# Abstract

Making hand movements in response to visual cues is common in daily life. It has been well known that this process activates multiple areas in the brain, but how these neural activations progress across space and time remains largely unknown. Taking advantage of intracranial electroencephalographic (iEEG) recordings using depth and subdural electrodes from 36 human subjects using the same task, we applied single-trial and cross-trial analyses to high-frequency iEEG activity. The results show that the neural activation was widely distributed across the human brain both within and on the surface of the brain, and focused specifically on certain areas in the parietal, frontal, and occipital lobes, where parietal lobes present significant left lateralization on the activation. We also demonstrate temporal differences across these brain regions. Finally, we evaluated the degree to which the timing of activity within these regions was related to sensory or motor function. The findings of this study promote the understanding of task-related neural processing of the human brain, and may provide important insights for translational applications.

Key words: intracranial electroencephalography, SEEG/ECoG, neural activation, spatio-temporal evolution, hand movement

# 1 Introduction

 Imagine stopping the car in response to a red light. Producing such motor actions in response to visual cues is one of the most [f](#page-13-0)undamental and essential functions in human daily life [\(Corbetta](#page-13-0) [and Shulman, 2002;](#page-13-0) [Botvinick and Cohen, 2014;](#page-12-0) [Ledberg et al.,](#page-14-0) [2007\)](#page-14-0). Despite being a simple behavior, the spatio-temporal neural dynamics underlying such visuomotor processing are rather complex and have remained relatively unexplored [\(Pesaran et al.,](#page-14-1) [2018;](#page-14-1) [Bressler and Menon, 2010;](#page-12-1) [Reichenbach et al., 2014\)](#page-15-0). Therefore, uncovering the corresponding mechanisms of brain dynamics over spatial and temporal scales during this process is of critical importance for both human neuroscience and potential translational applications [\(Miller et al., 2014;](#page-14-2) [Kopell et al., 2014;](#page-13-1) [Hauschild et al., 2012;](#page-13-2) [Franklin and Wolpert, 2011;](#page-13-3) [Coon and](#page-13-4) <sup>14</sup> [Schalk, 2016;](#page-13-4) [Coon et al., 2016\)](#page-13-5). 15

Addressing this question is greatly impeded by the lack <sup>16</sup> of a neuroimaging technique that can capture neural activity <sup>17</sup> with high spatial and temporal resolution across the brain. 18 Functional magnetic resonance imaging (fMRI) has excellent 19 spatial resolution and can identify functionally active networks 20 across the whole brain regions [\(Zalesky et al., 2014;](#page-15-1) [Bassett et al.,](#page-12-2) <sup>21</sup> [2011;](#page-12-2) [Oosterhof et al., 2012;](#page-14-3) [Floyer-Lea and Matthews, 2004\)](#page-13-6). <sup>22</sup> However, fMRI is also inherently constrained by its low temporal <sup>23</sup> resolution since blood-oxygen-level dependent (BOLD) signals are <sup>24</sup> unable to capture fast-changing neural activities across different 25 brain sites. Other non-invasive electrophysiologic approaches such <sup>26</sup> as electroencephalography (EEG) and magnetoencephalography <sup>27</sup> (MEG) provide high temporal resolution covering the entire <sup>28</sup>  surface of the brain and have been used for investigation of large-scale brain networks at the millisecond-level [\(Brovelli et al.,](#page-13-7) [2015;](#page-13-7) [Sakkalis, 2011;](#page-15-2) [Cohen, 2017;](#page-13-8) [Jerbi et al., 2007;](#page-13-9) [Thurer](#page-15-3) [et al., 2016;](#page-15-3) [de Pasquale et al., 2010\)](#page-14-4). However, these two techniques are still insufficient for characterizing the progression of neuronal activity in rich detail because of the limitations in spatial resolution (typically centimeter scales) [\(Lebedev and Nicolelis,](#page-14-5) [2017;](#page-14-5) [Cohen, 1968\)](#page-13-10). Invasive technologies such as single-unit or multi-unit recordings acquired using implanted microelectrode arrays can capture spatially and temporally detailed images of activity near the recording sites. Many studies have used single- or multi-unit recordings to probe the neural dynamics under [d](#page-14-6)ifferent visuomotor tasks within a specific brain region [\(Rao and](#page-14-6) [Donoghue, 2014;](#page-14-6) [Schall, 2015;](#page-15-4) [Perel et al., 2015;](#page-14-7) [Andersen and](#page-12-3) [Cui, 2009;](#page-12-3) [Ledberg et al., 2007;](#page-14-0) [Kuang et al., 2016\)](#page-13-11). However, this technique cannot readily simultaneously investigate the neural dynamics across larger cortical areas or subcortical regions.

 Intracranial electroencephalographic (iEEG) recordings using subdural electrodes (electrocorticography, ECoG) or depth electrodes (stereo-electroencephalograhy, SEEG) in patients with tumor or intractable epilepsy for pre-surgical monitoring sample neural activity at millimeter-spatial and millisecond-temporal resolution across relatively broad brain areas, and hence provide a tool that can be useful for both scientific research and translational [a](#page-14-9)pplications [\(Parvizi and Kastner, 2018;](#page-14-8) [Engel et al., 2005;](#page-13-12) [Miller](#page-14-9) [et al., 2010;](#page-14-9) [Schalk et al., 2017a;](#page-15-5) [Bartolomei et al., 2018;](#page-12-4) [Bonini](#page-12-5) [et al., 2014;](#page-12-5) [Li et al., 2022\)](#page-14-10). In addition, iEEG recordings have the ability to capture broadband gamma activity (i.e., activity at >60 Hz), which has been demonstrated to be a reliable indicator of local [n](#page-14-12)euronal activity [\(Nir et al., 2007;](#page-14-11) [Buzsaki et al., 2012;](#page-13-13) [Manning](#page-14-12) [et al., 2009;](#page-14-12) [Cardin et al., 2009;](#page-13-14) [Ray et al., 2008;](#page-14-13) [Lachaux et al.,](#page-14-14) [2012\)](#page-14-14). With these characteristics, iEEG broadband signals can chart the spatio-temporal evolution of the underlying task-related [n](#page-15-6)eurons among the recording sites [\(Miller et al., 2014;](#page-14-2) [Takahashi](#page-15-6) [et al., 2015;](#page-15-6) [Coon and Schalk, 2016;](#page-13-4) [Pei et al., 2011;](#page-14-15) [Banerjee](#page-12-6) [et al., 2010\)](#page-12-6). While iEEG recordings inevitably have the limitation of sparse sampling, this limitation can be mitigated by recording across different human subjects using the same task. Thus, group analyses with iEEG recordings can provide information about general features of the large-scale spatio-temporal dynamics of the human brain during the common behaviors [\(Thiery et al., 2020;](#page-15-7) [Betzel et al., 2019;](#page-12-7) [Arnal et al., 2019;](#page-12-8) [Avanzini et al., 2016;](#page-12-9) [Schalk](#page-15-8) [et al., 2017b;](#page-15-8) [Conner et al., 2014;](#page-13-15) [Posner et al., 2014;](#page-14-16) [Keller et al.,](#page-13-16) [2014;](#page-13-16) [Wander et al., 2013;](#page-15-9) [Lachaux et al., 2003\)](#page-14-17).

 In this work, we acquired iEEG recordings from a relatively large number of human subjects with the same visually-cued motor task. Using these recordings, we answered critical questions about the spatio-temporal neural dynamics of the human brain during the task using methodologies that embrace the capabilities of the broadband gamma response of iEEG signals, both at the level of single trials as well as across trials. Specifically, in our paper, we first uncover the brain regions involved during a visuomotor process, quantify their degree of involvement in the task, and then determine the large-scale temporal activation sequence of different task-processing brain regions using a single-trial-based method. Finally, we document the possible functions of these brain regions, e.g., neuronal representations as being primarily 'sensory' or 'motor' within the entire processing chain through the respective activation temporal profile across trials.

#### Subjects, Data Recordings, and Tasks 89

We acquired iEEG data from 36 right-handed subjects (14 female, 90 22 male, age:  $26.0 \pm 6.2$  years). The subjects were patients with 91 intractable epilepsy who had depth (SEEG) or subdural (ECoG) <sup>92</sup> electrodes implanted for pre-surgical assessment of their seizure 93 focus. 34 patients had SEEG electrodes and 2 patients had ECoG <sup>94</sup> electrodes (see also Supplementary Table 1). All configurations 95 of implantation were determined by clinical needs rather than <sup>96</sup> the needs of research. SEEG and ECoG signals were acquired <sup>97</sup> during the monitoring period in the hospital using a clinical <sup>98</sup> recording system (EEG-1200C, Nihon Kohden, Irvine, CA) with <sup>99</sup> sampling rates of 500-2000 Hz. All subjects participated in a <sup>100</sup> visually-cued finger and arm movements task that was previously <sup>101</sup> described in [Li et al.](#page-14-18) [\(2018\)](#page-14-18). In brief, in each trial, subjects were 102 instructed by a visual stimulus presented on an LCD screen to <sup>103</sup> rest for 4 s without any movement, before a visual cue appeared 104 for 1 s to inform the subjects of an upcoming movement. After 105 that, a picture of a gesture appeared for 5 s, and subjects <sup>106</sup> were instructed to repetitively perform that gesture as soon as 107 possible until the disappearance of the picture. For each subject, <sup>108</sup> we collected 100 trials in total (∼16.67 mins, Supplementary <sup>109</sup> Fig. 1). During the experiment, the subjects used the hand 110  $(L=15, R=21)$  contralateral to the hemisphere with the majority of 111 the implanted electrodes. Electromyographic (EMG) signals were 112 recorded simultaneously (using the same amplifier and the same 113 sampling rate as the iEEG signals) from the extensor carpi radialis 114 muscle of the moving hand using two surface EMG electrodes. All 115 recorded electrophysiological data exhibiting pathological activity <sup>116</sup> were discarded from the present study. This study was approved 117 by the Ethics Committee of Huashan Hospital (Shanghai, China, <sup>118</sup> Approval ID: KY2019518) and was conducted in accordance with 119 the Declaration of Helsinki. All subjects gave informed consent for <sup>120</sup> this study. 121

The 36 subjects had a total of 4986 electrodes implanted; the <sup>123</sup> 34 SEEG subjects had a total of 4536 depth electrode contacts <sup>124</sup> implanted  $(133\pm40 \text{ contacts and } 10\pm3 \text{ electrode shaft on average}, \quad 125$ 11/9 subjects were implanted on the left/right hemisphere, <sup>126</sup> respectively, and 14 subjects were implanted bilaterally, see <sup>127</sup> Supplementary Table 1) and 2 ECoG subjects had a total of 450 128 subdural electrodes implanted  $(242/208$  in the left hemisphere). 129 Each SEEG electrode shaft was 0.8 mm in diameter and contained 130 8-16 contacts along the shaft; each contact was 2 mm long with <sup>131</sup> a 3.5 mm center-to-center spacing distance (Huake Hengsheng <sup>132</sup> Medical Corp., Beijing, CN). ECoG electrodes were 1.8 mm in 133 diameter with a 5 mm inter-electrode distance (Huake Hengsheng <sup>134</sup> Medical Corp., Beijing, CN). The location of all electrodes was <sup>135</sup> identified in each individual brain model using pre-implant MRI <sup>136</sup> and post-implant CT images [\(Li et al., 2019\)](#page-14-19). In addition, <sup>137</sup> we identified the anatomical location for each electrode using <sup>138</sup> Freesurfer's cortical parcellation and subcortical segmentation <sup>139</sup> under the Desikan-Killiany atlas [\(Desikan et al., 2006;](#page-13-17) [Fischl et al.,](#page-13-18) <sup>140</sup> [2002\)](#page-13-18). Moreover, SEEG electrodes located at superficial white <sup>141</sup> matter (i.e., the white matter that is closest to the layer of divided 142 cortical regions, e.g., pre/post-central white matter, up to 36 <sup>143</sup> regions) were identified as well using white matter segmentation <sup>144</sup> results from the Freesurfer [\(Salat et al., 2009;](#page-15-10) [Guevara et al., 2017;](#page-13-19) <sup>145</sup> [Oishi et al., 2008\)](#page-14-20) and were used in this work, based on the findings <sup>146</sup>  that white matter also presented similar neural activation with the gray matter under tasks [\(Ding et al., 2018;](#page-13-20) [Li et al., 2021,](#page-14-21) [2022\)](#page-14-10). The electrodes from the same anatomical regions (both cortical and subcortical) were identified and grouped for further analysis. Finally, we mapped the electrodes from each subject to a standard brain model (Montreal Neurological Institute (MNI)) for subsequent group analyses [\(Collins et al., 1994\)](#page-13-21). All localization [p](#page-14-19)rocedures were incorporated into the iEEGview toolbox [\(Li](#page-14-19) [et al., 2019\)](#page-14-19). The location and related anatomical information of electrodes from all 36 subjects were illustrated in Supplementary <sup>157</sup> Fig. 2.

#### 158 Data Pre-Processing

 For all the obtained recordings in each subject, we first removed the channels whose line noise power at 50 Hz was larger than a subject-specific cut-off threshold from further analysis. 162 Specifically, the line noise power for each channel  $(LN)$  was computed as the mean value of absolute line noise signals (filtered signals using a  $2^{nd}$  order IIR peak filter at 50 Hz, *iirpeak* in MATLAB) across the entire recording session and the cut-off 166 threshold  $(T_{cutoff})$  for each subject was defined as the median line noise power across all channels within the subject plus 10 times 168 of their median absolute deviation  $(T_{cutoff} = median(LN_{all}) +$ 169 10 ·  $mad(LN_{all})$ ). This procedure eliminated 48 (0.96%) out of the total of 4986 channels from further analyses (see also Supplementary Table 1). In the second step, all signals were subjected to a 50 Hz comb notch filter to remove line noise and its harmonics (iircomb in MATLAB with a quality (Q) factor of 25). We then high-pass filtered the signals at 0.5 Hz using a  $6^{th}$  order Butterworth filter to remove slow signal drifts and re-referenced the filtered signals using a Laplacian montage to improve the signal quality [\(Li et al., 2018;](#page-14-18) [Liu et al., 2021\)](#page-14-22). Finally, we extracted broadband gamma power (BGP) from the processed signals [\(Voytek et al., 2015;](#page-15-11) [Ries et al., 2017\)](#page-15-12). In detail, we band-pass filtered the re-referenced signals between 60-140 Hz 181 using a  $6^{th}$  order Butterworth filter. We then applied the Hilbert 182 transform  $(Hb)$  of the filtered signal  $s(t)$  to get the analytic signal <sup>183</sup> (Eq. [1\)](#page-3-0).

$$
^{184}
$$

<span id="page-3-0"></span>
$$
s(t) + iHb[(s(t))] = a(t)e^{i\varphi(t)} \tag{1}
$$

185 where the  $a(t)$  and  $\varphi(t)$  were the instantaneous amplitude and <sup>186</sup> instantaneous phase of the analytic signals respectively.

<sup>187</sup> The BGP was then computed as the square of the instantaneous <sup>188</sup> amplitude, and the resulting signals were resampled to 200 Hz to <sup>189</sup> improve computational efficiency. The results of this procedure 190 were subjected to all subsequent analyses (termed as  $G(t)$  in this 191 work,  $G(t) = |a(t)|^2$ .

 For the purpose of subsequent analyses, EMG activity was processed separately to determine the onset of the subject's movement during the task. To do this, we first band-pass filtered 195 (55-145 Hz,  $6^{th}$  order Butterworth filter) the two EMG channels to extract the fast-changing neural activity and subtracted the results from each other. Then, for each trial, a joint detection algorithm was applied to identify the onset time of EMG activity. Specifically, we detected the first time point where absolute EMG activity exceeded 1.5 times the average absolute value of EMG activity in the motion period [\(Li et al., 2018\)](#page-14-18). Additionally, we also detected the time point when the absolute value of EMG activity first time exceeded an adaptive threshold using the envelope of the processed EMG activity [\(Sedghamiz, 2018\)](#page-15-13). The EMG onset time in each trial was defined as the earlier time point between these <sup>205</sup> two detections. As a result, the median EMG onset time across all <sup>206</sup> trials and all subjects was 565 ms. <sup>207</sup>

For each trial, three time segments of interest that carried <sup>208</sup> the most representative neural information (i.e., baseline period, <sup>209</sup> task period, and detection period) were defined and adopted in <sup>210</sup> further analysis. Specifically, the baseline period in each trial was <sup>211</sup> defined as the 1 s time interval at the end of the rest period <sup>212</sup> before the onset of the cue, the task period was defined as the <sup>213</sup> first 2 s of the 5-s motion period, and the detection period was <sup>214</sup> defined as the time interval from the appearance of movement <sup>215</sup> cue to 400 ms after EMG activity onset. The task period was <sup>216</sup> used here for more robust detection of the channels presenting 217 task-related modulations (described below). The detection period <sup>218</sup> was selected for the neural activation detection (described below) 219 since it could cover the first complete visuomotor process at the <sup>220</sup> same time minimize the interference from the following continuous 221 movements (e.g., the second movement). 222

#### Detection of Task-related Channels 223

For each subject, we identified the channels that changed their <sup>224</sup> broadband gamma activity significantly during the task compared <sup>225</sup> to baseline using the same method introduced in our previous <sup>226</sup> work [\(Li et al., 2018\)](#page-14-18). In brief, we first computed the median <sup>227</sup> values of BGP  $(G(t))$  for the baseline and task periods in each 228 trial, respectively (100 trials for each period), and correlated <sup>229</sup> those 200 power values with the baseline/task labels (Spearman <sup>230</sup> correlation coefficient), thus producing a correlation value  $(r)$  231 representing the observed relationship of power changes with the <sup>232</sup> movement states. We then performed a randomized permutation <sup>233</sup> test with 2500 repeats to generate a Gaussian distribution of <sup>234</sup> 2500 surrogate  $r$  values, where the task/baseline labels within 235 each channel were randomly shuffled in each repeat and the <sup>236</sup> corresponding r value was computed [\(Schalk et al., 2007\)](#page-15-14). The  $237$ computed channel was considered statistically significant when the <sup>238</sup> p value (Bonferroni corrected) of the observed r was within the 1st  $239$ percentile of the Gaussian distribution (Supplementary Fig. 3). <sup>240</sup> This process identified 1149 (23.0%) task-related channels from <sup>241</sup> all 4986 electrodes. Additionally, using the  $p$  value derived in the 242 permutation test, we also computed the correlation value between <sup>243</sup> each channel and the task  $(-log_{10}(p))$ , [Schalk et al.](#page-15-14) [\(2007\)](#page-15-14)). These 244 task-related channels were distributed across 31 different regions of <sup>245</sup> interest (ROIs, Fig. [1d](#page-6-0)). Finally, we obtained two ratios of task- <sup>246</sup> related neural activation for each of these ROIs by dividing the <sup>247</sup> number of task-related channels with either the total number of <sup>248</sup> channels in the same anatomical region or the total number of all <sup>249</sup> task-related channels from all subjects. <sup>250</sup>

#### Detection of Neural Activation Time

The neural processing underpinning a visuomotor task is generally 252 [v](#page-13-7)ery fast and may last for hundreds of milliseconds [\(Brovelli](#page-13-7) <sup>253</sup> [et al., 2015;](#page-13-7) [Rao and Donoghue, 2014\)](#page-14-6). Therefore, uncovering the <sup>254</sup> spatio-temporal neural dynamics underlying such behavior tasks <sup>255</sup> asks for a high temporal resolution detection algorithm that can <sup>256</sup> accurately capture the neural population activity in a short time <sup>257</sup> duration. Detection using neural activity in each single trial has <sup>258</sup> been proven to have higher temporal precision than using trial- <sup>259</sup> [a](#page-13-5)veraged signals [\(Coon and Schalk, 2016;](#page-13-4) [Perel et al., 2015;](#page-14-7) [Coon](#page-13-5) <sup>260</sup> [et al., 2016\)](#page-13-5) and its importance in probing brain activities has <sup>261</sup> been addressed previously [\(Rey et al., 2015\)](#page-15-15). <sup>262</sup>

 In this work, we captured the neural activation time for each task-related channel using a single-trial detection algorithm that was described in [Paraskevopoulou et al.](#page-14-23) [\(2021\)](#page-14-23). In brief, the algorithm finds in each single trial the first peak exceeding a channel- and trial-specific amplitude threshold within the detection period. Specifically, the detection consisted of several steps. In the  $1^{st}$  step, we z-scored the BGP activities in each trial for each identified task-related channel (described above). In the  $2^{nd}$  step, we applied the normalized BGP of each trial with a non-272 linear energy operator (NEO,  $\psi$ ) to boost the signal-to-noise ratio (SNR) and facilitate the detection (Eq. [2,](#page-4-0) [Koutsos et al.](#page-13-22) [\(2013\)](#page-13-22); [Maragos et al.](#page-14-24) [\(1993\)](#page-14-24)). In the  $3^{rd}$  step, using the transformed 275 BGP  $(\psi[G(t)])$  of each channel in the baseline and detection period (Methods: Data Pre-processing), we then determined a channel-specific threshold using an optimization procedure (Eq. [3\)](#page-4-1). More specifically, this procedure updated the threshold value from 2 to 8 with 0.1 increments, and then selected the amplitude threshold maximizing the difference between the number of peaks exceeding the assigned threshold in the detection period and the baseline period. However, considering that the amplitude of  $\psi[G(t)]$  during the task in some active trials may not exceed such a channel-specific threshold, we additionally determined for these trials with undefined detections a trial-specific threshold by implementing another optimization procedure in the  $4^{th}$  step. The procedure varied the threshold value between 2 and the identified channel-specific threshold with 0.1 increments, and then selected the threshold that maximized the difference (indicated by the smallest  $p$  value, Wilcoxon rank sum test) between the amplitude distribution of time points comparing with the threshold (represented by logical vectors, e.g., 1 if the amplitude larger than the threshold, else 0) in the detection period and the 294 baseline period. In case the maximal amplitude of  $\psi[G(t)]$  during the task in this trial exceeded the channel-specific threshold, the trial-specific threshold was the same as the identified channel-level threshold  $(3^{rd}$  step). Specially, if the number of  $\psi[G(t)]$  exceeding the threshold from the baseline period was more than that from the detection period in a trial, no neural activation detection was defined in that location for that trial. With this channel- and trial-specific amplitude threshold, this procedure produced at most one neural activation detection in each trial and for each channel (Supplementary Fig. 3).

<span id="page-4-0"></span>
$$
\psi[G(t)] = \left(\frac{dG(t)}{dt}\right)^2 - G(t) \cdot \left(\frac{d^2G(t)}{dt^2}\right) \tag{2}
$$

<span id="page-4-1"></span>
$$
\arg \max_{z=2,2,1,...,8} f(\psi_z) := dt(\psi_z) - db(\psi_z)
$$
 (3)

where  $\psi_z$  is the threshold,  $dt(\psi_z)$  and  $db(\psi_z)$  are the numbers <sup>307</sup> of detection in the detection and baseline period, respectively.

 For each task-related channel, the time of detected neural activation was then normalized within each trial (e.g., divided by the EMG onset in the same trial) to facilitate further group analyses across subjects. After that, we fit the normalized activation time of each channel with a Gaussian model (Fig. [2c](#page-7-0), f, i, and l, Eq. [4\)](#page-4-2), producing for each channel a mean activation time value  $(\mu)$  and a standard deviation of neural activation ( $\sigma$ ) separately (Fig. [2,](#page-7-0) see also Supplementary Fig. 3 for the illustration of data processing in this section).

<span id="page-4-2"></span>
$$
f(x) = a * e^{-\frac{(x-u)^2}{\sigma^2}} \tag{4}
$$

where  $\mu$  and  $\sigma$  are the mean value and the standard deviation 318 of the random variable  $X$ ,  $a$  indicates the amplitude of the fitting  $319$ model  $(f(x))$ .

With these fitting results, we further excluded the noisy task- <sup>321</sup> related channels from the following analysis. Specifically, we <sup>322</sup> removed from the successful fittings whose  $\sigma$  value was larger 323 than a specific threshold, where the threshold was set as 0.80 <sup>324</sup> after manual inspection across all channels. The operation was <sup>325</sup> based on the assumption that when the task was consistent, the <sup>326</sup> neural activation of task-related channels should be also relatively 327 stable (as measured by  $\sigma$ , Eq. [4\)](#page-4-2). This process identified 564 328 channels with valid detection across all task-related channels; <sup>329</sup> we labeled these channels as informative channels in this work. <sup>330</sup> Finally, the informative channels from the same anatomical region 331 (see Methods: Electrode Localization) were grouped separately. <sup>332</sup> This step identified 27 regions from 31 different task-related <sup>333</sup> ROIs. Using these informative channels, we computed the average 334 activation time for each ROI group. The average activation time <sup>335</sup> for each ROI was calculated as the real estimated time lag after <sup>336</sup> stimulus onset for illustration purposes. To do that, we multiplied 337 the average normalized activation time of each ROI by the average 338 EMG onset (565 ms). During the calculation, only the ROIs whose 339 number of samples exceeded the median sample numbers (e.g., <sup>340</sup> n=10) of all ROIs were used in order to make the analysis more <sup>341</sup> robust. This process identified 16 of all 27 ROIs. We termed these <sup>342</sup> refined ROIs as informative ROIs  $(n=16)$  and used them for the 343 subsequent analysis.  $344$ 

Moreover, we also implemented another brain segmentation <sup>345</sup> [m](#page-13-23)ethod which divided the brain into 7 main areas [\(Del Percio](#page-13-23) <sup>346</sup> [et al., 2019\)](#page-13-23), including the occipital, parietal, frontal, temporal <sup>347</sup> and central area, insula cortex, and limbic system (Supplementary <sup>348</sup> Table 2). This operation produced a more macro assessment of the <sup>349</sup> spatio-temporal evolution of the neural activities within the human 350 brain under the task. Using the same criteria (e.g., the number of <sup>351</sup> samples for each area should be larger than 10), we identified  $6\$  352 of such 7 areas and computed the corresponding mean activation <sup>353</sup> time for each area. 354

### Activation Pattern Evaluation 355

The single-trial detection method makes it possible to evaluate <sup>356</sup> the activation pattern (that is, neural activation temporal profile 357 across trials) for each informative channel. In this section, we <sup>358</sup> first investigated whether there is a certain relationship between <sup>359</sup> the activation time of informative channels and their activation <sup>360</sup> pattern. Then, we evaluated for each informative channel whether 361 the timing of neural activation suggested that this channel <sup>362</sup> was more related to sensory processing or motor response. <sup>363</sup> Different analyses were performed respectively to answer these two <sup>364</sup>

For the first question, we determined the correlation of each <sup>366</sup> informative channel with the response or stimulus by separately <sup>367</sup> correlating (using Pearson's correlation) the raw detected neural <sup>368</sup> activation of each informative channel across all trials with either <sup>369</sup> the EMG onsets or stimulus onsets across all trials (the 'response' <sup>370</sup> here indicates the appearance of motor behaviors and is measured 371 with EMG onsets). This process generated two correlation values 372 (i.e., with response or stimulus) for each informative channel. <sup>373</sup> Together with the average normalized activation time of each <sup>374</sup>

questions. 365

 informative channel, we separately analyzed the relationship between each two of these three measurements (i.e., one activation time and two correlation values) for all informative channels with a linear regression model.

<sup>379</sup> For the second question, we conducted two additional <sup>380</sup> computations:

 1) We checked how the EMG onsets from single trials were correlated with the detected neural activation of different informative channels. The basic notion is that the neural activation of the channels that are related to the motor response should correlate with the EMG onsets. To investigate this, we implemented a random permutation procedure using the detected neural activation for each channel. In brief, we first computed Pearson's correlation r for the detected neural activation of each channel and the EMG onsets from all trials. We then randomly shuffled the sequence of detected neural activation and computed the correlation with the EMG onsets for each repetition. This procedure was repeated 2500 times, thus, generating a distribution of surrogate r value and the subsequent p value for the observed r (Supplementary Fig. 3). The channel whose p value was smaller 395 than the significance level  $(p < 0.05$  after Bonferroni correction of channel numbers) was identified as response-locked channels (see Fig. [2h](#page-7-0) and [2k](#page-7-0) as examples);

 2) For the same channel, we then conducted another analysis to determine whether this channel was related to sensory processing (termed as the stimulus-locked channel in this work). Our assumption was that detected neural activation of the channels relating to the sensory processing should be time-locked to the stimulus onsets and have small variability on the time of neural activation across trials irrespective of the EMG onsets. To identify stimulus-locked channels, for each informative channel, we 406 computed the standard deviation  $(v)$  of detected neural activation from a certain number of trials (e.g., 60), which were randomly selected from all trials. This setting was implemented to attenuate the influence of some noisy trials. Then, this process was repeated 410 for  $10^6$  times and the average standard deviation  $(\bar{v})$  was obtained for each channel (Supplementary Fig. 3). After this, we then determined a threshold value to filter out the channels with large variations of detected neural activation. To do this, we concatenated all the detected neural activation from all valid channels together and conducted the same random selection process as the single channel to obtain an overall distribution for v. The threshold was then identified as the left boundary of  $95\%$ 418 confidence interval from the distribution. The channel whose  $\bar{v}$  was smaller than the threshold was identified as the stimulus-locked channel in this work (see Fig. [2b](#page-7-0) and [2e](#page-7-0) as examples).

 The identified stimulus-locked and response-locked channels were then grouped based on their anatomical locations (16 ROIs, described above). For each ROI, the ratio of stimulus-locked and response-locked channels was calculated respectively by dividing either the number of identified stimulus-locked or the number of identified response-locked channels by the number of informative channels within that group.

#### <sup>428</sup> Results

# 429 The Distribution of Neural Activation During The Task

<sup>430</sup> The recording electrodes from all subjects are distributed widely <sup>431</sup> within the entire brain (Supplementary Fig. 2). Among these  $432$  electrodes, we found that  $1149$   $(23.0\%)$  channels showed significant BGP changes during the task, and these channels are distributed 433 across multiple regions (n=31, Fig. [1d](#page-6-0), Supplementary Table <sup>434</sup> 2), covering cortical regions (central, frontal, parietal, occipital, <sup>435</sup> temporal area) and also deeper brain structures (e.g., insula cortex <sup>436</sup> (13.6% insula electrodes get activated) and limbic systems (such <sup>437</sup> as 36% electrodes in parahippocampus gyrus and 6.1% electrodes <sup>438</sup> in hippocampus)). Among these regions, several ones including <sup>439</sup> the precentral cortex (PRC,  $n=213, 18.5\%$ ), supramarginal gyrus  $440$  $(SMG, n=115, 10.0\%)$ , postcentral cortex (i.e., gyrus and sulcus)  $441$  $(POC, n=112, 9.7\%)$ , superior parietal cortex  $(SPC, n=105, 442)$ 9.1%), superior frontal gyrus (SFG,  $n=83, 7.2\%$ ) and insula cortex 443 (ISC, n=51, 4.4%), lateral occipital cortex  $(LOC, n=46, 4.0\%)$  444 occupied over 60% of all task-related channels (Fig. [1d](#page-6-0)). <sup>445</sup>

Overall, within each main brain region (Fig. [1d](#page-6-0)), several <sup>446</sup> regions, including the central area (e.g., 57.9% of electrodes in <sup>447</sup> PRC and  $52.6\%$  of electrodes in POC and  $51.8\%$  of electrodes 448 in paracentral cortex (PAC) were activated), parietal area (e.g., <sup>449</sup> 57.7% of electrodes in SPC and 44.1% of electrodes in SMG were <sup>450</sup> activated), occipital area (e.g., 62.2% of electrodes in LOC, 57.6% <sup>451</sup>  $(n=19)$  of electrodes in pericalcarine cortex  $(PCC)$  and  $29.0\%$  452  $(n=18)$  of electrodes in lingual gyrus  $(LGG)$  were activated), and 453 frontal area (e.g., 33.9% of electrodes in SFG were activated), <sup>454</sup> correlated substantially with the task. Moreover, this phenomenon <sup>455</sup> was further confirmed by the average correlation value of each <sup>456</sup> region with the task (Fig. [1f](#page-6-0)), where the average correlation <sup>457</sup> value, listed in order from high to low, resulted for the central <sup>458</sup> area (n=354, 15.78±0.48 (mean±s.e.)), occipital area (n=87, <sup>459</sup> 13.72±0.86), parietal area (n=279, 12.05±0.40), frontal area <sup>460</sup>  $(n=187, 11.30\pm0.53)$ , insula cortex  $(n=55, 9.29\pm0.71)$ , temporal  $461$ area (n=108, 9.15 $\pm$ 0.44), and limbic system (n=51, 7.77 $\pm$ 0.60), 462 respectively. In detail, the top five regions that had the highest <sup>463</sup> correlation value were LOC  $(17.20 \pm 1.24)$ , POC  $(16.89 \pm 0.88)$ ,  $464$ PRC  $(15.60\pm0.60)$ , SFG  $(14.64\pm0.98)$ , SPC  $(13.22\pm0.71)$  in order,  $465$ where the correlation in LOC, POC and PRC were significantly  $466$  $(p < 0.05$ , Wilcoxon rank sum test) higher than SPC and the  $467$ value in SPC was significantly  $(p < 0.05)$  higher than that in pars 468 opercularis (parsOPE, 10.03±1.03). The correlation distribution of <sup>469</sup> each electrode within the standard brain were shown in Fig. [1a](#page-6-0)-c. <sup>470</sup>

In addition, we also observed significant left hemispheric <sup>471</sup> lateralization on activation in the parietal area, including both <sup>472</sup> SPC (number of task-related/nontask-related channels: L=72/21, <sup>473</sup>  $R=33/56$ ,  $p < 0.001$ ,  $\chi^2$  test, FDR corrected) and inferior parietal 474 cortex (IPC, L=29/84, R=8/85,  $p < 0.05$ ) during the task.

# The Spatio-temporal Evolution of Neural Activation During 476 The Task 477

Among all task-related channels, we identified 564 informative  $478$ channels. The anatomical and spatial distribution of these <sup>479</sup> channels were shown in Fig. [1e](#page-6-0) and [3b](#page-8-0)-c, respectively. Four typical <sup>480</sup> samples of informative detections were illustrated in Fig. [2.](#page-7-0) These  $481$ channels, located at different anatomical regions, show differences <sup>482</sup> in their time of neural activation relative to the EMG onsets as <sup>483</sup> well (Fig. [2\)](#page-7-0). Moreover, these four channels clearly present distinct 484 activation patterns (i.e., time-locked to the stimulus or response), <sup>485</sup> indicating the underlying different roles during the task. The <sup>486</sup> average temporal activation sequence of the identified informative 487 ROIs (n=16) in relation to the task processing was shown in <sup>488</sup> Fig. [3a](#page-8-0). During the task, the activation of neurons roughly starts <sup>489</sup> from the occipital area and then spreads to the temporal area, <sup>490</sup> parietal area, and the limbic system, afterward, goes forward to the <sup>491</sup>

<span id="page-6-0"></span>

Fig. 1: The distribution of task-related electrodes across all subjects.  $a)/b/c$  The spatial distribution of task-related electrodes in the MNI brain and their corresponding correlation value with the task (Left/Right/Top view respectively). The electrodes are presented with balls. The color of each ball indicates the anatomical position of that electrode. We used the Desikan-Killiany atlas for brain segmentation. The diameter of the balls corresponds to the correlation value with the task. d) The anatomical distribution for all the task-related channels. For each anatomical label (ROI), the gray bar is calculated by dividing the number of task-related channels over the number of channels having the same anatomical label across all subjects, whereas the blue bar is calculated by dividing the number of task-related channels over the number of all task-related channels across all subjects. The anatomical label in the X-axis is encoded using the upper color balls for better visualization. The color of each ball corresponds to the color scheme in  $(a/b/c)$ . e) The anatomical distribution for all the informative channels. The green and gray bars are in the same configuration as the blue and gray bars in (d) but use informative electrodes instead. f) The average correlation value  $(-log_{10}(p))$  of each ROI across all subjects. The error bar indicates the standard error. Asterisks denote the significance of the difference between the correlation value of the two ROIs  $(*, p < 0.05,$  Wilcoxon rank sum test). The anatomical label in the X-axis is encoded using the upper color balls for better visualization. The color of each ball corresponds to the color scheme in  $(a/b/c)$ .

 frontal area, and with the central area positioned at the final stages (Fig. [3a](#page-8-0), see also Supplementary Fig. 4 for the temporal activation sequence of different ROIs from four typical single subjects). 495 Specifically, LOC ( $n=42$ , 183 $\pm 6$  ms (mean $\pm$ s.e.)) activates at the earliest stage on average after the stimulus onset, indicating the <sup>496</sup> start of visual stimulus processing. Then IPC activates  $(n=23, 497)$  $229\pm17$  ms), and such activation is significantly ( $p < 0.05$ , 498 Wilcoxon rank sum test) later than the LOC. Following that is  $\frac{499}{2}$ 

<span id="page-7-0"></span>

Fig. 2: Illustration of detected neural activation from four typical channels of different subjects. a) The position of the electrode on the original MRI image of each single subject. Red dots indicate electrodes. The text below indicates the anatomical position of each electrode. b) Single-trial neural activation detection results for the electrode shown in (a). The color map represents the normalized broadband gamma power (BGP) of all trials, where red color indicates higher BGP within each trial. Time zero indicates the onset of the stimulus. The black dot indicates the detected neural activation for each trial. The dark gray dot (Sigmoid shape) indicates the detected EMG onset of each trial. The purple line represents the average normalized BGP across all trials from that channel (the value is magnified by 20 fold for visualization purposes and is shown on the right side of the Y-axis). The detected neural activation and EMG onsets are presented here without normalization to give a better illustration of the difference in neural activation patterns. c) The average normalized activation time for the electrode shown in (a). The brown bars indicate the distribution of detected neural activation (after normalization, i.e., divided by the EMG onset in the same trial) from all trials shown in (b). The gray line indicates the curve-fitting result using a Gaussian model.  $\mu$  and  $\sigma$  indicate the mean value and standard deviation of the model. **d-f**)/g-i)/j-l) The detected neural activation for the second/third/fourth channel  $(d/g/j)$ . The configurations for all these subfigures are the same as  $(a/b/c)$ . The X-axis of  $(c/f)/l$  is scaled the same for comparison purposes. lh/rh: left/right hemisphere.

500 the activation from LGG (n=12, 247 $\pm$ 30 ms), SPC (n=59, 251 $\pm$ 17  $501$  ms), inferior temporal gyrus (ITG,  $n=32$ ,  $252\pm10$  ms), fusiform

<sup>502</sup> gyrus (FFG, n=14, 254±24 ms), precuneus cortex (PNC, n=10,

503 291 $\pm$ 32 ms), middle temporal gyrus (MTG, n=11, 291 $\pm$ 15 ms),

and rostral middle frontal gyrus (rMFG,  $n=16$ ,  $296\pm22$  ms), where 504 the SPC activates significantly  $(p < 0.05)$  earlier than the MTG. 505 Then the neural activity goes from SMG  $(n=57, 308\pm15 \text{ ms})$  to 506 the frontal area, including caudal middle frontal gyrus (cMFG, <sup>507</sup>

<span id="page-8-0"></span>

Fig. 3: The spatio-temporal activation results during the task. a) The activation time for all the applicable regions of interest (ROIs) during the task processing. For each ROI, the detected neural activation from all informative channels within the ROI was shown (blue dots). Time zero indicates the onset of the stimulus. The activation time shown here is calculated by multiplying the normalized activation time with the average EMG onset time (565 ms). The box indicates the 25 and 75 percentile of all the detected neural activation. The blue dot indicates the mean value. The whiskers extend to the limits of all the detected neural activation within that ROI. The light gray bar on the left indicates the percentage of informative channels belonging to each ROI within all informative channels. The digits on the right side indicate the temporal activation sequence. Statistical analysis are conducted between ROIs (\*, p < 0.05; \*\*, p < 0.01; \*\*\*,  $p < 0.001$ , Wilcoxon rank sum test). b)/c) Left/Top view of all the informative electrodes across all subjects in the MNI brain. All the electrodes are projected to the left hemisphere for visualization purposes. The color of electrodes within each ROI is colored using the average activation time of this ROI from  $(a)$ . d) The average activation time for all the applicable 6 areas during the task processing. The other configurations of this subfigure are the same as (a).  $\mathbf{e}/f$ ) Left/Middle view of spatio-temporal activation sequence for the 15 ROIs rendering on the flattened MNI brain. Results are shown with the cortical surface of the left hemisphere only. The digits correspond to the results shown in (a).  $g/h$  Left/Middle view of spatio-temporal activation sequence for the 6 brain areas rendering on the flattened MNI brain. Activation time is shown on the left hemisphere for illustration purposes. The digits correspond to the results shown in (d). Electrodes located in the hippocampus are used for the computation of the activation time of the limbic system. The hippocampus is not shown in this subfigure.

 n=13, 312±25 ms) and parsOP (n=14, 330±23 ms) and SFG (n=41, 396 $\pm$ 12 ms), where the parsOPE activates significantly ( $p < 0.001$ ) earlier than the SFG. Activation is also detected in PAC (n=13, 360 $\pm$ 35 ms) during this time segment. At the final step, the central area activates, where the PRC (n=99) activates 513 on average at  $424\pm11$  ms and significantly  $(p < 0.001)$  earlier than POC (n=47, 510±18 ms). The spatio-temporal evolution of neural activity during the task was presented in Fig. [3](#page-8-0) with the format of informative electrodes [\(3b](#page-8-0)-c) and cortical regions [\(3e](#page-8-0)-f).

 To give a more macro view on the footprints of neural processing during the task, we also computed the mean activation time for six different task-related cortical regions in a broader area (see Methods: Detection of Neural Activation Time). The temporal activation sequence for these broader areas was shown <sup>521</sup> in Fig. [3d](#page-8-0) (see also Supplementary Fig. 5 for the results from <sup>522</sup> four typical single subjects). As can be seen from the figure, the <sup>523</sup> occipital area (n=66) gets activated first with a  $206\pm10$  ms latency 524 on average after stimulus onset. Following this is the temporal area <sup>525</sup>  $(n=67)$ , which activates at  $256\pm9$  ms after stimulus onset. The 526 occipital area activates significantly  $(p < 0.001,$  Wilcoxon rank 527 sum test) earlier than the temporal area. The mean activation time 528 after stimulus onset is  $272\pm10$  ms for the parietal area  $(n=149)$ , 529  $309\pm24$  ms for the limbic system (n=17, parahippocampal gyrus 530  $(n=9)$ , hippocampus  $(n=6)$ , posterior cingulate gyrus  $(n=2)$ ). 531 Then the activation spreads to the front area at a latency of <sup>532</sup>  $347\pm10$  ms (n=91), where the frontal area activates significantly 533

<span id="page-9-0"></span>

Fig. 4: The activation pattern evaluation results. a) The relationship between the activation time and its correlation with the response onsets for each informative channel (see Methods: Activation Pattern Evaluation). Average normalized activation time is used here for each informative channel, where time zero indicates the onset of the stimulus and time one indicates the onset of response (i.e., motor behavior). Each colored dot indicates the result from one informative channel. The black line represents the fitted line generated using the least square method.  $k$  indicates the slope of the fitted line.  $r$  and  $p$  indicate Pearson's correlation values  $r$  and corresponding  $p$ values, calculated between the fitted value and the real value. b) The relationship between the activation time and its correlation with the stimulus onsets for each informative channel. The configurations for this subfigure are the same as (a). c) The relationship between the correlation with response time and the correlation with stimulus time for each informative channel. The configurations for this subfigure are the same as (a). d) Percentage of stimulus-locked and response-locked channels within each ROI. The ROIs are the same as Fig. [3.](#page-8-0)  $e/f$  Left/Middle view of the distribution of response-locked channels on a flattened MNI brain. Results are shown with the left hemisphere only. The darkness of the colored cortex indicates the percentage value shown in (d). Darker color indicates a higher percentage.

 $534 \left(p < 0.001\right)$  later than the parietal area. At the final stage, the <sup>535</sup> central area (n=159) gets activated with an average latency at 536 444 $\pm$ 10 ms, and such activation is significantly ( $p < 0.001$ ) later <sup>537</sup> than the frontal area. The temporal evolution of the cortical neural

# <sup>538</sup> activities for these regions is shown in Fig. [3g](#page-8-0) and [3h](#page-8-0).

# The Pattern of Neural Activation During The Task 539

To investigate the possible role of each informative electrode <sup>540</sup> with respect to task processing, we evaluated if there existed a <sup>541</sup> certain relationship between the activation time of these channels 542 and their correlation with stimulus and/or response onsets. Our 543 results show that the channels that activate earlier correlate more <sup>544</sup> with the stimulus onsets  $(k = -0.48, r = 0.63, p < 0.001, k$ : 545

 the slope of the fitted line, Fig. [4b](#page-9-0)), while the channels that activate later tend to correlate more with the response onsets  $(k = 0.25, r = 0.44, p < 0.001, Fig. 4a)$  $(k = 0.25, r = 0.44, p < 0.001, Fig. 4a)$  $(k = 0.25, r = 0.44, p < 0.001, Fig. 4a)$ . Such correlation with the stimulus onsets and the value with the response onsets is reversely 550 correlated  $(k = -0.63, r = 0.47, p < 0.001,$  Fig. [4c](#page-9-0)). This result indicates the existence of an at-least two-stage neural process during the task processing, where the first stage is characterized by a stimulus-locked activation pattern, indicating the sensory information processing; the other stage is characterized by a response-locked activation pattern, representing the generation of the motor response.

 We then evaluated the percentage of stimulus-locked and response-locked channels detected within each of the informative ROIs. The results show that wide areas of the entire brain, including most parts of the occipital area, the entire parietal area, parts of the temporal, frontal area, and even the central area, present stimulus-locked activation patterns (Fig. [4d](#page-9-0)). The current observation suggests the importance and complexity of sensory information processing prior to motor execution. More specifically, within these regions, the highest percentage of stimulus-locked channels was found in LOC, reaching 83.3%. Following that, the SPC (71.2%) was also a rich source of producing stimulus- locked activation. As the final stage of the task processing, the central area contained the lowest percentage of stimulus-locked channels (see also Supplementary Fig. 6 for the distribution of these areas). As a comparison, the central area, including POC (36.2%) and PRC (27.3%), has the highest percentage of response-locked channels. Besides, some parts of the frontal area (parsOPE (21.4%), SFG (14.6%), cMFG (7.7%)), a small portion of the parietal area (e.g., SMG (9%)) have also been found contain response-locked channels (Fig. [4d](#page-9-0)-f), indicating the possible function of these ROIs in relation to the generation of movement.

#### <sup>579</sup> Discussion

 In this work, using iEEG recordings from 4986 channels and 36 human subjects, we investigated the spatio-temporal dynamics of human cortical activity during a visually-cued motor process. Specifically, we answered three relevant scientific questions by conducting group analyses with high-frequency neural activities. In detail, we first identified the distribution and strength of brain regions involved in task processing. We then extracted the temporal activation sequence of different ROIs during the task. Finally, we analyzed the possible role (e.g., relating to sensory information process or motor response) of each informative ROI involved in the processing chain.

#### <sup>591</sup> The Distribution of Neural Activation Within The Brain

 We found rather broad regions of neural activation during the current task. Within the task-related regions, the most active regions were observed in the central, parietal, and occipital area, the regions in the frontal area that are close to the PRC, and the inferior part of the temporal area, demonstrating the essential roles of these cortical areas in visuomotor processing. Importantly, besides the lateral direction, we also give an overview of the neural activation along the depth direction (Fig. [1\)](#page-6-0). For instance, the deep brain structures, such as the insula cortex, parahippocampal gyrus, and hippocampus, have also been observed present task-related activation. The current observations further enrich the findings from previous ECoG [\(Keller et al., 2014\)](#page-13-16) and MEG 603 studies [\(Brovelli et al., 2017\)](#page-12-10). Moreover, our results also suggest 604 that the processing of a visuomotor task needs to recruit neural 605 networks spanning brain regions from both cortical and subcortical 606 levels. On this basis, revealing how neural activities interact 607 between cortical and subcortical regions will be interesting and <sup>608</sup> deserves further exploration in the following studies. 609

Apart from this, this work also gives additional spatial <sup>610</sup> information on the activation of the parietal area, since we <sup>611</sup> have found the existence of significant left lateralization on 612 the activation within this area during the current visuomotor <sup>613</sup> process. The present finding provides valuable implications for <sup>614</sup> future parietal area-based studies, especially the research adopting 615 neural activities from the parietal area for the brain-machine <sup>616</sup> [i](#page-15-16)nterface purpose [\(Aflalo et al., 2015;](#page-12-11) [Li et al., 2022;](#page-14-10) [Wang](#page-15-16) <sup>617</sup> [et al., 2020\)](#page-15-16). More importantly, similar phenomena have been <sup>618</sup> also detected under other cognitive processes, including the tool- <sup>619</sup> action observation [\(Caruana et al., 2017\)](#page-13-24), auditory and visual <sup>620</sup> stimulus processing [\(Molholm et al., 2006\)](#page-14-25), and visual and <sup>621</sup> motor imagery aspects of hand shape encoding [\(Klaes et al.,](#page-13-25) <sup>622</sup> [2015\)](#page-13-25). Moreover, such left-lateralized activation is reported to 623 [b](#page-15-17)e independent of handedness [\(Haaland et al., 2004;](#page-13-26) [Vingerhoets](#page-15-17) 624 [et al., 2012;](#page-15-17) Króliczak and Frey, 2009). Hence, all these  $625$ observations may together suggest the existence of the action <sup>626</sup> observation/execution network involving this area, which possibly 627 mediates the identification of the basic goal of the observed action 628 for both humans and monkeys [\(Rizzolatti et al., 2014\)](#page-15-18). <sup>629</sup>

# The Spatio-temporal Evolution of Neural Activation During 630 The Task 631

In this work, we analyzed and presented the evolution of neural 632 activation across the human brain during a visuomotor task using <sup>633</sup> the neural recordings from all subjects (Fig. [3\)](#page-8-0). The results <sup>634</sup> were further supported by the consistent results observed among 635 the partially-covered ROIs from the individual subjects (see <sup>636</sup> Supplementary Figs. 4 and 5). Roughly, early activation is shown 637 in the lateral part of the occipital area, the superior and posterior 638 part of the parietal area, and the posterior and inferior part of 639 the temporal area. Then, the activation spreads to the frontal <sup>640</sup> area and finally ends with the central area. It is also of interest <sup>641</sup> to compare our data with the results reported by [Johnson et al.](#page-13-28) <sup>642</sup> [\(1996\)](#page-13-28) and [Nishitani and Hari](#page-14-26) [\(2000\)](#page-14-26). The former authors studied  $\qquad$  643 the activation pathway during a visually guided reach movement 644 with nonhuman primates' single-neuron recordings. They found 645 the activation begins in the visual cortex and passes through the <sup>646</sup> posterior parietal cortex to the dorsal premotor cortex and then 647 to the primary motor cortex. The subsequent study reported the <sup>648</sup> temporal sequence of three ROIs during hand action imitation <sup>649</sup> using MEG recordings, where the visual cortex in the occipital <sup>650</sup> lobe first activates, and then the inferior frontal cortex activates 651 (parsOPE in this work), following that is the activation in the <sup>652</sup> primary motor area (PRC in this work). These results are in good 653 agreement with our ones. Meanwhile, distinct from these studies, <sup>654</sup> our work extends the results to more and wider regions of the <sup>655</sup> entire human brain, and hence can provide a comparatively more 656 intact overview of the 'footprints' of neural activity during the <sup>657</sup> task. It is worth noting that the spatio-temporal sequence reported 658 here should be interpreted carefully since the results are derived 659 from group analysis. Thus, our results cannot detect variations in 660 activation time among subregions of different ROIs or the same <sup>661</sup> <sup>662</sup> ROIs (Supplementary Fig. 4). At the same time, our results make <sup>663</sup> it clear that there is a definitely consistent temporal sequence <sup>664</sup> across these ROIs.

 Notably, although temporal activation sequence results show that POC activates lastly among all the informative ROIs (Fig. [3\)](#page-8-0), the identified POC activation represents more than the somatosensory feedback after motor execution. Because the 669 average activation time of POC  $(510\pm18 \text{ ms})$  in our work is slightly ahead of the movement onset (565 ms on average), indicating that some neurons in POC start firing prior to the movement onset (see also Supplementary Fig. 4a). Such early activation provides further evidence supporting the additional role of the somatosensory cortex in sensory information encoding that relates to the anticipation of movements [\(Wolpert et al., 1995;](#page-15-19) [Sun et al.,](#page-15-20) <sup>676</sup> [2015\)](#page-15-20).

 Besides, we have detected  $13.6\%$  (n=51) of electrodes located in the insula cortex presenting task-related activation, denoting the substantial involvement of this area during the visuomotor 680 task. However, only a few of them are informative enough  $(n=8,$  395 $\pm$ 44 ms) for the calculation of activation time. This may be because of the observation that most of the task-related channels in this area tend to activate in an irregular way (i.e., the onsets of activation are distributed sparsely across trials). The neural mechanism behind such neural activation patterns is not well understood yet. Consistently, [Bartoli et al.](#page-12-12) [\(2018\)](#page-12-12) also reported that the insula cortex exhibits an increase in broadband gamma activity under a button press task but such activation is less robust and later than the inferior frontal cortex (see also Fig. [3\)](#page-8-0). Together, the current results imply that the insula cortex may play an indispensable role in sensory-motor processing, and the detailed function of this area still needs further investigation.

# <sup>693</sup> The Possible Role of The ROIs During The Task

 Within the detected processing chain of the visuomotor task, on the average level, our data support the general understanding that the neurons that activate early tend to correlate more with the visual stimulus delivery, while the neurons holding late activation tend to associate more with the motor response (Fig. [4a](#page-9-0)-c). Furthermore, we also analyze the neuronal representations as being 'sensory' or 'motor' for each informative channel based on whether the neural activation is more closely linked to the onset of a stimulus or the initiation of a response (Fig. [4d](#page-9-0)). The earliest activation and highest percentage of stimulus-locked channels presented in our results demonstrate together the role of the lateral occipital cortex in the visual information processing during the task [\(Tallon-Baudry et al., 2004;](#page-15-21) [Larsson and Heeger, 2006\)](#page-14-27). Then, a high percentage of stimulus-locked channels in the parietal area and temporal area indicate as well the important function of these areas in visual information processing. Such visual representation gets weak when the process evolves to the frontal and central areas. Moreover, we have also detected obvious involvement from the parietal and frontal areas in the early stage of neural processing relating to the initiation of motor response. Previous reports have consistently suggested that motor function from the parietal area is related to the sensorimotor transformation [\(Andersen and Cui,](#page-12-3) [2009\)](#page-12-3), including hand trajectory information [\(Hauschild et al.,](#page-13-2) [2012\)](#page-13-2) and motor intentions, where the intention in the parietal [a](#page-13-25)rea may be processed in relation to sensory predictions [\(Klaes](#page-13-25) [et al., 2015\)](#page-13-25). Whereas the motor function in the frontal area represents higher-level aspects of movement planning and decision making in relation to motor execution [\(Rizzolatti et al., 2014;](#page-15-18) 721 [Miller and Cohen, 2001;](#page-14-28) [Schall, 2015\)](#page-15-4). On these bases, our results 722 further enhance the understanding of the critical sensorimotor- <sup>723</sup> related functions for these two areas [\(Andersen and Buneo, 2002;](#page-12-13) <sup>724</sup> [Corbetta and Shulman, 2002\)](#page-13-0). At the last stage of the neural <sup>725</sup> processing chain, the central area presents the highest percentage <sup>726</sup> of response-locked neural activity, indicating their function in <sup>727</sup> motor execution and somatosensory processing [\(Scott, 2004;](#page-15-22) <sup>728</sup> [Lemon, 2008\)](#page-14-29). Interestingly, within the central area, we also detect 729 a minority of channels in the PRC that present early stimulus- <sup>730</sup> locked activation (Figs. [4d](#page-9-0) and [3a](#page-8-0)). These findings promote the <sup>731</sup> understanding of the intact functions of this motor area, where the <sup>732</sup> view that the PRC is an integral part of a cue-to-action network so 733 [a](#page-14-6)s to make immediate responses to environmental stimulus [\(Rao](#page-14-6) <sup>734</sup> [and Donoghue, 2014\)](#page-14-6), may account for the observation. 735

Taken together, the neural processing results during the <sup>736</sup> visuomotor task revealed in this work likely support the opinion <sup>737</sup> that visual information is firstly processed and segregated along <sup>738</sup> two pathways (Figs. [1,](#page-6-0) [3](#page-8-0) and [4\)](#page-9-0), where the ventral stream <sup>739</sup> (occipito-temporal cortex) computes vision for perception and <sup>740</sup> the dorsal stream (occipito-parietal cortex) computes vision for <sup>741</sup> action [\(Culham and Valyear, 2006\)](#page-13-29). The parietal and frontal <sup>742</sup> areas play an important role in the transformation of sensory <sup>743</sup> information to motor-related information. Specifically, the parietal <sup>744</sup> area participates in the early stage of such processing while the <sup>745</sup> frontal area tends to engage more in the motor execution. At <sup>746</sup> the final stage of motor execution, PRC generates motor signals <sup>747</sup> from an already highly processed sensory input and other internal <sup>748</sup> signals, following that is the production of the somatosensory 749 feedback from POC after motor execution (but also see discussion 750 above). Apart from this, we also conducted additional analyses <sup>751</sup> to further investigate whether the reaction time of a subject <sup>752</sup> is associated with the motor cortex only. To do this, we first <sup>753</sup> computed the average reaction time (computed as the trial- <sup>754</sup> averaged EMG onsets within each subject) and the average <sup>755</sup> raw activation time (without normalization) for all informative <sup>756</sup> channels within each informative ROI across subjects. Then, for <sup>757</sup> each informative ROI, we computed a Spearman correlation value 758 between the average reaction time and the average raw activation <sup>759</sup> time for all informative channels within this region. Finally, 760 the ROIs producing significant correlations  $(p < 0.05)$  were 761 identified. In this analysis, we find that, besides the central area, <sup>762</sup> the activation time from multiple regions, including temporal, <sup>763</sup> parietal, and frontal areas, also correlates significantly with the <sup>764</sup> reaction time of subjects for the current task (results not shown 765 here). This finding denotes that the reaction speed of a human is 766 not attributed to a single region (e.g., the well-known PRC), but <sup>767</sup> an entire task-related brain network including both sensory and <sup>768</sup> motor information processing. 769

#### Implications, Limitations, and Future Work 770

The current work presents the overall large-scale spatio-temporal 771 neural evolution of the human brain during a visuomotor task <sup>772</sup> and evaluates the possible functions across different ROIs. The <sup>773</sup> findings from this study enhance the understanding of the neural <sup>774</sup> responses under the task for neuroscientific studies. Moreover, <sup>775</sup> the findings also bring valuable insights for future movement- <sup>776</sup> related brain-machine interface research, which is also a focus of 777 this work (e.g., besides the traditional sensorimotor area, paying <sup>778</sup> additional attention to brain areas such as the frontal and parietal 779

 area for the decoding of movement parameters). There are also limitations in this work. For example, despite the comparatively large number of electrodes across the human brain in our study, the number of informative channels is still limited. In this point, the current analysis delivers an observation on most of the crucial regions involving the neural processing network under the current task, but may still not cover all of them. Besides, to make a robust group analysis, we combine the results of informative channels from both hemispheres during the computation of the average activation time of different ROIs, the generated result hence should be interpreted as a macro-level spatio-temporal evolution under the current task. Hence, recording from a larger number of channels will still be essential and valuable for further revealing the neural dynamics of the human brain in more detail. Notably, we have identified the neuronal representations as being 'sensory' or 'motor' for informative channels from multiple ROIs. Meanwhile, we also detected a number of channels occupying positions that are intermediate between these two extremes [a](#page-13-30)nd can not be described by either label (Fig. [4d](#page-9-0), [DiCarlo](#page-13-30) [and Maunsell](#page-13-30) [\(2005\)](#page-13-30)). These channels generally display multiple firing patterns or present irregular neural responses that do not fit the two categories analyzed here. Making additional assessments of the functions for these channels presenting irregular firing patterns using new experiments or analysis methods (e.g., functional connectivity [\(Bastos and Schoffelen, 2015\)](#page-12-14)) remains an important topic and deserves further investigation. Lastly, this study concentrates solely on the high-frequency component of the neural recordings, but some other simultaneous movement- relevant phenomena relating to the lower-frequency activity have been reported as well, such as the sensorimotor rhythm (SMR) in the mu and beta band and movement-related cortical potentials (MRCP) of the slow waves [\(Liu et al., 2020\)](#page-14-30). What is largely unknown, is the relationship between these different measurements (e.g., the modulation of low-frequency activity to high-frequency ones) and the underlying mechanism between such relationship. In the future, it would be interesting to comprehensively address this question using a larger number of neural recordings.

# Supplementary Materials for Spatio-temporal Evolution of Human Neural Activity During Visually-cued Hand Movements

This PDF file includes:

Table S1 and S2 Figures S1 to S6

Supplementary Table 1. Clinical profiles of all 36 subjects that participated in the study. Among these subjects, 34 were implanted with SEEG depth electrodes, and 2 (Sub. 32, Sub. 35) were implanted with ECoG grid electrodes. Abbreviations for this table: RS (Recording hemisphere), SR (Sampling rate), EL (Number of electrode shafts), CH (Number of contacts), OH (Operating hand during the experiment), TH (Cut-off threshold during the line noise detection for each subject, see Sec. Data Pre-Processing of Materials and Methods), BC (Bad Channel, i.e., Number of channels whose line noise power exceeds the cut-off threshold).

Sub ID	Gender	Age	RS	SR(Hz)	EL	CH	OH	TH $(\mu$ V)	BC

Supplementary Table 2. Information of brain regions reported in this study. Electrode number indicates the number of electrodes implanted in the listed brain region across all 36 subjects.

ID	<b>Brain Regions</b>		Abbreviation Electrode Number	Groups	
$\mathbf{1}$	superior frontal gyrus	<b>SFG</b>	245		
$\overline{2}$	rostral middle frontal gyrus	rMFG	311		
3	caudal middle frontal gyrus	cMFG	174		
$\overline{4}$	lateral orbitofrontal gyrus	<b>OFG</b>	54	Frontal Area	
5	pars opercularis	parsOPE	119		
6	parstriangularis	parsTRI	98		
7	parsorbitalis	parsORB	32		
8	precentral cortex	PRC	368		
9	postcentral cortex	POC	213	Central Area	
10	paracentral cortex	<b>PAC</b>	56		
$\mathbf{1}$	superior parietal cortex	SPC	182		
12	inferior parietal cortex	<b>IPC</b>	206	Parietal Area	
13	supramarginal gyrus	<b>SMG</b>	261		
14	precuneus cortex	<b>PNC</b>	183		
15	superior temporal gyrus	<b>STG</b>	390		
16	inferior temporal gyrus	<b>ITG</b>	193	Temporal Area	
17	middle temporal gyrus	<b>MTG</b>	325		
18	transverse temporal gyrus	<b>TTG</b>	43		
19	fusiform gyrus	<b>FFG</b>	102		
20	banks of the superior temporal sulcus	bankssts	53		
21	lateral occipital cortex	<b>LOC</b>	74		
22	pericalcarine cortex	PCC	33	Occipital Area	
23	lingual gyrus	LGG	62		
24	cuneus cortex	CNC	18		
25	insula cortex	<b>ISC</b>	374	Insula	
26	parahippocampal gyrus	<b>PHG</b>	50		
27	posterior cingulate gyrus	PCG	77	Limbic System	
28	Hippocampus	N/A	196		
29	caudal anterior cingulate gyrus	cACG	49		
30	rostral anterior cingulate gyrus	rACG	25		
31	Amygdala	N/A	85		

Supplementary Figure 1. Experiment protocol of the current study. Each subject performed five different hand or arm movements (see Cue). In each trial, one of five tasks was randomly selected and displayed (Cue, the onset of movement cue was set as time 0 in this study). They performed each type of movement 20 times (5 s each, [0, 5] s). Before the movement, each subject rested for 4 s ([-5, -1] s), and then a warning sign ([-1, 0] s) prompted the subject for movement initiation.

Supplementary Figure 2. Electrodes localization results of all 36 subjects. a)/b)/c)/d) Right/Left/Frontal/Top view of all the electrodes projected to the standard Montreal Neurological Institute (MNI) template. The electrodes (SEEG and ECoG) are shown with small balls. Different colors indicate different anatomical positions, where the red indicates the gray matter, the blue indicates the white matter, the purple indicates the hippocampus, the dark green indicates the amygdala, the yellow indicates the putamen and the gray indicates the other structures.  $LH/RH$ :  $L$ eft/Right hemisphere.

Supplementary Figure 3. The illustration of data processing in this work. The flow chart corresponds to the data processing from the section (Methods: Data Pre-Processing) to the section (Methods: Activation Pattern Evaluation). Specifically, to identify the response-locked channels (left lower subfigure), we first computed Pearson's correlation for the detected neural activation of each informative channel and the EMG onsets across all trials. Then, the sequence of detected neural activation was randomly shuffled and the correlation with the EMG onsets was computed again. This procedure was repeated 2500 times, thus, generating a distribution of surrogate correlation value (the histogram) and the subsequent p value (vertical red line) for the observed correlation value. The channel whose p value was smaller than the significance level ( $p < 0.05$  after Bonferroni correction) was identified as the response-locked channel. To identify the stimulus-locked channels (right lower subfigure), for each informative channel, the standard deviation of detected neural activation from randomly selected 60 trials was first computed. Then, this process was repeated for  $10^6$  times and the average standard deviation of these repetitions (the histogram) was obtained for each channel. The channel whose average standard deviation is smaller than the threshold (vertical red line) is identified as the stimulus-locked channel (see Methods: Activation Pattern Evaluation for more details).

Supplementary Figure 4. The spatio-temporal activation results during the task from four typical subjects (Sub. 02 (a), Sub. 06 (b), Sub. 27 (c), Sub. 32 (d)). The results are presented in groups based on the region of interest (ROI) where each informative electrode of this subject is located (same as Fig. 3a/e/f, see also Supplementary Table 2). a) The neural activation time of different ROIs from a single subject (Sub. 02). The boxplot presents the distribution of neural activation time for all the samples detected within each ROI. The colored dot indicates the result of each informative electrode. The vertical line within the boxplot indicates the median value. The right subfigure presents the position of each informative electrode (colored the same as the left subfigure) in the MNI brain. The black dots denote all the electrodes implanted for this subject.  $b/(c)/d$ Results from the other typical subjects. Same configurations as a).

Supplementary Figure 5. The spatio-temporal activation results during the task from four typical subjects (Sub. 02 (a), Sub. 08 (b), Sub. 09 (c), Sub. 34 (d)). The results are presented in groups based on the broader brain area where each informative electrode of this subject is located (same as Fig.  $3d/g/h$ , see also Supplementary Table 2). a) The neural activation time of different broader brain areas from a single subject (Sub. 02). The boxplot in the left subfigure presents the distribution of neural activation time for all the samples detected within each broader brain area. The colored dot indicates the result of each informative electrode. The vertical line within the boxplot indicates the median value. The right subfigure presents the position of each informative electrode (colored the same as the left subfigure) in the MNI brain. The black dots denote all the electrodes implanted for this subject.  $b)/(c)/d$ ) Results from the other typical subjects. Same configurations as a).

Supplementary Figure 6. Left(a)/Middle(b) view of the distribution of stimulus-locked channels on a flattened MNI brain. Results are shown with the left hemisphere only. The darkness of the colored cortex indicates the percentage value shown in Fig.4d of the main content. Darker color indicates a higher percentage. See Methods: Activation Pattern Evaluation for more details.
