitments that arose are not intended to  
104 establish dogma or legitimize the use of TVs but rather to serve as a conservative starting point  
105 which we expect will evolve with societal attitudes, scientific evidence, and technology.

106

#### 107 **INTRINSICALLY SAFE, BIOLOGICALLY COMPELLING VACCINE DESIGNS**

108 Flexible vaccine designs are most easily accommodated using recombinant vaccines that consist  
109 of two parts engineered into one genome: a relatively benign animal virus (the vector) and a short  
110 genetic segment from the pathogen (the antigenic insert or transgene), which induces an immune  
111 response. The goal is to preserve the capacity for transmission between individuals, while adding  
112 the ability to immunize, thereby magnifying the vaccination coverage derived from each directly  
113 vaccinated individual.

114 As vaccine safety hinges predominately on the properties of the vector, we propose eligibility  
115 criteria. First, vaccines derived from cross-species transfer (e.g., myxomavirus-based RHD  
116 vaccine) may spread unpredictably causing ecological disruption. New selective environments,  
117 including the possibility of novel co-infections with recombination-compatible viruses, might also  
118 promote evolution towards previously unobserved, harmful phenotypes (5). Vectors would  
119 therefore need to be both isolated from and returned to their natural host species. Because  
120 competition between TVs and their ancestral (wildtype) or descendant (reversion to non-vaccine  
121 strain) viruses may inhibit vaccine spread, vectors that can infect hosts with prior or concurrent  
122 wildtype infections are desirable. Alternatively, competition with the wildtype may be overcome  
123 by repeatedly introducing the vaccine or constructing it using locally rare or absent strains (6, 7).

124 Second, vaccines that cross species boundaries during transmission in nature present similar  
125 risks to deliberate cross-species transfer. Vectors would therefore need to be host specific, as  
126 demonstrated by representative surveys for cross-species infections in nature, co-evolutionary  
127 analyses supporting host-virus co-speciation over host switching, laboratory studies of cellular  
128 tropism, and animal inoculation studies. Ecologically plausible exposures in sympatric, non-target  
129 species (i.e., those that are not part of the planned vaccination campaign) would need to lead to  
130 insufficient replication to cause clinical disease or vaccine transmission. Ecological plausibility  
131 might be derived from local knowledge, expert opinion, and/or *in silico* predictions of  
132 susceptibility. In cases where multiple host species independently maintain the pathogen and a  
133 single viral vector infects these species, safety and efficacy studies should include all relevant  
134 hosts.

135 Third, viruses that would require attenuation (reducing virulence) to align with management  
136 goals and stakeholder desires are excluded since perturbing the co-evolved virus-host equilibrium  
137 might select for a return to the undesirable ancestral state (fig. S1). Unlike reversion of attenuated  
138 vaccines, reversion of TVs to their ancestral phenotype creates no novel health or environmental  
139 risks because the ancestral virus naturally circulates in the same host species. This strategy also  
140 alleviates the potential concern that TVs could gain pathogenicity by recombining with wildtype  
141 strains (8).

142 Misuse of the knowledge acquired during the development of new technology is always a  
143 concern. Consistent with the core ideology of exploiting natural traits of viruses as built-in safety  
144 features, engineering of viral vectors would avoid modifications that increase host range,  
145 pathogenicity, or transmissibility. More generally, any technology that could plausibly be harmful  
146 if applied to a human-infecting virus should be avoided in TVs designed for animals. For instance,  
147 discovering novel molecular mechanisms that augment spread or enhance evolutionary stability  
148 might benefit vaccine coverage but could have malicious applications elsewhere. If increased  
149 stability is required to reach management objectives, methods could be limited to transgene  
150 identity, size, copy number, and placement (9). Alternatively, more intensive or efficient  
151 deployment can increase coverage (10).

152

153 **STAGED DEVELOPMENT WITH ESTABLISHED CHECKPOINTS**

154 We believe the criteria described above maximize the safety of TVs without undermining their  
155 potential efficacy (10,11). Nevertheless, unforeseeable issues may arise during the vaccine  
156 development process which may prompt suspension of a TV's development. A staged  
157 development process is needed for early identification and containment of emergent risks.  
158 Specifically, TV development would advance from *in vitro* studies in laboratories, to *in vivo* animal  
159 testing within appropriate biological containment, to limited trials in populations that are naturally  
160 (e.g., islands, mountains) or experimentally (e.g., enclosures, semi-field systems) isolated (Figure  
161 1). Following an Open Science approach, quantitative benchmarks for safety and efficacy would  
162 be defined in advance and transparently shared as checkpoints to continue or not with a given  
163 vaccine candidate. Instability of recombinant TVs through silencing or purging of the transgene is  
164 expected and detrimental to efficacy but acts advantageously as a natural self-limiting mechanism  
165 against uncontrolled spread. When technically possible, vaccines themselves should be staged,  
166 with early experiments using vaccines expected to have a short evolutionary half-life, mitigating  
167 risks of prolonged circulation of an undesirable prototype in the event of laboratory escape.

168 Accountable systems to monitor vaccine release, evolution, and spread will be critical throughout  
169 the development process. These include re-sequencing of the vaccine to monitor evolutionary changes  
170 and periodic *in vitro* monitoring of growth rate or cellular tropism. Since vaccinated animals possess  
171 immunity only to pathogen proteins included within the antigenic insert, immunological monitoring  
172 could differentiate previously infected and vaccinated animals. The potential for vaccines to create  
173 secondary hazards, such as exposure to vehicles used in vaccine deployment (e.g., topical gels, baits,  
174 aerosols), also needs to be considered and monitored when appropriate. Researchers should establish  
175 contingency plans for foreseeable risks (noting that a contingency plan can include 'no action') and  
176 implement appropriate management systems for timely responses to unforeseen events.

177

## 178 **EQUITABLE PARTNERSHIPS WITH INTERNATIONAL GOVERNANCE**

179 While the impossibility of individual consent prohibits consideration of TVs for human use,  
180 complex ethical issues around consent also arise for TV use in animals. Concerns and requirements  
181 around technology development, staged delivery timelines, and identification of any ecological  
182 ramifications of reducing pathogen circulation would require reciprocal engagement with relevant  
183 stakeholders, including government agencies that regulate vaccine use in animals, wildlife  
184 population managers, public health officials, non-government agencies, and affected communities

185 ('co-development'). Initiating this process at project inception and certainly before engineering of  
186 vaccine prototypes benefits vaccine developers by identifying technical and community values-  
187 based constraints that would alter deployment or development targets (12). Communities affected  
188 by zoonotic spillover may desire rapid or geographically expanded TV deployment or, due to the  
189 novelty of TVs, may alternatively focus on potential risks while overlooking benefits. Scientists  
190 and communicators with expertise in managing expectations and identifying community  
191 champions will play a key role by ensuring that information about vaccine performance or safety  
192 is accurately portrayed, thus empowering communities to help make decisions with free, prior, and  
193 informed consent. Communication and engagement should also raise awareness of the potential  
194 for discussions of TVs to reduce acceptance of conventional vaccines, thereby inadvertently  
195 harming health.

196 As with any vaccine, TV development will be subject to existing local, national and international  
197 regulations for scientific research, production and testing, environmental impacts, and to funders'  
198 discretion. One motivation for TVs is to reduce the disproportionate burden of pathogen spillover from  
199 wildlife in lower- and middle-income countries. It is therefore unavoidable that some developmental  
200 stages for some TVs (e.g., contained field trials) would be undertaken in these countries, while other  
201 stages (e.g., vaccine engineering and laboratory-contained animal trials) may be undertaken in  
202 countries with more funding and infrastructure. As regulatory requirements also vary across countries,  
203 stringent oversight as a shared, international responsibility underpins credibility, for example, requiring  
204 ethical and biosafety practices approaching the most conservative standard among partner nations  
205 involved. TVs developed to conserve wildlife may avoid the potential geographic mismatches between  
206 TV use and development. Greater investment in this area could provide valuable proof of concept for  
207 TVs targeting zoonotic spillover. Regardless of management targets, equitable collaborations, wherein  
208 risks taken and benefits gained are proportionate and undertaken by nationally diverse teams, are  
209 warranted across developmental stages.

210

## 211 **TOWARDS DEPLOYMENT**

212 In principle, TVs are suited to well-studied host-pathogen systems where spillover from  
213 established reservoir hosts is predictable, recurrent, and costly (e.g., rabies virus, Lassa fever virus,  
214 Nipah virus, Marburg virus) or where low-cost, scalable interventions could reduce pathogen  
215 threats to wildlife (e.g., WNS in bats, Ebola virus disease in non-human primates, retrovirus

216 infection and Chlamydiosis in koalas). In practice, whether TVs are pursued over conventional  
217 alternatives should be evidence driven. For example, to evaluate whether host behavior or life  
218 history may constrain vaccine transmission to impractical levels, the maximum coverage that could  
219 be expected from a TV can be estimated from the proportion of individuals in target host  
220 populations that are naturally infected with the candidate viral vector. Similarly, the geographic  
221 extent of spread can be inferred from vector population genetics (7). Dynamic models derived  
222 from these data, and similar data describing the transmission dynamics of the target pathogen  
223 (including the potential roles of alternative host species in long-term maintenance), would be  
224 expected to support positive benefit-cost ratios of TVs over alternatives, whether through increased  
225 levels of vaccine coverage or improved immunological protection. When appropriate, models  
226 should consider sensitivity to vaccine reversion, reduced vaccine fitness from genetic  
227 manipulation, and competition with the wildtype virus (10, 11).

228 Deployment of biological agents that spread in natural populations raises distinct regulatory  
229 considerations and may require a broad view of incentives for industrial investment (e.g.,  
230 philanthropic benefits). When developed and applied carefully, self-spreading agents have  
231 benefitted human health (e.g., reduction of dengue using *Wolbachia* endosymbionts in mosquitoes  
232 (13)) and agriculture (e.g., control of plant pathogens using phage cocktails and baculoviruses  
233 (14)). The TVs we propose add complexity through their requirement for genetic modification.  
234 However, other self-spreading interventions harnessing genomic engineering (CRISPR, gene  
235 drives) are advancing, creating blueprints for how staged co-development can empower evidence-  
236 based policymaking and find solutions to regulatory, financial, and social challenges (12, 15).  
237 Provided that a TV can be safely developed and shows promise for disease control, decisions on  
238 real world use would need to consider the balance of knowable harm done by withholding use and  
239 knowable harm done by release. The commitments presented here are intended to encourage  
240 deliberations characterized by understanding, accountability, and transparency, advancing a  
241 collaborative future in which TVs may contribute to the public good.

321 **Box 1. Seven proposed commitments for the responsible development of transmissible**  
322 **vaccines for infectious disease control in animals**

- 323 1. Vaccines will use naturally occurring, and host specific viruses as vectors, that would be  
324 isolated from and returned to their natural host species after antigen insertion.
- 325 2. Genetic modifications that increase host range, pathogenicity, or transmissibility, or create  
326 secondary hazards will not be intentionally pursued.
- 327 3. Technologies that could plausibly be harmful if applied to a human virus should be avoided.
- 328 4. Development will be staged with defined checkpoints and carried out within appropriately  
329 controlled environments.
- 330 5. Unintended spread and consequences will be monitored throughout development stages, with  
331 contingency plans.
- 332 6. Development will be transparent and community-led.
- 333 7. Safety standards will approach the strictest standards of partner nations involved.
