Vortex recapture underpins the exceptional mobility of nature’s finest fliers and swimmers. Utilized by agile fruit flies and efficient jellyfish, this phenomenon is well-documented in bulk fluids. Despite extensive studies on the neuston—a vital fluidic interface where diverse life forms interact between air and water—neuston vortical hydrodynamics remain unexplored. We investigate epineuston (on water) vortical hydrodynamics in *Microvelia americana*, one of the smallest and fastest water striders, skating at 50 BL/s (15 cm/s). Their middle legs shed counter-rotating vortices, re-energized by hind legs, demonstrating epineuston vortex recapture. High-speed imaging, particle imaging velocimetry, physical models, and CFD simulations show re-energization increases thrust by creating positive pressure at the hind tarsi, acting as a virtual wall. This vortex capture is facilitated by the tripod gait, leg morphology, and precise spatio-temporal placement of the hind tarsi during the power stroke. Our study extends vortex recapture principles from bulk fluids to the neuston, offering insights into efficient epineuston locomotion, where surface tension and capillary waves challenge movement. Understanding epineuston vortex hydrodynamics can guide the development of energy-efficient microrobots to explore the planet’s neuston niches, critical frontlines of climate change and pollution.

1 The unseen ballet of vortical forces orchestrates
2 nature’s most efficient swimmers and fliers [1–7].
3 These interactions, fundamental to minimizing en-
4 ergy expenditure and maximizing thrust, allow or-
5 ganisms to utilize energy from their own or others’
6 wakes [1, 2, 8–10]. Jellyfish boost thrust by captur-
7 ing vortices during relaxation, creating high-pressure
8 zones [5, 11]. Fruit flies capture leading-edge vortices
9 during the fling motion, minimizing the energy re-
10 quired to generate new vortices [12, 13]. Fish exhibit
11 such efficient wake capture that even dead fish can
12 swim upstream by resonating with oncoming Kármán
13 street vortices [14, 15].

14 While these examples occur in bulk fluids, the
15 neuston interface — a vital ecological niche — teems
16 with life. From zooplankton, insects, and spiders to
17 birds, reptiles, and plants, countless organisms in-
18 teract at this boundary in marine and freshwater
19 ecosystems [16–27]. Despite the challenges of bal-
20 ancing surface tension, drag, buoyancy, and capil-
21 lary waves, no documented examples of vortex re-
22 capture at this interface exist. Driven by curiosity
23 about neuston vortical interactions, we reveal a vor-
24 tex re-energization mechanism in *Microvelia ameri-*
25 *cana* (Hemiptera, Veliidae).

26 These millimeter-sized water walkers are
27 epineustonic, living on the water surface and
28 are one of the smallest and fastest on this ecological

niche ($u_B \sim 50$ BL/s, Figure 2.d). Part of the
29 infraorder Gerromorpha, they are found in creeks
30 and ponds worldwide and include over 200 species
31 (Figure S1) [28–31]. Unlike most water striders that
32 use elongated middle legs for rowing, *Microvelia*
33 employ all six legs to walk and run using a tripod
34 gait [16, 17, 32, 33]. Their unique morphology and
35 kinematics enable them to recapture vortices shed
36 from their middle legs, allowing them to speedily
37 skate across the water surface. These amphibious
38 insects, whose ancestors were terrestrial and used a
39 tripod gait for movement on land, evolved to move
40 on water while retaining this gait [16, 34–37]. Using
41 high-speed imaging, particle imaging velocimetry,
42 physical models, and CFD simulations, we describe
43 the epineuston vortex interactions during the water
44 skating behavior of *Microvelia*.
45

RESULTS

46
47 **Skating on water.** *Microvelia* possess dense hair
48 coverage on their bodies and legs (Figure 1.a) [38].
49 SEM analysis reveals a tarsal hair density of $\sim 15,000$
50 hairs/mm² ($n = 3$), comparable to *Velia caprai* and
51 *Gerridae*. [16, 39, 40]. This dense coverage enables
52 *Microvelia* to maintain a Cassie-Baxter state [41],
53 limiting water infiltration and maintaining superhy-
54 drophobicity leading to dimples at air-water surface
55 contact points (Figure 1.b). The low Weber num-
56 ber, $We = \rho v^2 l / \sigma \ll 1$ (see Table S1) indicates that

Figure 1: Behaviour and morphology of epineustonic *Microvelia americana* (a) Dorsal view of *Microvelia americana* with inset showing a SEM image of the dense hair coverage on middle leg tarsus (*pseudo-colored*). (b) *Microvelia Sp.* feeding on a trapped insect in a creek (Brunei), with legs deforming the water surface, forming dimples. (c) Size comparison showing *M. americana*'s small body size relative to commonly found water striders, *Gerridae*. (d) Alternating tripod gait plot for *M. americana* locomoting on water surface, showing the gait cycle of each leg performing power (color filled boxes) and recovery strokes (empty boxes). (e) Snapshots showing the side view of *M. americana* walking on water. (f) Dynamics of *M. americana* on water, indicating short skating escape-sprints (~2 s) and intermittent walking behavior over a time span 5 minutes.

57 surface tension forces dominate over inertial forces
 58 in their interfacial locomotion, similar to other water
 59 striders like *Gerridae* [24].

60 Unlike water striders such as *Gerridae* that use a
 61 rowing gait, *Microvelia* employ an alternate tripod
 62 gait typical of terrestrial insects. In this gait, at least
 63 three legs – the front leg (FL), the contralateral mid-
 64 dle leg (ML), and the ipsilateral hind leg (HL) – per-
 65 form a power stroke on water (Figure 1.d,e), while
 66 the other legs recover in air or sometimes on water

(SI Video 1).

To understand their epineustonic locomotion be-
 68 havior, we examine their dynamics over a 5-minute
 69 period in the lab. During this time *Microvelia*
 70 primarily engage in intermittent walking, spending
 71 99.6% of the time in this mode. However, they occa-
 72 sionally sprint as an escape response, skating a dis-
 73 tance of ~ 30 mm in ~ 2 seconds (Figure 1.e). The
 74 temporal trajectory of the middle and hind legs shows
 75 overlapping paths during this skating mode, indicat-
 76

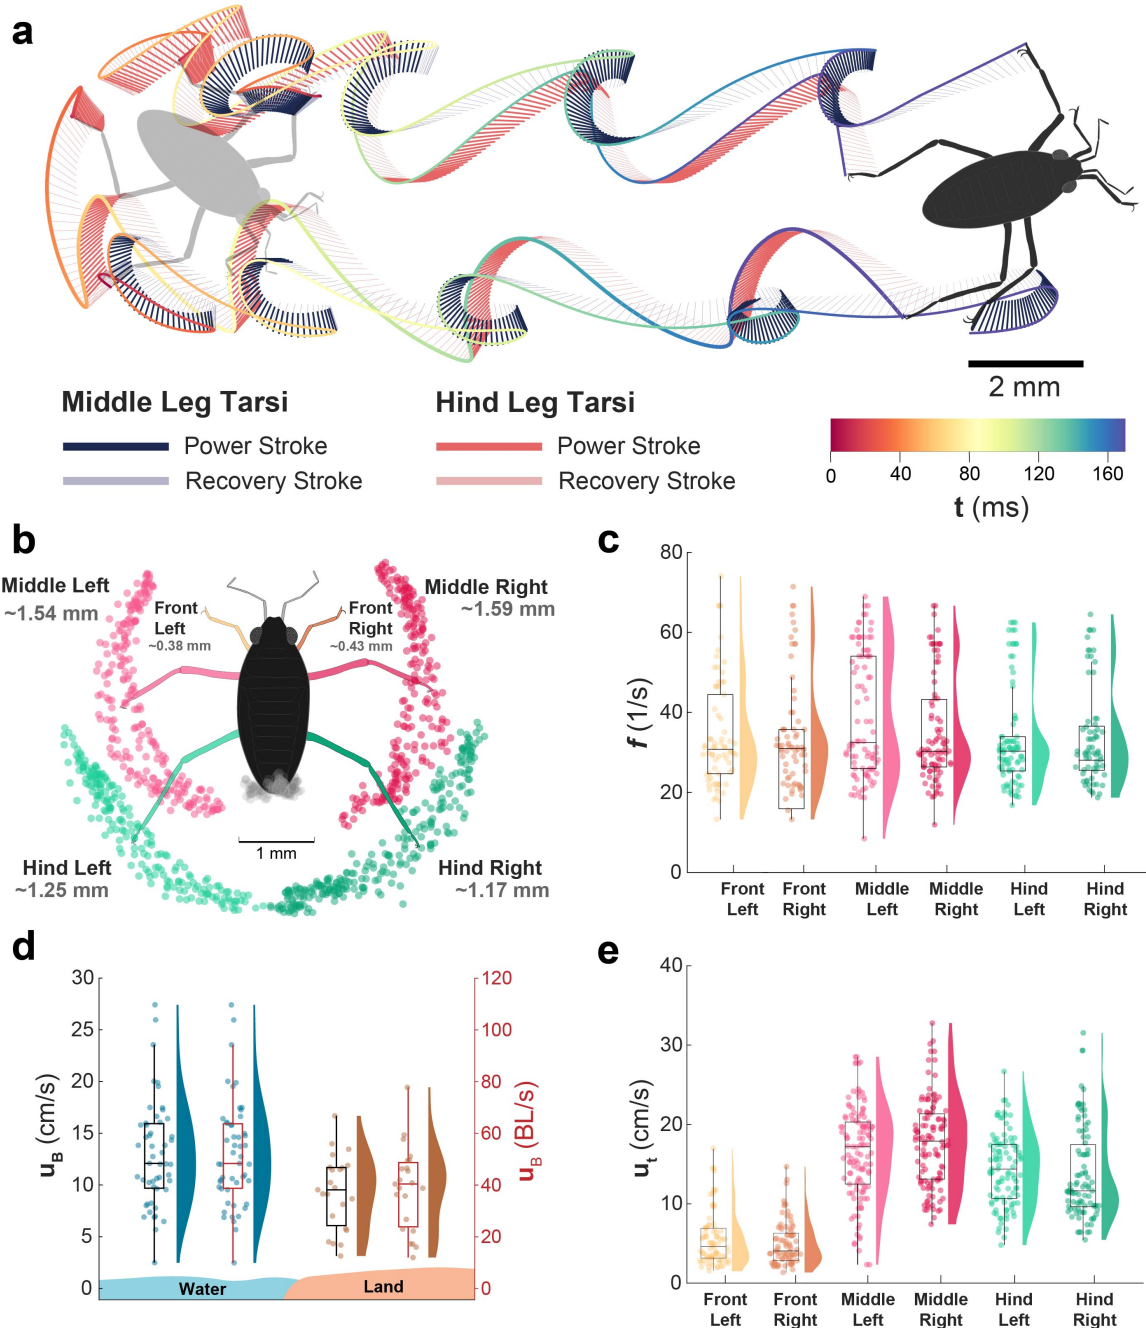

Figure 2: Epineustonic kinematics of *Microvelia*. (a) Tarsal trajectories of middle and hind legs of *Microvelia*. The solid lines represent the power strokes, while the faded blue and red lines show the recovery strokes. The trajectories illustrate the time spent by the tarsi during movement. (b) Stroke amplitudes of the middle and hind legs ($n = 15$), illustrated with their tarsal tip trajectories relative to the motion of their respective shoulder joints. The middle legs exhibit larger stroke amplitudes ($\lambda_{ML} \sim 1.54 \pm 0.43$ mm and $\lambda_{MR} \sim 1.59 \pm 0.74$ mm) compared to the hind legs ($\lambda_{HL} \sim 1.25 \pm 0.46$ mm and $\lambda_{HR} \sim 1.17 \pm 0.47$ mm). (c) Stroke frequency ($N = 3$, $n = 15$) of the middle and hind tarsi, showing an average stroke frequency of $f \sim 30$ strokes/s. (d) Body speed of *Microvelia* on water and land (styrofoam) in cm/s (left Y axis) and BL/s (body lengths per second, right Y axis). The average maximum body speed on water is ~ 15 cm/s (~ 50 BL/s), compared to ~ 10 cm/s (~ 40 BL/s) on land. (e) Peak tarsi speeds of *Microvelia* on water. The middle legs achieve higher peak linear speeds during power strokes (~ 17 cm/s) compared to the hind legs (~ 14 cm/s). This indicates that the middle legs act as the main hydrodynamic thrust propulsors, with higher acceleration (~ 2500 cm²/s) compared to the hind legs (~ 2000 cm²/s).

ing interfacial vortical interactions (Figure 2.a).

During the skating mode, the middle legs of *Microvelia* act as the main hydrodynamic thrust propulsors [32, 33]. These legs exhibit a stroke amplitude 23% larger than the hind legs, while maintaining the same stroke frequency (Figure 2.b,c). This larger amplitude allows for greater displacement with each stroke, enhancing thrust. The middle legs also achieve higher peak linear speeds during power strokes, 21% faster than the hind legs (Figure 2.e). This increased speed, coupled with greater acceleration—about 25% higher than that of the hind legs—indicates their dominant role as forceful thrust generators [33].

Epineuston hydrodynamic interactions. During the power stroke, the middle leg tarsi shed pairs of counter-rotating vortices (Figure 3.a, stage I). These vortices travel downstream, interacting with the hind tarsi, which enter the water at various spatio-temporal locations. The front tarsi generate weak vortices that dissipate without interacting with other tarsi (SI video II).

The exact location and timing of the incident hind tarsi relative to the vortices dictate the outcome of these interactions. Favourable interactions result in vortex re-energization, increasing the vortices' strength (Figure 3.a, Stage II and III). Body rocking and turning can misalign these interactions, altering the hind legs' angle of attack and leading to vortex annihilation or no interaction (Figure 3.b). Additionally, if *Microvelia* moves at high speed, its body can pass over the middle leg vortices before the hind legs can interact with them, emphasizing the importance of timing (Figure 3.f).

We measure the circulation of vortex pairs generated by the middle tarsi during re-energization until they dissipate after hind tarsi interaction. Circulation, $\Gamma = \int \int_S \omega \cdot dS$, where ω is the vorticity and S is the bounded area, measures the vortices' strength. As the middle leg initiates the power stroke (Figure 3.c, point 1), the vortices' circulation increases, peaking at $\Gamma = 2 \text{ cm}^2/\text{s}$ ($t = 71 \text{ ms}$), corresponding to the maximum tarsal speed (22 cm/s, $t = 70 \text{ ms}$). The middle leg then decelerates, reducing Γ as the vortices dissipate (point 3). The hind tarsi then enters the wake, re-energizing the vortices to enhance the circulation to a second, lower peak of $\Gamma = 1.6 \text{ cm}^2/\text{s}$ ($t = 88.5 \text{ ms}$) due to a lower hind-tarsal speed of 17 cm/s (Figure 3.c, point 4). This cycle ends with the hind tarsi completing their power stroke and dissipating the vortices (SI video II, Figure S2).

Across 52 instances in 6 specimens, we observe that 60% of the interactions result in re-energization, 27% show no interaction, and the remainder lead to vor-

tex annihilation (Figure 3.e). We compare the normalized peak circulation before and after their hind tarsal interaction ($\tilde{\Gamma} = \Gamma_2/\Gamma_1$) with normalized body speed ($\tilde{\mathbf{u}} = \mathbf{u}_B/\mathbf{u}_t$) and the time interval (Δt) between strokes (Figure 3.d). Vortical re-energization primarily occurs when the hind tarsi strike between the middle tarsi vortices with shorter Δt (typically $< 6 \text{ ms}$), during initial acceleration phase of the skating sprint (Figure 3.f). At higher body speeds, longer Δt , or due to body turning or rocking, the hind tarsi miss the vortices resulting in no interaction. When the hind legs skate across the pair of vortices rather than slaloming between them, the interactions tend to weaken the vortices, leading to vortex annihilation (Figure 3.d). Collectively, this reinforces that both the hind tarsi's entry position relative to the middle tarsi (angle-of-attack) and the inter-stroke interval play critical roles in determining the outcome of these interactions.

Epineuston vortical recapture increases thrust in *Microvelia*. Reconstructed pressure fields from PIV-measured velocity fields reveal insights into vortical interactions with the hind tarsi of *Microvelia* (Figure 4.a). During vortex re-energization, a local pressure gradient forms from upstream to downstream of the hind tarsi, generating the highest relative pressure ($\Delta p \sim 5 \text{ Pa}$). In contrast, vortex annihilation results in lower relative pressure ($\Delta p \sim 2 \text{ Pa}$, Figure S3), with cases of no interaction showing similarly low pressure.

We calculate the total impulse by integrating the relative pressure over time, $\mathbf{I} = \int_T \Delta p A dt$, where T is the duration of the power stroke and A is the planar area containing the tarsi and its wake (Figure S3). Normalizing the impulse, $\tilde{\mathbf{I}} = \int_T \Delta p dt / (\rho \tilde{\mathbf{u}}_{t,n}^2 A)$, isolates the impact of hind tarsal interaction from tarsal speed. Excluding the impulse from the middle tarsi yields the relative impulse, $\tilde{\mathbf{I}}_r = \tilde{\mathbf{I}}/\tilde{\mathbf{I}}_{middle}$.

Our results show that vortex re-energization produces a normalized impulse ($\tilde{\mathbf{I}}_r \sim 1.08$), 34% higher than vortex annihilation (~ 0.81) and 15% higher than no interaction (~ 0.94) (Figure 4.b). This increased impulse results from enhanced fluid entrainment during re-energization, which raises pressure in the tarsal plane. When hind tarsi step into the center of the vortex pair, they entrain more fluid mass due to the converging flow driven by the vortical motion [44], leading to increased pressure and greater thrust.

The observed rise in normalized impulse during re-energization illustrates *Microvelia*'s ability to harness energy from its own wake, a phenomenon we call 'Epineuston Vortex Recapture'. Typically, wakes signifies lost energy to the environment. By step-

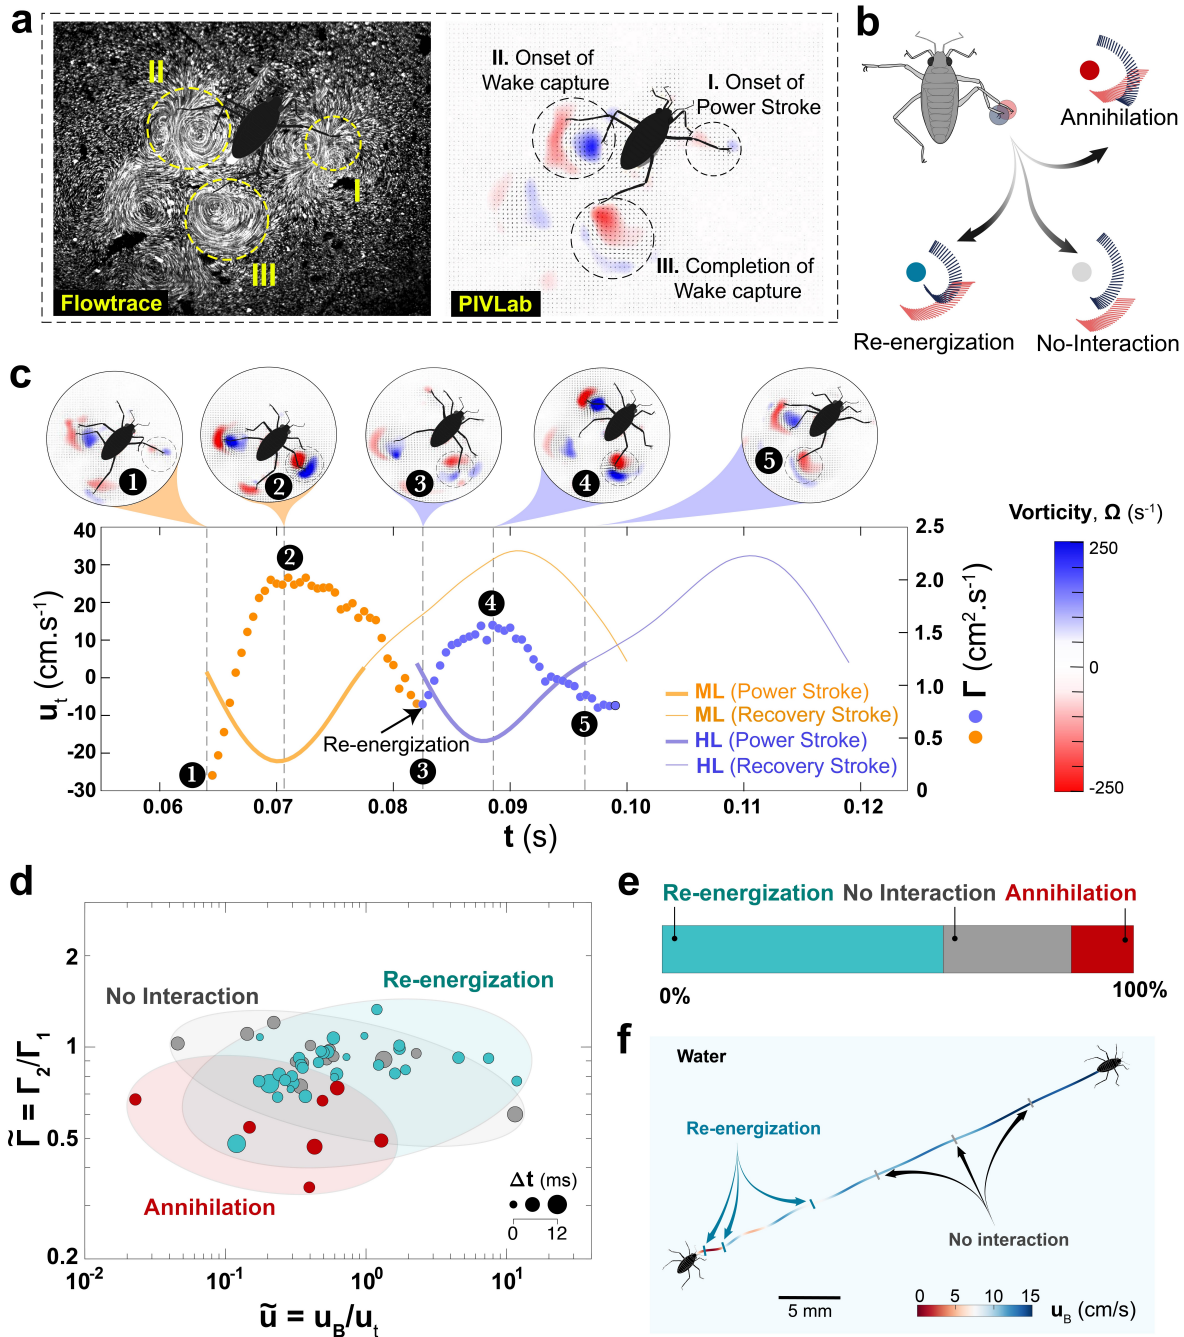

Figure 3: Hydrodynamic interactions in *Microvelia*'s epineustonic locomotion. (a) Stages of vortical shedding from the power strokes of the middle tarsus and their subsequent interactions with the hind tarsus. LHS: Flowfield streamlines visualization in Flowtrace [42] and RHS: vorticity field generated in PIVlab [43]. Stage I - Vortices generated during the onset of the power stroke of the middle right tarsus, (II) Hind legs stepping into the vortices shed from the middle left tarsus, (III) re-energized vortices from the hind right tarsus; LHS shows the vorticity field corresponding to the frame on the right. (b) Illustrations represent the three different outcomes of vortical interactions based on the trajectory of the hind and middle tarsi. (c) Representative tarsal velocity profiles of the middle-right and hind-right tarsi of *Microvelia* walking on water and the corresponding circulation (filled circles) of the vortices for the case of vortex re-energization. (d) Effect of normalized body speed (relative to hind tarsi speed) on the circulation ratio of vortices originating from the middle legs pre- and post-interactions with the hind tarsi. (e) Percentage outcomes of the vortical interactions of the hind tarsi with vortices shed from the middle tarsi, and (f) Different vortical interactions within a single run on water in *Microvelia*.

185 ping into vortices generated by its middle legs during
186 previous strokes, *Microvelia* harnesses this energy to
187 increase thrust production by the hind legs. This
188 mechanism, driven by its tripod gait and interfacial
189 movement, enables *Microvelia* to effectively generate
190 thrust at the air-water interface.

191 **Physical models validate inter-stroke interval**
192 **in epineustonic vortical interactions.** To evalu-
193 ate the effect of inter-stroke intervals (Δt) on vorti-
194 cal interactions, we use a physical model. The model
195 simulates *Microvelia*'s middle and hind tarsi power
196 strokes on water, varying Δt to alter the hind tarsi's
197 angle of attack to the vortices shed by the middle
198 legs. The Reynolds number of the model (~ 18) is
199 within the range of *Microvelia* ($Re \sim 2 - 21$, see Ta-
200 ble S1). The first arm generates a counter-rotating
201 vortex dipole, which the second arm interacts with,
202 depending on Δt (Figure 4.c).

203 For large $\Delta t = -116$ ms, the first arm's vortices
204 dissipate before the second arm's entry, resulting in
205 no interaction (SI Video III, Figure S4). Reducing the
206 interval allows for re-energization, with the second
207 arm's vortices showing higher normalized circulation
208 ($\tilde{\Gamma} > 1$) (Figure 4.d). However, at very short inter-
209 vals ($-10 < \Delta t < 10$ ms), capillary waves generated
210 by the arms disrupt the vortices, leading to annihila-
211 tion. The normalized circulation ($\tilde{\Gamma}$) compares both
212 *Microvelia* and the physical model, revealing that opti-
213 mal inter-stroke intervals enhance re-energization
214 and thrust (Figures S4, S5). Vortical re-energization
215 in *Microvelia* doesn't always imply $\tilde{\Gamma} > 1$ due to re-
216 duced hind legs' tarsal speed, imparting less energy
217 to the vortices (Figure 2.e).

218 **CFD analysis of thrust enhancement dur-**
219 **ing vortex re-energization.** We simulate thrust
220 enhancement through vortex capture using 2D CFD
221 models of high aspect ratio ($AR = 20$) rectangular
222 plates undergoing prescribed rotation and transla-
223 tion. Mimicking the physical model configuration,
224 the first plate rotates counterclockwise, and the sec-
225 ond rotates clockwise, starting with a time gap (Δt),
226 traversing the first plate's vortical wake (SI Video
227 4, Figure S5). These simulations evaluate the role of
228 vortex re-energization on thrust via robotic arms' tra-
229 jectory rather than mimicking the precise kinematics
230 of *Microvelia*.

231 Streamline analysis shows differences in flow ve-
232 locity magnitudes for different Δt intervals (Figure
233 4.e). For $\Delta t = 0.2$ s, the second plate captures
234 the first plate's wake, entering its recirculation region
235 closely (SI video 4). As a result, the vortex cores with
236 the same sense of rotation from both plates co-align
237 to increase the resultant circulation, augmenting the
238 propulsive force. In contrast, for $\Delta t = 0.5$ s, the sec-

239 ond plate fails to interact effectively, leading to vortex
240 annihilation with lower flow velocities and thrust due
241 to the absence of effective wake capture.

242 To reinforce our findings, we present the tempo-
243 ral evolution of the coefficient of thrust (C_T) for the
244 second plate, showing vortical re-energization, com-
245 pared to no interaction (Figure 4.f). The C_T , defined
246 as $2T/(\rho_f \mathbf{u}_r^2 A)$, where T is the thrust force, ρ_f is the
247 fluid density, \mathbf{u}_r is the relative linear velocity, and A
248 is the plate's projected area, illustrates the influence
249 of interaction on vorticity fields at different times.

250 For $\Delta t = 0.2$ s, C_T peaks at $t = 1.2$ s as vortex
251 dipoles from both plates interact, augmenting circula-
252 tion. As the plates separate, C_T decreases, show-
253 ing reduced wake interaction. Thrust enhancement
254 via wake capture correlates with changes in fluid im-
255 pulse, influenced by circulation and vortex core ve-
256 locities. This unsteady flow situation is consistent
257 with pressure data from *Microvelia* and the physical
258 model (Figure 4.a,b), where optimal stroke timing
259 increases entrainment and thrust, demonstrating en-
260 hanced thrust through vortex re-energization.

261 Conclusions and Outlook

262 Our findings illuminate vortical interactions within
263 the neuston, the dynamic water-air boundary that
264 supports diverse life forms. *Microvelia*, among one
265 of the smallest and fastest epineustonic animals, cre-
266 ate nearly 2D vortices due to their minute size and
267 weight, forming shallow dimples on the water sur-
268 face [45, 46]. Their alternating tripod gait, inherited
269 from terrestrial ancestors, enables versatile movement
270 across water, land, and duckweed [17, 32, 47].

271 Although less energy-efficient than rowing gait, the
272 alternatig tripod gait excels in amphibious locomo-
273 tion, providing *Microvelia* with a strategic advantage
274 in foraging and evading predators [16, 24, 46]. This
275 gait and leg proportions facilitate epineuston vortex
276 recapture combination, where hind leg tarsi boost the
277 circulation and fluid entrainment of vortices shed by
278 middle legs. This re-energization creates a positive
279 pressure at the hind tarsi, acting as a virtual wall
280 that augments thrust [46]. In other genera such as
281 *Mesovelia*, longer middle legs prevent effective vortex
282 recapture, underscoring the critical role of leg size in
283 this mechanism (Figure S7).

284 Epineuston vortex interactions hinge on the spatial
285 location, angle of attack, and trajectory of hind leg
286 tarsi, determining whether vortices are re-energized,
287 annihilated, or minimally interacted with. Our
288 robotic arm physical model and CFD simulations re-
289 inforce the impact of inter-stroke intervals on these
290 interactions. The data indicate that optimal timing

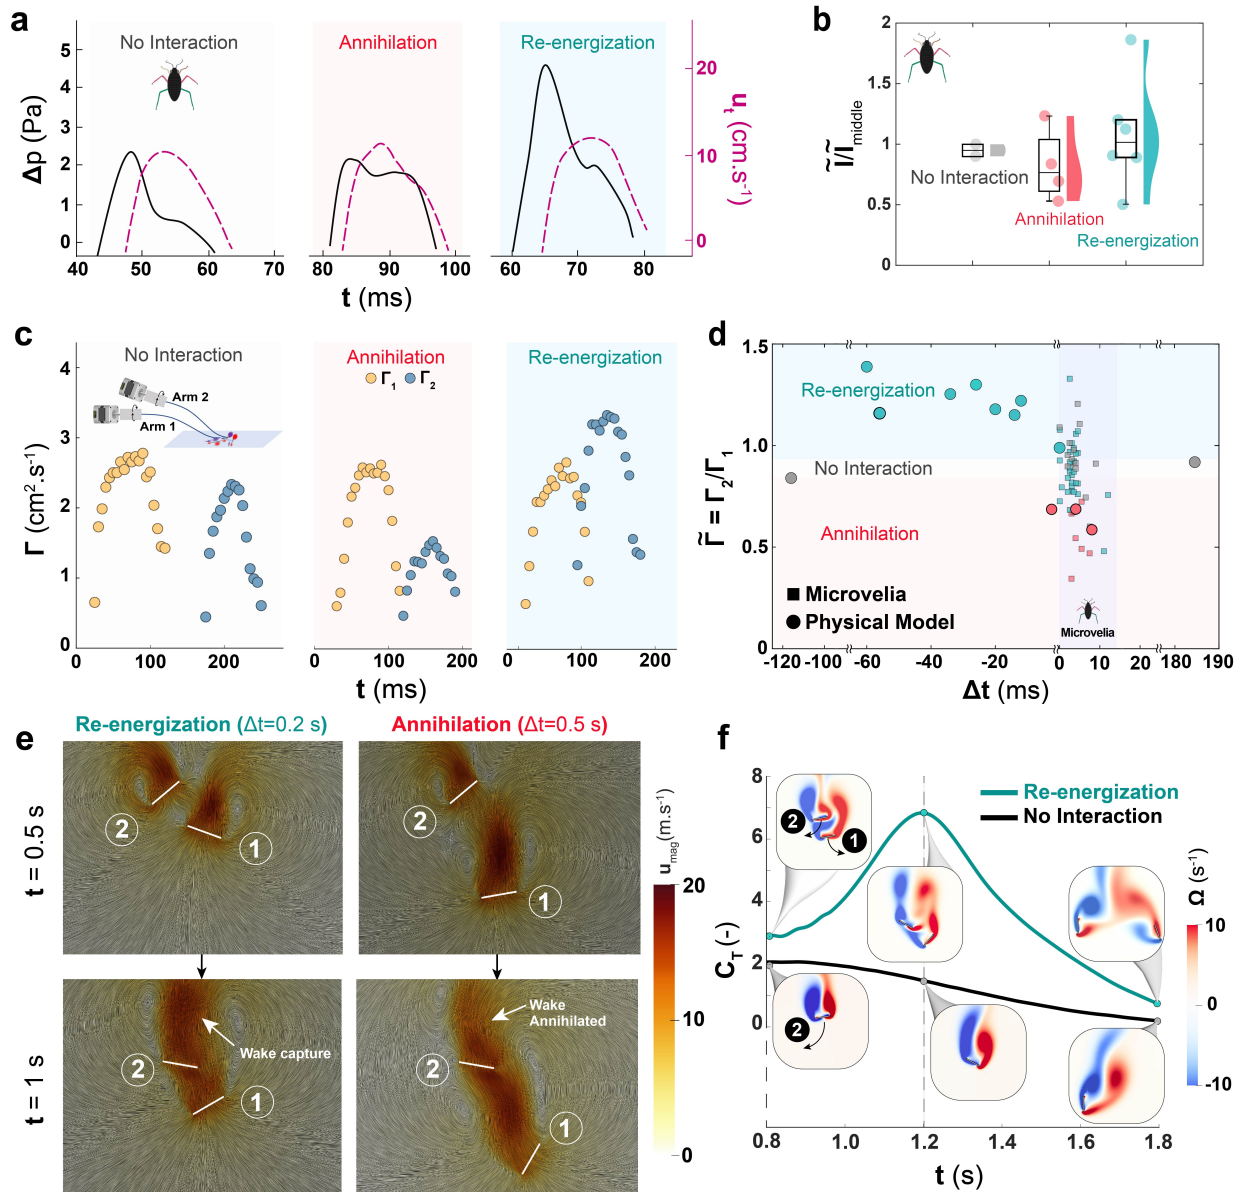

Figure 4: Quantifying epineuston vortical interactions through physical models and CFD analysis. (a) Temporal evolution of relative pressure (ΔP) and tarsal speed (v_t) of the hind leg. No-interaction and annihilation cases represent the the hind left tarsi, while re-energization corresponds to the hind right tarsi. (b) Normalized impulse for different types of vortical interaction. The semi-violin plot shows the distribution of the data as a jitter plot, while the box and whisker plot represent the median and the four quartiles (25%, 50%, 75%, and 100%) for *Microvelia* specimens ($N=3$) and strokes ($n = 12$). (c) Temporal evolution of the vortex circulation Γ for each robotic arm with varying Δt showing different vortical interaction outcomes. (d) Regime map of normalized circulation (Γ_2/Γ_1) for varying Δt . Γ_1 and Γ_2 represent peak circulation from the middle leg (or first arm) and hind leg (or second arm), respectively ($N=7$, $n=53$). (e) CFD results showing effect of the time interval between plate movements (in quiescent fluid) on vortical interactions depicted by velocity magnitude contours. The second plate starts moving at $t = 0$ s with $\Delta t = 0.2$ s for re-energization and $\Delta t = 0.5$ s for annihilation. In snapshots at $t = 1$ s, arrows indicates the enhanced and reduced velocity field due to wake capture and wake annihilation respectively. (f) Temporal evolution of the coefficient of thrust (C_T) of the second plate for re-energization and no interaction. Snapshots show the interaction's impact on instantaneous vorticity fields at different times.

291 and positioning of leg strokes enhance thrust through
292 vortex re-energization, offering new insights into fluid
293 dynamics at the air-water interface. Exploring mi-
294 crovelia juvenile nymphs, multiphase CFD simula-
295 tions, and turbulent flow regimes will further deepen
296 our understanding of these interactions.

297 By uncovering the physics behind the vortical re-
298 capture in *Microvelia*, we extend similar mechanisms
299 observed in jellyfish and fruit flies to the neuston [5,
300 11, 12]. Epineuston vortex recapture could inspire
301 the development of efficient water-skating devices and
302 amphibious robots, enhancing our exploration of the
303 oceanic and freshwater neuston niches [26].
