PROJECT

**Counterparty and Liquidity Risk: an analysis of the negative basis**

Vladimir João de Oliveira Lopes Dias da Fonseca

Supervision: Raquel M. Gaspar

19.10.2011

## **Abstract**

In this study we analyse the equivalence between credit default swap (CDS) spreads and corporate bond yield spreads from March 2007 to March 2011 for investment graded corporate entities in the eurozone. We find evidence of cointegration between the two markets and that CDS prices tends to lead corporate yield spreads. We find support for significant effects of counterparty and funding risks in the basis, measured as the difference between CDS and corporate yield spreads, with negative impact, and that liquidity also matters in this context.

Key words: Credit Default Swaps, CDS, Bond, Basis, Counterparty Risk, Liquidity Risk, Cointegration, Lead-Lag Relationship, Corporate Yield Spread, Interest Rate

## Resumo

No contexto da relação teórica de equilíbrio entre os preços dos CDS e as *yield spreads* das obrigações das empresas face a taxas de juro sem risco, este trabalho conclui que existe cointegração entre estas duas variáveis para entidades de referência na zona euro no período que decorre entre Março de 2007 e Março de 2011. A análise efectuada revelou que o risco de contraparte e o risco de liquidez em ambos os mercados tiveram um impacto significativo na base, entre os CDS e os referidos *spreads*, e que os preços dos CDS tenderam a liderar as *yield spreads* das obrigações no período em análise.

Palavras-chave: CDS, Risco de Contraparte, Risco de Liquidez, Cointegração, Base, Obrigação, Taxa de Juro

## **Acknowledgments**

I am grateful to my supervisor, Raquel Gaspar, for her detailed and constructive comments in all phases of this project, especially in the critical ones. Thank you very much for your support. I would also like to thank Paulo Silva and Patricia Pereira for the initial information provided and also Bruna Vieira, Ines Gomes, Ines Lopes, Jorge Costa and Ranato França, for the brainstorming and debate in the early stages of this project.

## **Chapter 1**

### **Introduction**

IN THE PAST SEVERAL YEARS, the importance of credit derivative markets has been growing rapidly. The single most important instrument in this market is the credit default swap (CDS). A CDS is a bilateral agreement to exchange the credit risk of a reference entity. In this agreement, one party (the protection buyer) pays a periodic fee (CDS premium) to another party (the protection seller) in exchange for compensation in case of a credit event (bankruptcy, failure to pay, default, restructuring, repudiation or moratorium, among others) of a given reference entity. In theory, this CDS premium is expected to reflect the perceived credit risk of the reference entity in a pure way.

Therefore, these CDS contracts provides a new way to measure the size of the default component in corporate spreads and many authors argue that an arbitrage relationship exists between CDS prices and corporate yield spreads for a given reference entity, as first discussed by Duffie (1999)<sup>1</sup> and then pointed out by Blanco, Brennan et al. (2005) in their empirical analysis of the dynamic relations between bond and CDS markets.

Blanco, Brennan et al. (2005) argue that if an investor buys a T year par bond with yield to maturity  $y$  and at the same time buys credit protection in CDS market on the same reference entity for T years at a cost of  $p_{CDS}$  (annually), she has eliminated most of the default risk associated with the bond at an annual return of  $y - p_{CDS}$ . By arbitrage, this net return should be approximately equal to the T year risk free rate,  $x$ . For example, if  $y - p_{CDS}$  is less than  $x$ , then shorting the bond, selling protection in CDS market and buying the risk free instrument would be a profitable arbitrage opportunity<sup>2</sup>.

In this context, an equilibrium theoretical condition is expected to hold in the long run between the corporate yield spreads and the CDS prices, even though, significant deviations are documented in many empirical studies, especially in the short term.

Why this basis, between CDS prices and corporate yield spreads, deviates from zero? If in one hand, a liquidity premium may be included in the corporate yield spreads, driving this basis negative, in the other hand, other factors affecting the CDS premium also contribute to obscure this relationship, namely the counterparty risk (as CDS are OTC

---

<sup>1</sup> Duffie (1999) has demonstrated that the CDS price should be equal to the spread between a par risky floating rate note over a risk free floating rate note.

<sup>2</sup> Likewise, the same authors explain that, if  $y - p_{CDS}$  is more than  $x$ , buying the bond, buying protection in CDS market and shorting the risk free instrument would then be profitable.

products, this risk tend to lower the CDS premium because protection buyers face greater uncertainty in receiving the asset value should the default occur, and therefore are only willing to pay a lower premium as agued by De Wit (2006)) and the liquidity risk of the CDS itself, which would tend to turn the basis positive.

The notion that liquidity is priced in corporate yield spreads started with Amihud and Mendelson (1986). They studied the effect of bid-ask spreads in asset pricing and returns. Among other relevant articles, Ericsson and Renault (2006) provides a comprehensive insight on the impact of the liquidity risk in the corporate yield spreads, developing a structural model that simultaneously captures liquidity and credit risk. This study documents positive correlation between illiquidity and default component and supports a downward-sloping term structure for liquidity spreads. Chen, Lesmond et al. (2007) provides an extensive analysis on how “more illiquid bonds earn higher yield spreads” using several liquidity measures and covering more than 4,000 corporate bonds, over different categories.

The recent financial crisis has stressed out the importance of the liquidity risk in the financial markets. In this period, the CDS premium has experienced a tremendous increase, as much as many studies documented the basis (between CDS and corporate yield spreads) to be strongly negative. This fact sparked new questions about the possibility of CDS prices to include significant risks other then credit risk, namely the counterparty and CDS own liquidity as stated before, not pricing correctly the reference entity default risk, which also has increased tremendously in this period with great impact in the corporate bond yields.

In this context, the present study proposes, under the non-arbitrage condition above discussed, an empirical assessment in to what extend the equilibrium between the CDS prices and the corporate yield spreads has hold in the last few years and what were the determinants of the basis spread changes for corporate investment graded reference entities in the eurozone, including the role of counterparty and liquidity risk.

The reminder of this text is organized as follows. Chapter 2 defines the main concepts and discusses the general theoretical approach and the main estimation methods to be applied in the empirical analysis to be developed later on. Chapter 3 presents a case study of France Telecom, in order to provide more details on the conceptual framework to be applied to the full data sample. Chapter 4 describes the full data set. Chapter 5 investigates empirically the lead-lag relationship between the CDS and the bond markets, including a cointegration analysis and Chapter 6 develops a regression analysis on the determinants of the basis spread changes with proxies for counterparty risk, liquidity risk and other market conditions. Chapter 7 contains concluding remarks.

## **Chapter 2**

### **Conceptual Framework**

At this point, it is useful to clarify some of the concepts and terminology that will be used throughout this text. The CDS premium (or sometimes referred to as CDS price, or CDS spread, or just CDS) is the premium paid by the protection buyer to the protection seller, quoted in basis points per annum (usually paid quarterly) and it is a very straightforward measure that tends to reflect the credit risk of a given reference entity.

However, different concepts of corporate yield spreads exist, depending on the riskless benchmark choice and the calculation procedures. For the purpose of this study, the term bond spread will be used to denote the difference between the yield on a corporate bond and the yield on a riskless bond with identical promised cash flows, as defined in Longstaff, Mithal et al. (2005), with the riskless benchmark being the European Central Bank (ECB) spot yield curve<sup>3</sup>.

A second approach to the corporate yield spread will also be used as alternative to the bond spread above defined, as many authors, including Blanco, Brennan et al. (2005), now argue that government bonds are no longer the ideal proxy for the risk free rate, naming factors like taxation treatment, repo specialness, scarcity premium, impacting its behaviour. Also, Longstaff, Mithal et al. (2005) use three different alternatives of risk-free rate to generate their riskless discount function in order to robust check their findings.

Therefore an alternative proxy of the risk-free rate, very much used nowadays, is the interest rate swap curve, although some may argue that swaps contain a credit premium because there is some counterparty risk. The differential between the yield on a corporate bond and interpolated swap rates<sup>4</sup> is called i-spread and will be used as an alternative measure of corporate yield spread and be denoted as i-spread.

Both spread measures above will be expressed in basis points per annum, in order to compare with the CDS spread, originating two more measures: the CDS-bond basis, as the difference between the CDS spread and the bond spread (using government bonds as

---

<sup>3</sup> This (spot) yield curve is estimated from a sample of “AAA-rated” euro area central government bonds, using the Svensson model. The selection criteria and additional information are available in the ECB website.

<sup>4</sup> In this case euro vs. euribor (one year) interest rate swap.

the benchmark) and the CDS-i-spread basis as the differential between the CDS spread and the i-spread (using the swap curve as the benchmark).

With the purpose to access (1) the equilibrium condition between the CDS prices and the corporate yield spreads and (2) the determinants of the basis spread changes, and considering that the data to be processed will consist in time series observations for each variable, it is necessary to evaluate and select an appropriate estimation method. The first approach would be to use a standard ordinary least square (OLS) method to estimate a regression model with selected explanatory variables but, since the use of non stationary variables can lead to spurious regression the evaluation of that condition and the estimation model to be applied will have to take this into consideration.

A stationary series can be defined as one with a constant mean, constant variance and constant autocovariances for each given lag, Brooks (2008). For a stationary series, the “shocks” will gradually die away and the series will cross its mean value frequently. In a non stationary series, shocks to the system will persist in time and the series can drift long time away from their mean, which they cross rarely.

A standard way to cope with this problem (of regressing non stationary variables) is to differentiate the series instead of using the levels. If a non stationary series have to be differentiated one time before becoming stationary it is said to contain one unit root, or to be integrated of order one, I(1). If it has to be differentiated d times before it becomes stationary, it is said to be integrated of order d, I(d).

Still according to Brooks (2008), most financial time series contains one unit root, so testing this hypotheses will be the first step before any estimation procedure<sup>5</sup>. For the purpose of this study, and among others available methods, the augmented Dickey-Fuller test<sup>6</sup> (ADF test) will be used for unit root testing and, in other to test the robustness of the results, the KPSS<sup>7</sup> test, Kwiatkowski, Phillips et al. (1992), will be performed, following the *confirmatory data analysis* proposed in Brooks (2008).

In order to evaluate the equilibrium condition between CDS and bond markets, an *error correction model* will be used. Considering that pure first difference models have no

---

<sup>5</sup> This is an important issue as differentiating more than necessary to achieve stationarity will introduce an MA (moving average) structure to the errors, and not differentiating enough times will still lead to a non stationary series, both undesirable situations.

<sup>6</sup> Developed by Fuller (1976) and Dickey and Fuller (1979), this test has unit root under the null hypothesis.

<sup>7</sup> Kwiatkowski-Phillips-Schmidt-Shin test. This test is known as a stationarity test as the null hypothesis in this case is stationarity.

long term solution<sup>8</sup>, *error correction models* (or *equilibrium correction models*) can overcome the non stationarity issue by combining first differences and lagged levels of cointegrated<sup>9</sup> variables. These models are in the base of the modelling strategy called the *Engle-Granger 2-step method*, in which, using a residual based approach, in the first step, a cointegrating equation is estimated.

If a cointegrating relationship is found in step 1, the appropriate modelling strategy in this framework is to use this stationary linear combination of the variables in hand in a general equilibrium model for the analysis. If not, the appropriate strategy for econometric modelling would be than to use first differences specifications only. This strategy will be detailed in the next section case study of France Telecom to analyse cointegration and lead-lag relationship between CDS and bond markets.

---

<sup>8</sup> As pointed out in Brooks (2008) , if we consider two series  $y_t$  and  $x_t$ , both  $I(1)$ , the model one may consider estimating is  $\Delta y_t = \beta \Delta x_t + \varepsilon_t$ . For the model to have a long run solution, the variables must converge to some long term value and so, no longer changing, meaning  $y_t = y_{t-1} = y$  and  $x_t = x_{t-1} = x$ , i.e.  $\Delta y = 0$  and  $\Delta x = 0$ , cancelling everything in the equation. Therefore this model has little to say about any equilibrium condition between  $y_t$  and  $x_t$ .

<sup>9</sup> In most cases, the linear combination of two  $I(1)$  variables will also be  $I(1)$ . Even so, sometimes, some series are non stationary but tend to move together in time, like they are bound by some kind of long term relationship, despite some short term deviations. In this case there is a linear combination of these (two)  $I(1)$  variables that is stationary. If that is the case, the variables are said to be cointegrated. A general definition of cointegration is detailed in Engle and Granger (1987).

## Chapter 3

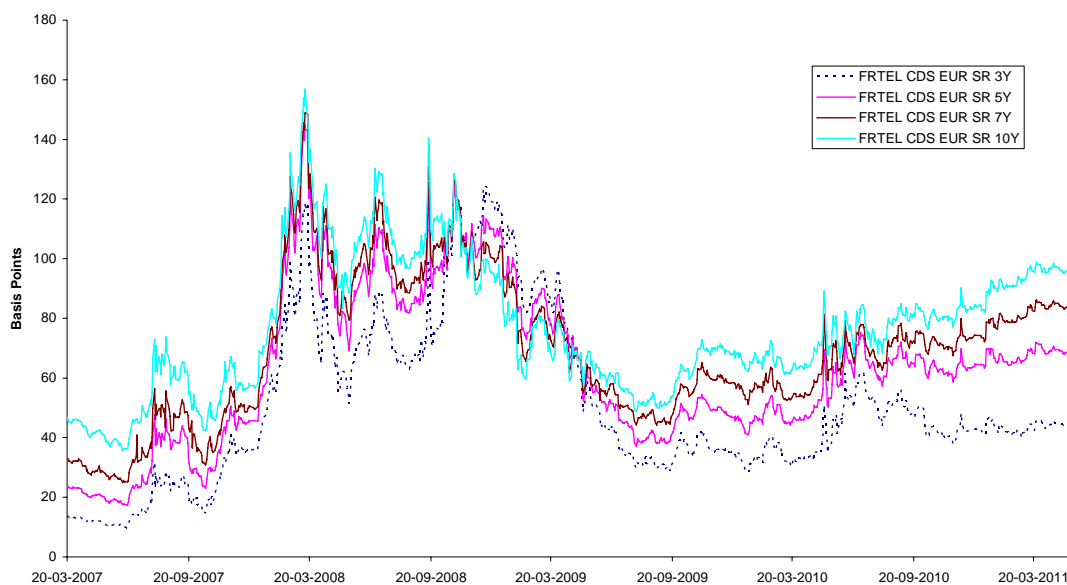

### Methodology Illustration: France Telecom Case Study

In order to address the investigation problem in hand, it is useful to illustrate first the above discussed methodology via a case study, France Telecom, during the period from 2007, i.e. before the 2008 financial crisis, to the present (March 2011). This timeframe comprises both pre-crisis and post-crisis scenarios, as well as the great financial markets turmoil period of 2008.

#### 3.1 The Basis

The CDS data consists of daily mid, bid and ask quotations for credit default swaps on senior France Telecom debt, with maturities of 3, 5, 7 and 10 years, obtained from Bloomberg financial terminal covering the period from March 2007 to March 2011. Figure 1 plots the evolution of the CDS spreads over the analysis period. As shown, the premium increases with the maturity in most of the time, as expected, and an enormous enlargement occurred during the 2008 crisis period from around 20 basis points in the 5 year tenor to more than 100 basis points. The after crisis period, in 2009, is characterized by a steady upward trend in all maturities, except for the 3 year tenor, after the decrease from the extremely high 2008 values.

**Figure 1 - Time series plot of France Telecom CDS premium mid quotations at 3, 5, 7 and 10 years maturity**

Since all the CDS in the sample have constant maturities, the problem now is to find the appropriate corporate spread measure to compare with. While it is not possible to always find a bond with an exact maturity to match with the CDS premium, and then compare the spreads, it is necessary to find an appropriate approach to this maturity matching problem. Many approaches are available in the related literature, including Gaspar and Pereira (2010), but in this regard, a quite robust one is presented in Longstaff, Mithal et al. (2005). Rather than focusing in a specific bond to compute the corporate yield spread, those authors prefer to apply a disjoint method, in which they propose to select a basket of bonds with maturities that bracket the desired horizon (5 year in their case) to compute the corporate yield spread.

To compute the corporate yield spread, they use the following procedure: for each bond in the basket set, they solve for the yield on a riskless bond with the same maturity and coupon rate, using three different riskless benchmark curves. Subtracting this riskless yield to the respective corporate bond yield, they find the yield spread for that particular bond. To obtain the desired 5-year maturity, they regress the yield spreads obtained for each bond in the basket set on their maturity and use fitted value at 5-year as the estimate for the corporate yield spread. They also present in the appendix B of their paper a very useful list of criteria for the bonds selection process.

Following this procedure, a set of eight bonds were selected for the France Telecom case study, with maturities ranging from less than 3-years to 25-years, to cover all maturities in analysis and with a “term structure” the most homogeneous as possible. The bond selection criteria included only large issued senior debt, denominated in euro and with fixed coupon rate.

**Table 1 - Basket of France Telecom bonds for the corporate yield spread calculation**

ISIN Code	Name	Issue Date	Maturity	Coupon
FR0000471476	FRTEL 7 12/09	23-12-2002	23-12-2009	7,00%
FR0010245548	FRTEL 3 10/10	14-10-2005	14-10-2010	3,00%
FR0010038984	FRTEL 4-5/8 01/12	23-01-2004	23-01-2012	4,63%
FR0000471948	FRTEL 7-1/4 01/13	28-01-2003	28-01-2013	7,25%
XS0365092872	FRTEL 5-1/4 05/14	22-05-2008	22-05-2014	5,25%
XS0286705321	FRTEL 4-3/4 02/17	21-02-2007	21-02-2017	4,75%
XS0500397905	FRTEL 3-7/8 04/20	09-04-2010	09-04-2020	3,88%
FR0000471930	FRTEL 8-1/8 01/33	28-01-2003	28-01-2033	8,13%

As above stated, two alternative corporate yield spread measures will be used in this study. The bond spread, with the riskless benchmark being the ECB spot yield curve, and the i-spread, that uses the interest rate swap curve as benchmark. Three sets of data are required at this point: bond data, ECB yield curve data and swap curve rates.

Full description of the bonds, including ISIN code, name, coupon rate, maturity, rating and daily series of bid, ask and mid quotations for prices and yields to maturity were obtained from a from a Bloomberg financial terminal covering the period in analysis. The ECB yield curve is based in the Svensson model and the spot rate,  $z$ , for any desired maturity can be obtained using the following equation:

$$z(TTM) = \beta_0 + \beta_1 \left[ \frac{1 - e^{\left(\frac{-TTM}{\tau_1}\right)}}{\left(\frac{TTM}{\tau_1}\right)} \right] + \beta_2 \left[ \frac{1 - e^{\left(\frac{-TTM}{\tau_1}\right)}}{\left(\frac{TTM}{\tau_1}\right)} - e^{\left(\frac{-TTM}{\tau_1}\right)} \right] + \beta_3 \left[ \frac{1 - e^{\left(\frac{-TTM}{\tau_2}\right)}}{\left(\frac{TTM}{\tau_2}\right)} - e^{\left(\frac{-TTM}{\tau_2}\right)} \right] \quad (1)$$

Where  $TTM$  is the term to maturity and  $\beta_i$  and  $\tau_i$  are the model parameters to be estimated. The ECB provides daily series for the parameters above, so daily discount factors for our riskless bond with the same maturity and coupon rate can be computed. In this case, for each bond in the basket set and in a daily basis, an identical bond with the same promised cash flows was considered and each cash flow was discounted at its own riskless rate to obtain the riskless yield for that particular bond.

For the alternative measure, i-spread, the difference between the yield to maturity of each bond in the basket set and the interpolated swap rate was computed. Table 2 details the calculations for the first bond of France Telecom case study in reference to the 20<sup>th</sup> of March 2007 (the first day of the analysis period).

**Table 2 - Bond spread and credit spread computation procedure**

This table reports the computation procedure for bond spread and i-spread measures for the bond FR0000471476 FRTEL 7 12/09. For each day in the sample, the 20<sup>th</sup> of March 2007 in this example, the Svensson model parameters for the AAA-rated eurozone government bonds yield curve were retrieved from the ECB in order to compute the discount factors to apply to the promised cash flows of an equivalent bond and to determine its theoretical risk free price and then its yield ( $y_{RF}$ , that was 3,93% in this case). The SWAP interest rates were downloaded from Bloomberg financial terminal, and interpolated for the maturity of the bond in analysis in the 20<sup>th</sup> of March 2007, 2,76 years. The basis were computed as the respective differences in basis points to the bond yield to maturity in that date, 4,36%.

Date:	20-03-2007	
ECB Svensson Model Parameters		Swap Interest Rate
$\beta_0$	4,2429	2-years 4,1545
$\beta_1$	-0,7780	3-years 4,1265
$\beta_2$	0,3560	
$\beta_3$	-1,3269	
$\tau_1$	0,4377	
$\tau_2$	3,0657	
FR0000471476	FRTEL 7 12/09	Bond Price: 101,1410
		Bond Yield: 4,3553

Table 2 (Continued)

	23-12-2007	23-12-2008	23-12-2009
Cash Flows	7%	7%	107%
TTM (D)	278	644	1009
TTM (Y)	0,7616	1,7596	2,7644
$z(\text{TTM})=r(t,T)$	3,8405	3,8712	3,8398
$B(t,T)$ (discount factors)	0,9712	0,9342	0,8993

  

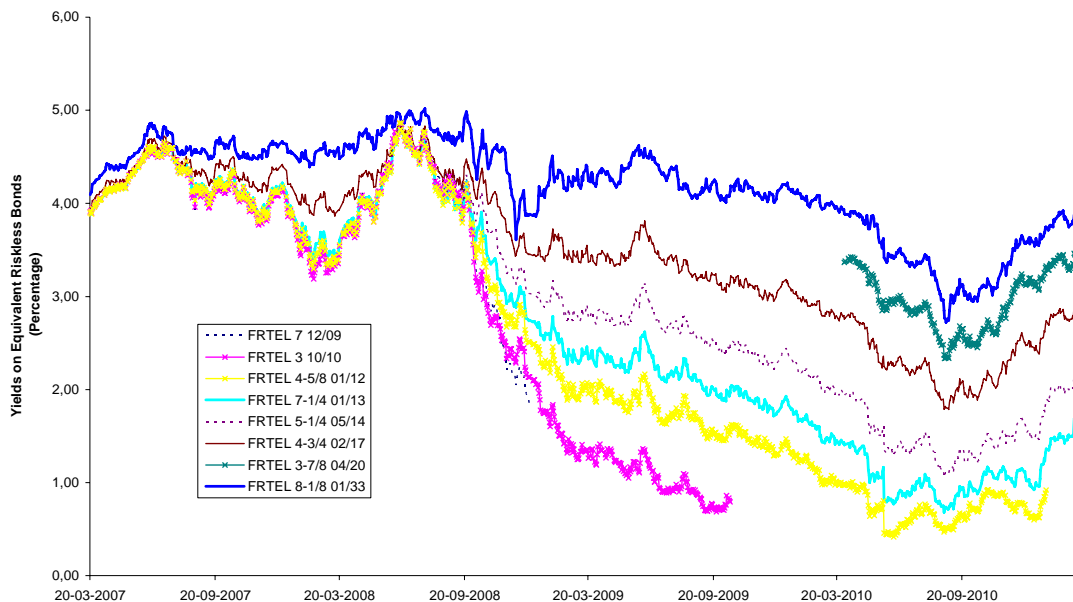

Gross Price <sub>RF</sub>	Settl. Date	Int. Accr. Date	Accr. Int.	Clean Price <sub>RF</sub>
109,5615	23-03-2007	23-12-2006	1,7260	107,8355
$y_{RF}$ (%)	3,9322		Bond Spread (bp)	33,4655
i-swap rate (%)	4,1331		I-Spread (bp)	13,3719

The above procedure was repeated for the remaining bonds in the basket set and for the period in analysis. Figure 2 pictures the evolution of the riskless yield obtained for each bond in the set. As expected the riskless bonds with high maturity presented higher yields during most of the period, especially after the 2008 period. It is remarkable the flattening of the yields that has occurred in June 2008, few months before the Lehman Brothers collapse and great turmoil in financial markets. The short term interest rates were very high.

Figure 2 - Computed yields on equivalent riskless bonds

The pre-crisis period was characterized by the flattening of the yield curve, namely in June 2008.

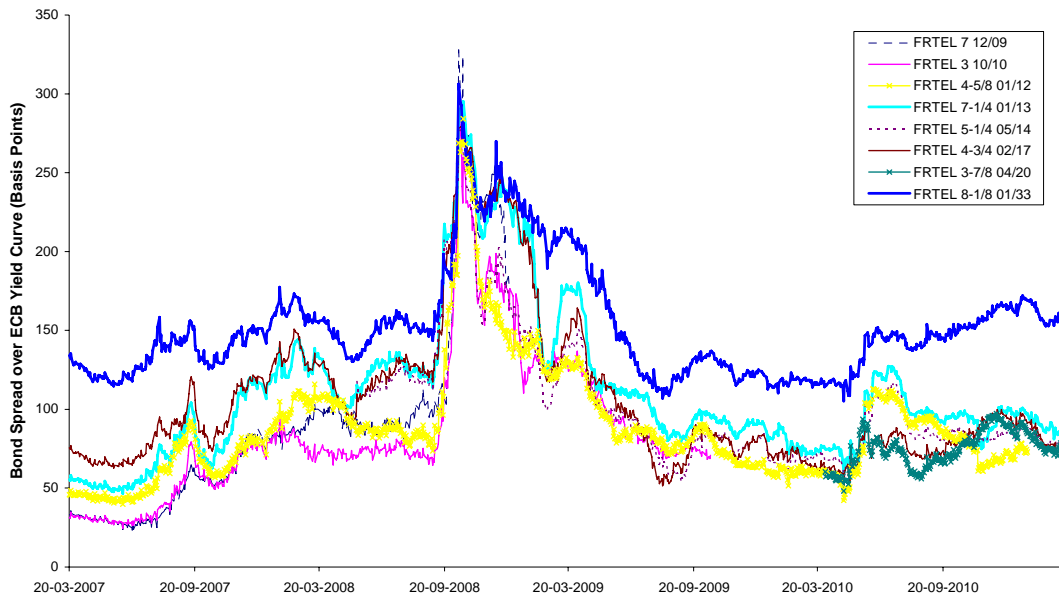

This flattening effect, not as narrow as in the yield curves, has occurred in the bond yields mostly in October 2008, just after the Lehman Brothers collapse in September.

At this point, after some intervention of the authorities lowering the short term interest rates, the shape of the yield curves began to normalize.

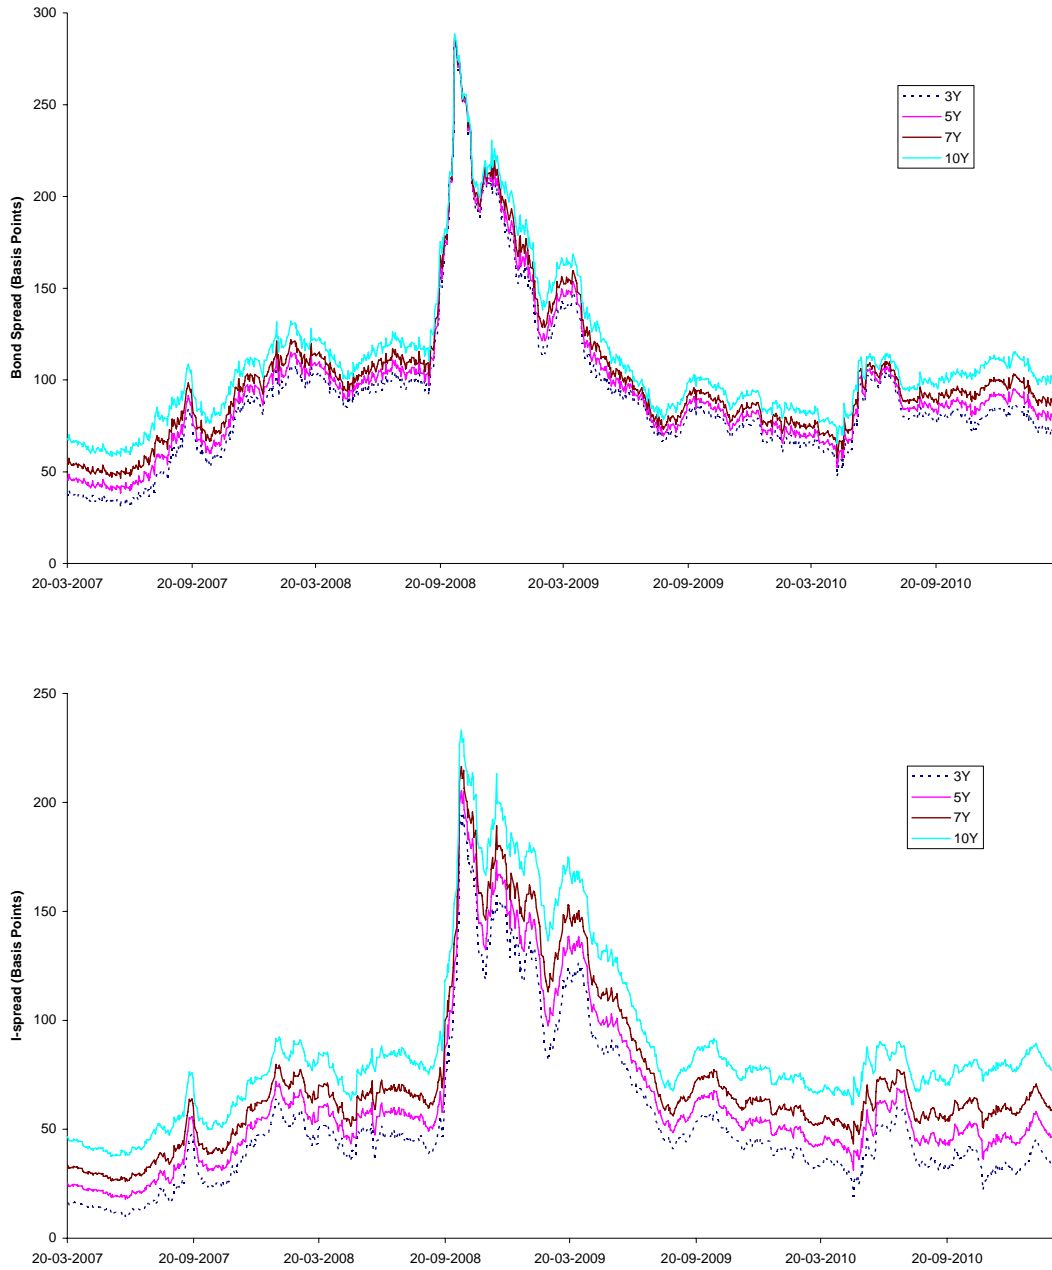

Following Longstaff, Mithal et al. (2005) procedure, Figure 3 presents the corporate yield spread over ECB spot yield curve obtained for each France Telecom bond in the set for the period in analysis. These spreads contained the desired maturities of the CDS.

**Figure 3 - Individual bond spreads (ECB yield curve as benchmark) for each France Telecom selected bonds, from March 2007 to March 2011.**

The next step was to regress them on their maturities in order to obtain four time series to compare with the CDS series on the selected maturities of 3-years, 5-years 7-years and 10-years. Figure 4 (top) presents the obtained results. An equivalent procedure was followed for the i-spread. After interpolating the swap rates for each bond in the basket set and obtained the respective i-spread series, the adjusted curve for the desired maturities were obtained by regression, as also presented in Figure 4 (bottom).

Figure 4 - Corporate spread measures, bond spread on top and i-spread bellow, for France Telecom from March 2007 to March 2011

The basis, which is the difference between the CDS premium (from Figure 1) and corporate spreads (from Figure 4) are presented in Figure 5.

Figure 5 - Corporate basis measures, CDS-Bond basis on top and CDS-i-Spread basis below, for France Telecom from March 2007 to March 2011

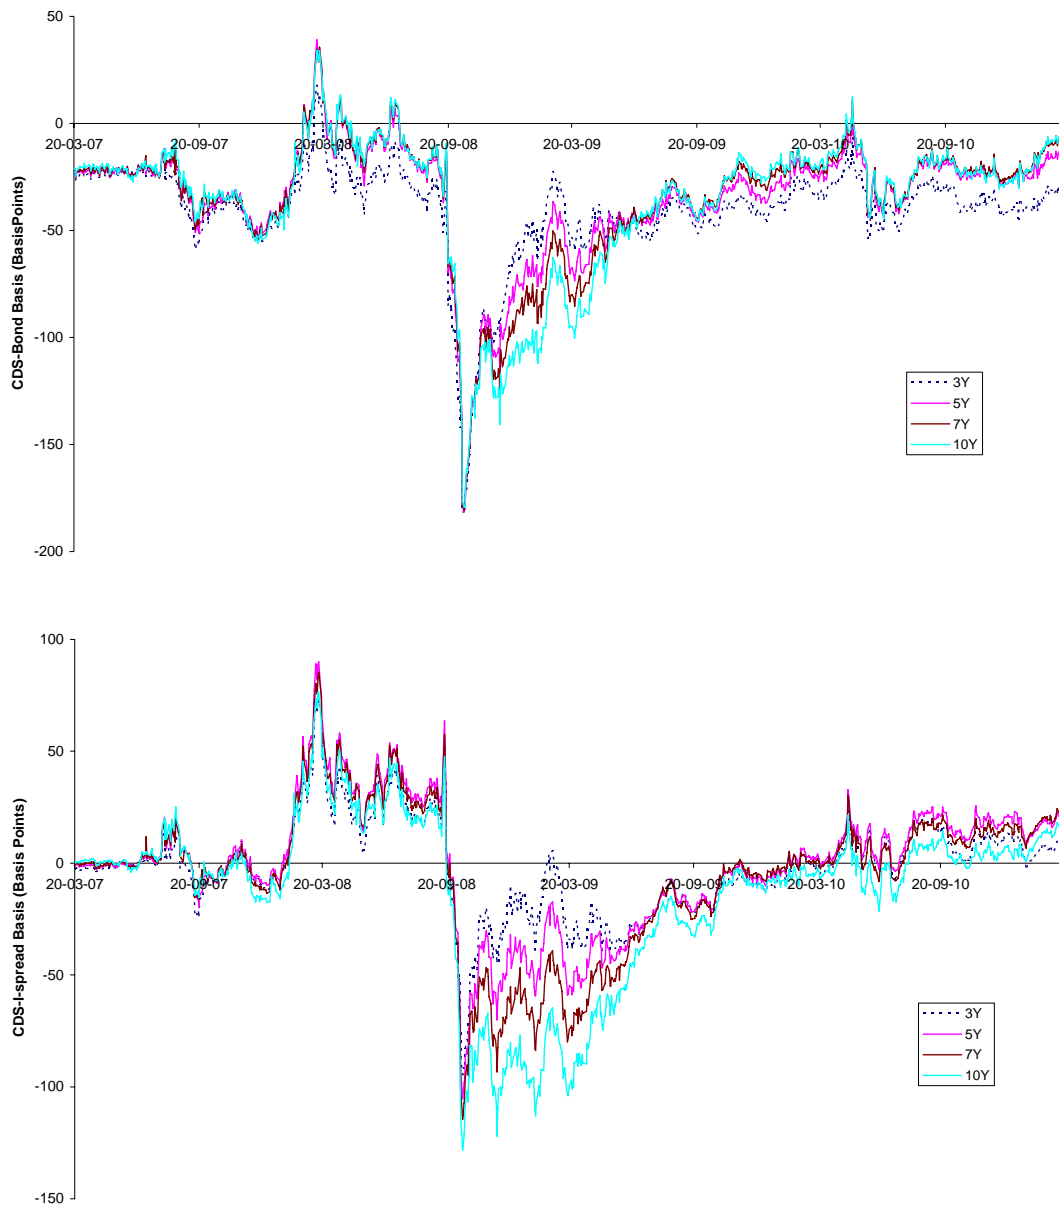

Figure 5 reports the CDS-bond basis essentially negative during the analysis period with a massive decrease in the post Lehman Brothers crisis period. The CDS-i-spread basis exhibited a similar evolution pattern and a consistent average of 30 basis point in addition to the CDS-bond basis. This difference is related to the use of different risk-free rate proxies, as above discussed, and may include, among others, factors like liquidity differences between bonds and swap markets, taxation treatment or repo specialness.

*Counterparty and Liquidity Risk: an analysis of the negative basis*

It is possible then to split the analysis period in four, a pre crisis period in 2007 (up to the end of the year), a crisis period before Lehman Brothers collapse and another after this event in September 2008 and a post crisis period with the markets recovery that began in March 2009. Table 3 presents descriptive statistics for the above discussed variables obtained for France Telecom.

**Table 3 - Descriptive Statistics**

Var.	Period	Term	Mean	Std. Dev.	Minimum	Maximum	Skewness	Kurtosis	Obs
CDS	I	3	20,1918	8,7599	9,7920	41,0710	0,6970	-0,7281	197

In the period I, the CDS premium and the bond spreads were relatively low and the basis measures were at their equilibrium point. The CDS-i-spread basis was near zero, suggesting that the theoretical non arbitrage condition was holding relatively well during this period. The CDS-bond basis was 30bp negative, but this difference may be related to liquidity and other factors as above discussed.

The period II saw a large increase of the CDS premium, leading to what would be the tendency later on for the corporate spread measures, suggesting this leading effect of the CDS prices in its lead-lag dynamics with corporate yield spreads, documented by many authors, including Blanco, Brennan et al. (2005), that argues that price discovery tends

to occur in the CDS market, that leads to some extend corporate spreads in the short term. As a result, the basis, measured with swap benchmark turned into positive territory. Other possible factors that could drive the basis positive is discussed by De Wit (2006), and may include CDS cheapest to deliver option, as in case of default, protection buyers hold a delivery option and are free to choose the cheapest from a basket of deliverable bonds. Protection sellers will tend receive the less favourable option and therefore to increase the CDS premium if this risk increases. He also appoints other factors like bonds trading bellow par and profit realization among others.

Period III documents a large increase in the corporate yield spread measures reflecting in parte the great increase of the default risk that occurred in this period, after the Lehman Brothers collapsed. The level of CDS spreads were not increasing as much as the corporate spreads and the basis became highly negative. Some authors, like De Wit (2006), could argue that the CDS premium was reflecting some of the high counterparty risk that CDS market was experiencing in that period, when banks were not lending to each other on generalized bankruptcy fears, lowering the CDS premium as protection buyers were facing great uncertainty in receiving the defaulted bond value from CDS sellers. Others may find that liquidity scarcity was the major issue driving the basis negative. Probably both factors played a significant role in this case, as well as other factors also pointed out by De Wit (2006) like funding issues and technical factors.

In the period IV it was possible to see some normalization returning to the markets. CDS spreads decreased significantly as a result of strong interventions from the authorities in both providing liquidity and implementing measures to restore confidence on the financial system. One set of measures to reduce systemic risk and improve market transparency was the introduction of the central counterparties (CCP) in securities lending.

### **3.2 Lead-Lag and Long Term Relationship Between CDS and Bond Markets**

The present section will concentrate on the cointegration analysis between the CDS and corporate yield spreads and will evaluate to what extend the lead-lag relationship argued by Blanco, Brennan et al. (2005) held in the period in analysis for France Telecom. This analysis will be conducted within the *Engle-Granger 2 step method* procedure above mentioned and, in the first step, it will be possible to assess weather a cointegrating relationship exists between the two variables.

The variables in hand are, the CDS premium at 3, 5, 7 and 10 years maturities and the correspondent (1) bond spreads and (2) i-spreads. The first step is to test all series for

the existence of a unit root using ADF test<sup>10</sup>. To make sure the order of integration of the variables is I(1), first differences are also tested and, finally, confirmatory analysis is conducted on the variables in levels using KPSS<sup>11</sup> test as above discussed. Table 4 summarises the results of ADF tests and, as one might anticipate, all series contained one unit root. Null hypothesis of a unit root could not be rejected for all variables in levels at 10% level, and was strongly rejected for all variables in first differences. KPSS test confirmed these results, as shown Table 5 for all variables in level.

**Table 4 - Unit root testing**

This table reports the results of ADF test conducted in CDS premium at 3, 5, 7 and 10 years maturities and the correspondent bond spreads and i-spreads. It included up to 1018 observations (sample adjusted from 20/03/2007 to 18/03/2011, depending on the number of lags selected) and the number of lags was selected according to Schwarz Info Criterion. Test regression included a constant for all variables and, because a trend could be identified in the data series under the null hypothesis, a trend for CDS premium at 5, 7 and 10 years, as indicated in specification column [Lags / Intercept (Y/N) / Trend (Y/N)]. \* denotes null hypothesis cannot be rejected at 1% level, \*\* denotes null hypothesis cannot be rejected at 5% level, \*\*\* denotes null hypothesis cannot be rejected at 10% level. <sup>1</sup> denotes MacKinnon, Haug et al. (1999) one-sided p-values.

Therefore, in order to avoid regressing non stationary series, a statistically valid model would be in first differences and, for this model to have a long run solution, a cointegrating relationship (suggested by the theory) should be found first and then it is valid to include this cointegrating term (which is also stationary), along with first differenced terms, in an error correction model in a second step.

### ***Engle-Granger 2 step method***

#### *Step 1: Estimation of cointegrating equation*

This method tests for cointegration in a regression using a residual based approach. For each maturity, the residuals of a standard OLS regression between the corporate yield spread and the CDS spread should be tested for the existence of a unit root. If this residual series can be considered stationary, one can conclude that the two variables are cointegrated. Therefore, the residuals ( $u_t$ ) of the following potential cointegrating equation should be tested:

$$Bonds\ spread_t = \gamma_0 + \gamma_1 CDS_t + u_t \quad (2)$$

If the residuals  $u_t$  can be considered stationary, one can conclude for the existence of a cointegrating relationship between the two variables. In this case, the estimated stationary liner combination of CDS and bond spread,  $\hat{u}_t = bonds\ spread_t - \hat{\gamma}_0 - \hat{\gamma}_1 CDS_t$ ,

is known as the cointegrating term. In this case the cointegrating vector would be  $[1 - \hat{\gamma}_1]$ . The results for France Telecom are given in Table 6.

**Table 6 - Estimated potentially cointegrating equations and residual tests for France Telecom**

This table reports the results of standard OLS regression between corporate yield spreads and CDS prices and the correspondent residual tests using ADF and KPSS tests. The cointegrating equations are  $bondsread_t = \gamma_0 + \gamma_1 CDS_t + u_t$  and  $i-spread_t = \gamma_0 + \gamma_1 CDS_t + u_t$ . Included observations: 1018, from 20/03/2007 to 18/03/2011 for OLS regression and KPSS test (and adjusted for ADF test depending of number of lags included). In ADF tests \* denotes null hypothesis is rejected at 10% level, \*\* denotes null hypothesis is rejected at 5% level, \*\*\* denotes null hypothesis is rejected at 1% level. In KPSS tests \* denotes null hypothesis cannot be rejected at 1% level, \*\* denotes null hypothesis cannot be rejected at 5% level, \*\*\* denotes null hypothesis cannot be rejected at 10% level.

i-Spread	10	37,6447	0,6746	-1,6841	0,4391	unit root***	0,5507	Stationary *	Not Cointegrated

Using the *confirmatory data analysis*, the conclusion from Table 6 is that bond spreads and CDS were cointegrated in the 3-year and 5-year maturity for France Telecom in the period in analysis. The cointegration between i-spreads and CDS only held for the 3-year term. The estimated slope coefficient in the cointegrating equation is close to unity, as expected from theory.

### Step 2: Error correction model

The final step in this framework is to use a lag of the first step residuals,  $\hat{u}_{t-1}$ , in levels, as the equilibrium correction term in the general equation when the cointegrating relation holds (the error correction model), or estimate a model with just differences if not. In the last case it will be a short term model. The overall model is:

$$\Delta(bondsread)_t = \beta_0 + \beta_1 \Delta(bondsread)_{t-1} + \alpha_1 \Delta(CDS)_{t-1} + \delta u_{t-1} + \varepsilon_t \quad (3)$$

The general error correction model allows for actual, t, and lagged terms, t-1, t-2, etc. In the present case, we are specifically interested in the effects of lagged changes of CDS prices, therefore, following one of the approaches described in Brooks, Rew et al. (2001) in the context of spot and futures markets, only one lagged term of the variables are included in the general error correction model. Brooks, Rew et al. (2001) examined the lead-lag relationship between the FTSE 100 index and its futures contract using a

number of models and found that lagged changes in future prices can help to predict spot price changes.

Table 7 reports the coefficient estimates for this model in the case of France Telecom. It is valid to analyse the signals and the significance of the coefficient estimates because all variables in the equation are stationary. Considering first the  $\Delta(CDS)_{t-1}$ , the estimate for  $\alpha_1$  is positive and highly significant for the four analysed maturities. This indicates that CDS do indeed lead corporate yield spreads (both bond and i-spreads as above defined), since lagged changes in CDS prices lead to a positive change in the subsequent corporate yield spread.

**Table 7 - Estimated error correction model for France Telecom**

This table reports the results of standard OLS regression between corporate yield spread changes and lagged CDS changes, including an error correction term when cointegration holds. The equations are  $\Delta(bondspread)_t = \beta_0 + \beta_1 \Delta(bondspread)_{t-1} + \alpha_1 \Delta(CDS)_{t-1} + \delta u_{t-1} + \varepsilon_t$  and  $\Delta(i-spread)_t = \beta_0 + \beta_1 \Delta(i-spread)_{t-1} + \alpha_1 \Delta(CDS)_{t-1} + \delta u_{t-1} + \varepsilon_t$ . Included observations: 1016 after adjustments, from 22/03/2011 to 18/03/2011.

Var.	Term	$\beta_0$	p-value	$\beta_1$	p-value	$\alpha_1$	p-value	$\delta$	p-value	Adj R-Square
$\Delta(\text{Bond Spread})$	3	0,0387	0,7369	-0,0959	0,0029	0,1886	0,0000	-0,0045	0,4131	0,0197
$\Delta(\text{Bond Spread})$	5	0,0363	0,7462	-0,0868	0,0060	0,1668	0,0001	-0,0099	0,0208	0,0242
$\Delta(\text{i-Spread})$	3	0,0135	0,8809	0,1505	0,0000	0,1175	0,0007	-0,0114	0,0078	0,0396
$\Delta(\text{i-Spread})$	5	0,0150	0,8618	0,1706	0,0000	0,1182	0,0002	-	-	0,0408

$\beta_1$  is the coefficient on lagged corporate yield spread. It is also highly significant, indicating autocorrelation in corporate spreads (positive auto correlation in the case of credit spread at 3 year maturity). Finally,  $\delta$ , the coefficient on the error correction term, is negative and significant for bond spread at 5 year maturity and i-spread at 3 year maturity. This means that if the difference between corporate yield spreads and CDS is positive in one period, the corporate yield spreads will fall in the next to restore equilibrium, and vice versa. This dynamic could not be proved for the bond spread at 3 year maturity, as  $\delta$  revealed not significant.

### 3.3 The Determinants of Basis Spread Changes

This section concludes the proposed negative basis analysis by using variables suggested by theory to model the dynamics of the basis spreads changes. In this respect, one can identify two approaches in the literature. If in one hand, some studies, such as Longstaff, Mithal et al. (2005) and Zhu (2006) examines the properties of the basis, after isolating the default component in the first case or directly after computing the difference between CDS and corporate yield spreads in the second, in the other hand, many studies focus on the analysis of the full measure of the corporate spread against

proxies of explanatory variables, namely Collin-Dufresne, Goldstein et al. (2001), Blanco, Brennan et al. (2005), Ericsson and Renault (2006), among others.

Longstaff, Mithal et al. (2005), in line with Elton, Gruber et al. (2001), argue that asymmetry in taxation between corporate bonds and treasuries may explain a portion of the basis, as treasuries are exempted from local and state taxes and corporate bonds are not. Therefore, being CDS purely contractual in nature, CDS premium should not include a tax related component and reflect only the credit risk of the underlying entities. Another possible determinant of non default component appointed by Longstaff, Mithal et al. (2005) is the illiquidity of corporate bonds. Therefore these authors test for tax effects, using coupon rate as proxy and liquidity factors using the following proxies: average bid-ask spread, notional amount (to measure the overall availability), age, time to maturity of selected bonds, among others. They also perform a time series analysis against market liquidity measures. They report to have found evidence that the non default component is strongly related to liquidity measures, while for the taxation issues the results were not conclusive.

Zhu (2006) uses panel data techniques to explain the determinants of basis spread movements, and explanatory variables included lagged basis spreads, changes in CDS spreads, ratings and rating events, contractual arrangements (using dummy variables) liquidity factors (using bid-ask spreads in CDS and bond markets) and proxies for broad market conditions (including equity indexes).

The approach followed by Blanco, Brennan et al. (2005) in this respect has its roots in the work of Collin-Dufresne, Goldstein et al. (2001). They argue that yield spreads on corporate bonds occur for mainly two reasons: the possibility of default and the recovery rate (as the bond holder receives only a portion of the contracted payments, should the default occur). As such, they consider several variables as proxies for default component (namely changes in the spot interest rate, changes in the slope of the yield curve, changes in equity prices, changes in implied volatility) and for recovery rate (which they relate with overall business conditions). Additionally, they also refer to changes in liquidity affecting both changes in corporate spreads and CDS prices (and proxy it with on-the-run/off-the-run spread of long-dated US treasury yields). They use OLS regression individually for each reference entity and cross sectional regressions and pooled estimates.

Another set of articles focus more on liquidity effects on corporate yields. Following the work of Amihud and Mendelson (1986), Bangia, Diebold et al. (1998) provides a more general approach to liquidity risk, developing a liquidity methodology that can be integrated in standard value-at-risk models, referring to the concepts of exogenous

liquidity, associated with general market characteristics, which include measures like conventional bid-ask spread, percentage quoted spread and other spread measures; and endogenous liquidity, connected with specific positions and exposure of one participant due to its own actions. In this respect, a study by Gaspar and Sousa (2010) provides an application of Bangia, Diebold et al. (1998) model to the insurance sector in Portugal, computing the liquidity risk using the percentage quoted spread.

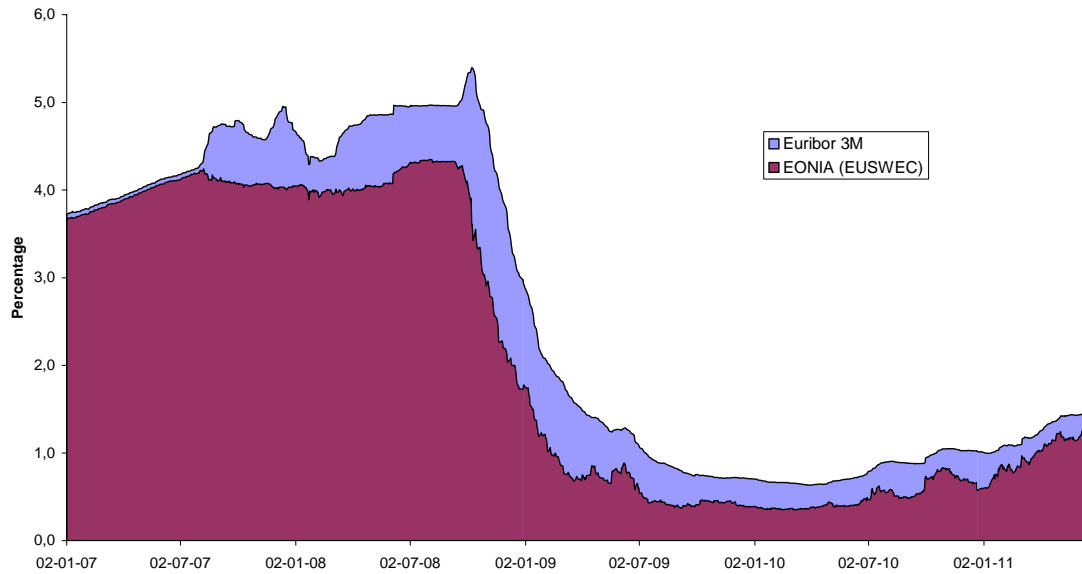

Specific approaches to liquidity in corporate yield spreads include the works of Ericsson and Renault (2006) and Chen, Lesmond et al. (2007), as above discussed. They refer to different proxies for liquidity including bid-ask spreads of corporate bonds.

The above authors mainly focus on the effects of liquidity in bond markets, except for Zhu (2006), which specifically used CDS bid-ask spreads in his analysis. In this respect, another set of recent researches explore in more detail the effects of liquidity in CDS pricing, for example Yan and Tang (2007), that estimated a 20% liquidity premium in CDS prices, Bühler and Trapp (2009) and Fontana (2010), that explored the issue of counterparty risk in CDS markets and included as proxy the Libor-OIS spread (LOIS), arguing that if Libor 3 months is the rate which banks are willing to lend to each other and OIS the overnight rate on a derivative contract generally fixed by central bank and considered risk free in the US, the (widening of) gap between can be considered a measure of risk in the inter-bank lending market, because it reflects what the banks believes is the risk of default in lending to other banks.

Based upon the literature, it is now proposed the following variables to analyse the determinants of basis changes:

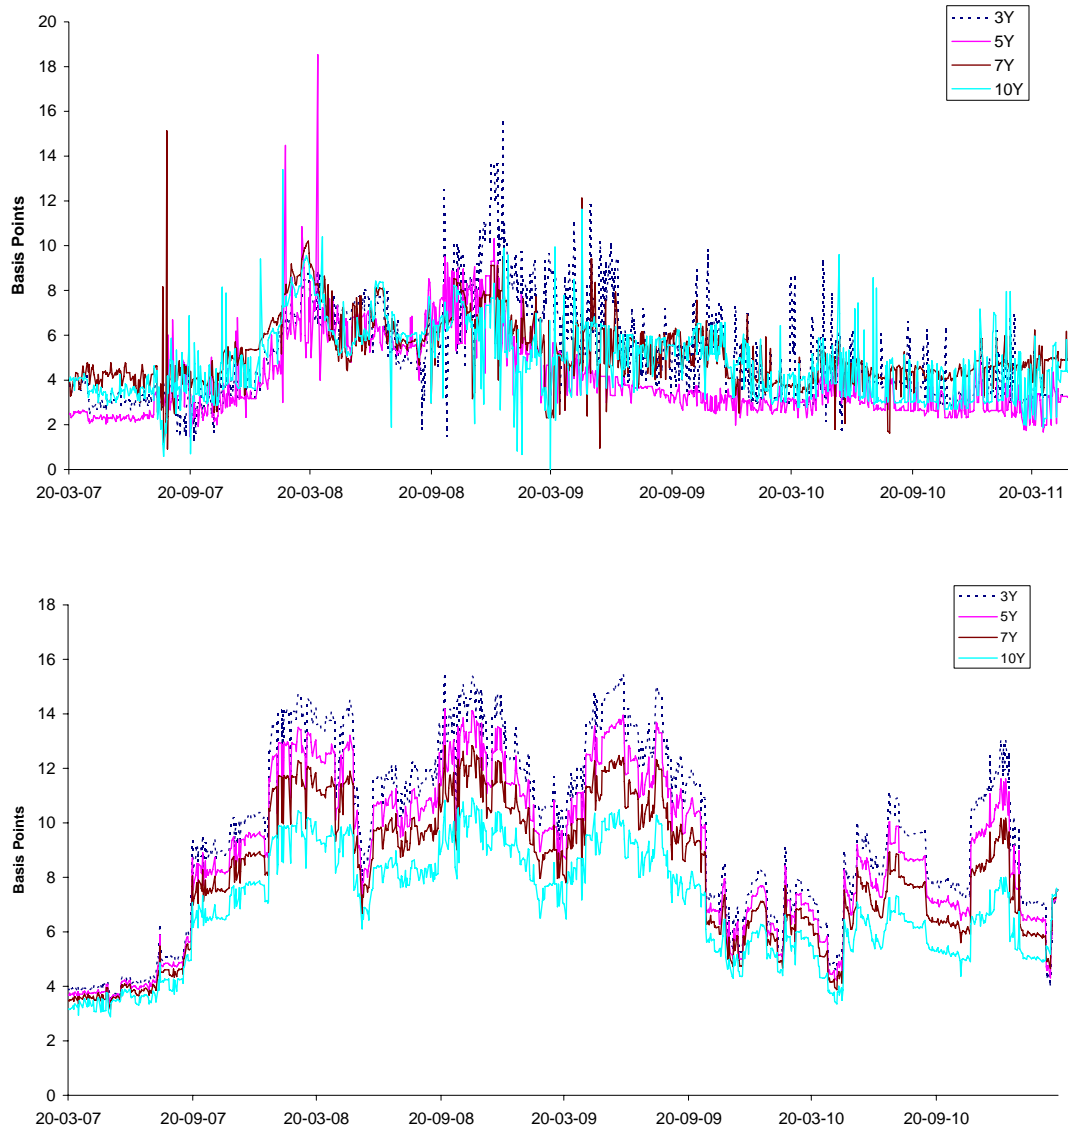

1. *Lagged basis changes*. With this variable it will be possible to evaluate the autocorrelation on the basis changes, specifically, and as stressed in Zhu (2006), being average basis a mean reverting process, a coefficient between 0 and 1 confirms the mean reverting feature (the smaller the faster the speed of adjustment to the long run equilibrium).
2. *Changes in Euribor 3 months – EONIA spread*. This can be considered as the equivalent in Europe of LOIS. As used by Fontana (2010), one can assess the effects of counterparty risk and funding liquidity risk with this variable. Figure 6 shows its evolution in the period in analysis. It is possible to verify a great widening of this spread in the second semester of 2007, from about 6 bp to more than 50 bp. In 2008, after the Lehman Brothers collapse it reach its peak with near 200 bp.

Figure 6 - Euribor-EONIA spread evolution in 2007-2011 period

3. *Liquidity proxies.* In order to assess the liquidity of both markets effects on the basis, the bid-ask spread (BAS) is taken as proxy, as it is not easy to implement other measures (mostly due to the availability of data). In the case of CDS markets, BAS is available from Bloomberg for CDS premium for all maturities. Concerning bond market it is possible find in Bloomberg bid and ask quotations for both bond prices and yields. While some studies average them out and use one measure, there is no reason to believe that this measure is the same for all maturities. In CDS market the 5 year segment tends to be more liquid, and the BAS tends to be smaller. Ericsson and Renault (2006) found support for a downward-sloping term structure of liquidity spreads in corporate bonds. Therefore to measure bond liquidity, it is used bond yield BAS in this study, following the same maturity matching procedure above discussed for the bond spread: computing the BAS spread for each bond in the basket set and regressing them to the desired maturity. Figure 7 illustrates the results for France Telecom case.

Figure 7 - Bid-Ask spreads for France Telecom CDS (on top) and bond yields (bellow)

4. *Market conditions.* In order to assess the effects of general market conditions, three variables are included: a volatility index, which tend to be associated with instability in the markets and with the risk of default (VDAX), an equity index (CAC 40 in this case) and one proxy for the country risk of default (France sovereign CDS at 5 year maturity in this case). After ensuring that all variables are I(1), the following model is applied:

$$\begin{aligned} \Delta(CDS - Bond\_Basis)_t = & \beta_1 \Delta(CDS - Bond\_Basis)_{t-1} + \beta_2 \Delta(EES)_t + \\ & \beta_3 \Delta(BAS^{CDS})_t + \beta_4 \Delta(BAS^{Bond})_t + \beta_5 \Delta(VDAX)_t + \beta_6 \Delta \log(CAC40)_t \\ & + \beta_7 \Delta(CDS^{France})_t + \varepsilon_t \end{aligned} \quad (4)$$

Where  $EES$  denotes Euribor 3 months - EONIA spread and  $\varepsilon_t$  is an error term. Table 8 present the results for France Telecom.

**Table 8 - Regression of basis spreads on counterparty and funding risks, liquidity and broad market conditions proxies for France Telecom**

This table reports the results form regressing the CDS-Bond basis and CDS-i-Spread changes, in basis points, for maturities ranging from 3 years to 10 years, against the proxies of counterparty and funding risks, liquidity and broad market conditions. Included observations: 916 after adjustments, from 22/03/2007 to 18/03/2011.

$$\Delta(CDS-Bond\_Basis)_t = \beta_1\Delta(CDS-Bond\_Basis)_{t-1} + \beta_2\Delta(EES)_t + \beta_3\Delta(BAS^{CDS})_t + \beta_4\Delta(BAS^{Bond})_t + \beta_5\Delta(VDAX)_t + \beta_6\Delta\log(CAC40)_t + \beta_7\Delta(CDS^{France})_t + \varepsilon_t$$

Several findings emerge from Table 8. First, broad market conditions, except for the volatility index in this case, were highly significant in the period in analysis. The equity index had a negative impact on the basis across all maturities and its magnitude was stable. The perceived country risk of default had a positive impact on the basis but its magnitude was much greater in the CDS-Bond basis than in CDS-i-Spread Basis. Some authors may argue that in equilibrium these factors should be equally priced in both CDS and bond markets and therefore these variables should not be significant. Nevertheless, considering the crisis period, these findings supports the idea that in this period credit conditions was not efficiently priced in the two markets (or at least equally).

Second, the counterparty and funding risks, measured by the Euribor-Eonia spread was significant for CDS-Bond basis and with negative impact on the basis. This result suggests that counterparty risk have negative impact in the CDS prices, as the bond

spreads, especially when using government bonds as benchmark, is less sensitive to this risk. This result did not hold entirely for the CDS-i-Spread basis. One possible explanation is that i-spreads uses swap curve as benchmark and swaps, being OTC products, may be more sensitive to counterparty risk than government risk free instruments, as above mentioned.

Finally, lagged basis revealed significant for the CDS-i-Spread basis. Its value is less than 1, suggesting to some extent (this result could not be proven for the CDS-Bond basis) the mean reverting feature expected for the basis (cointegration).

## Chapter 4

### Full Data Set

Having illustrated the general approach with France Telecom, it is now time to extend the analysis to a sample of investment graded firms in the eurozone using an extensive set of data from Bloomberg. This dataset includes CDS mid, bid and ask quotations for 3, 5, 7 and 10 years contracts and a full set of corporate bonds to cover the procedure above described, for the time period from 20<sup>th</sup> of March 2007 to the 18<sup>th</sup> of March 2011. The starting point was the reference entities included in the i-Traxx Europe index, published by Markit. The i-Traxx Europe is a CDS index covering reference entities from Financial, Auto & Industrial, Consumers, Energy and TMT (Telecommunications, Media and Technology), with maturities ranging from 3 to 10 years and with composition reviewed every 6 months. Table 9 summarizes the included data.

**Table 9 - Dataset summary**

This table summarizes the reference entities included in this project. The data covers investment graded reference entities from France, Germany, Italy, Portugal and Spain, and maturities from 3 years to 10 years.

	Sector	Country	Ratings S&P (Jun 2011)	Maturities	Bonds	Obs.

Table 10 also documents higher spreads in period III, post Lehman Brother collapse, in Auto & Industrial and TMT sectors, in Italy, Portugal and Spain and in lower graded entities.

## **Chapter 5**

### **Lead-Lag and Long Term Relationship between CDS and Bond Markets**

This section reports the results for the cointegration and lead lag relationship between CDS and bond markets for the reference entities in analysis. As expected, all series contained one unit root in the period in analysis, as reported in Table A.1 in Appendix.

Considering first cointegration analysis, Table 11 (top) reports cointegration in 7 out of 17 studied cases in the 5 year maturity. Results for the full data set are presented in Appendix, Table A.3. Cointegration held in 33 out of 78, 42% of the analysed cases. Previous papers reported cointegration in more than 60% of the cases. In this respect, Blanco, Brennan et al. (2005) reported cointegration in 70% of the cases, between 02/01/2001 and 20/06/2002, Zhu (2006) reported 62,5%, between 01/01/1999 to 31/12/2002 and De Wit (2006) 61% between 01/01/2004 to 30/12/2005<sup>13</sup>. This lower than expected result may be associated with the fact that the general market conditions are still not fully stabilized, with increasing prospects of an European sovereign debt crisis (March 2011).

The results for the error correction model regression are also presented in Table 11 (bottom) for bond spread in the 5 year maturity, and support the conclusion that CDS spreads leads corporate yield spreads. The estimate for  $\alpha_1$  is positive and highly significant in the great majority of the cases. This is in line with previous studies as Blanco, Brennan et al. (2005) and Zhu (2006) both report that CDS tends to lead bond markets.

---

<sup>13</sup> Blanco, Brennan et al. (2005) studied 33 reference entities between 02/01/2001 and 20/06/2002, Zhu (2006) 24 between 01/01/1999 to 31/12/2002 and De Wit (2006) 144 between 01/01/2004 to 30/12/2005.

## Chapter 6

### The Determinants of the Basis Spread changes

This section reports the results from regressing the basis spread changes on proxies of counterparty and funding risks, liquidity in both CDS and bond markets and general market conditions. Figure 8 plots the time series of the variables in hand for reference entities in the energy sector. It documents an enormous increase of CDS prices for ENEL and Repsol during the 2008 crises, much greater than the increase observed for the other entities in the sector, with direct impact on the basis that was strongly positive in the first case.

Figure 8 – Regressing variables for energy sector

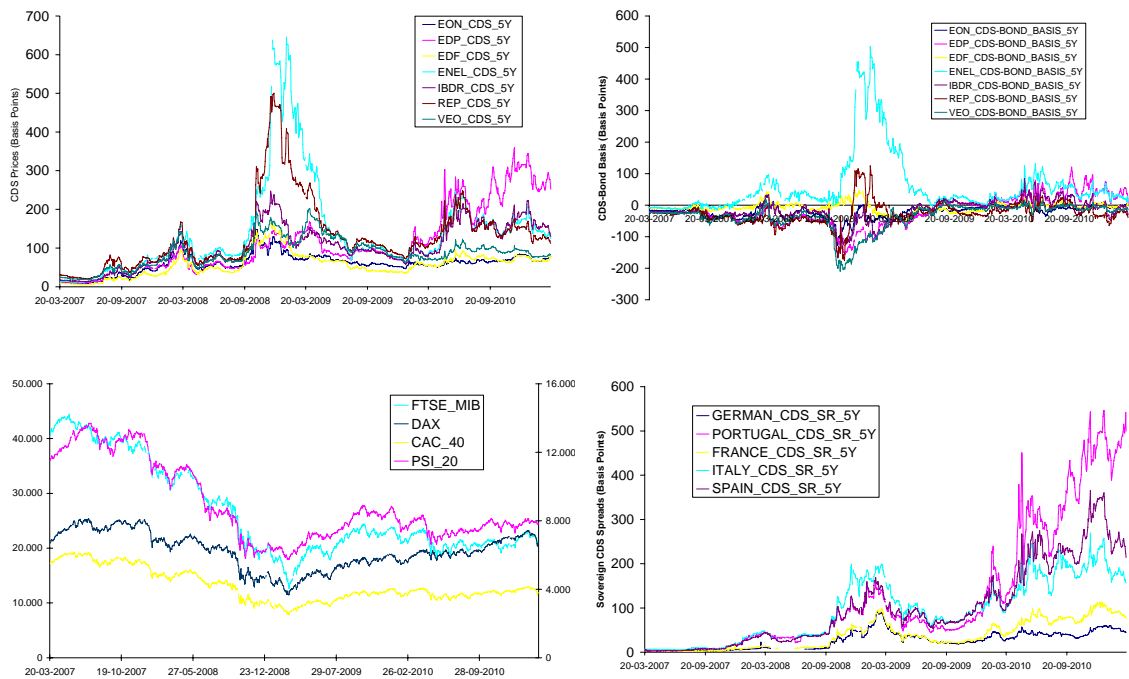

Figure 8 also documents, from 2010, an increase of CDS spreads for Portuguese, Spanish and Italian local energy companies, probably related with the increasing country sovereign CDS spreads also above illustrated.

Table 12 reports the final results for CDS-Bond basis in the 5 year maturity. The equity index and the country perceived risk of default revealed always highly significant and the volatility index in most of the cases, which supports the idea that general credit conditions were not priced efficiently by both markets in the period in analysis (particularly the risk of default, proxied by the volatility index, VDAX, in this case).

*Counterparty and Liquidity Risk: an analysis of the negative basis*

Counterparty and funding risks, proxied by the Euribor – EONIA spread, was significant in nearly 50% of the cases, mostly with the expected signal (negative), as much as the liquidity proxies, mostly in bond markets. Table A.5 in annex presents the results for CDS-i-Spread basis. Counterparty and funding risks revealed significant in approximately 40% of the cases, and liquidity in CDS markets in 65% of the cases.

**Table 12 – Regression of CDS-Bond basis on counterparty and funding risks, liquidity and broad market conditions proxies**

This table reports the results from regressing the CDS-Bond basis, in basis points, for 5 year maturity, on proxies of counterparty and funding risks, liquidity and broad market conditions. Included observations from 20/03/2007 to 18/03/2011.

$$\Delta(\text{CDS-Bond Basis})_t = \beta_1\Delta(\text{CDS-Bond Basis})_{t-1} + \beta_2\Delta(\text{EES})_t + \beta_3\Delta(\text{BAS}^{\text{CDS}})_t + \beta_4\Delta(\text{BAS}^{\text{Bond}})_t + \beta_5\Delta(\text{VDAX})_t + \beta_6\Delta\log(\text{Equity Index})_t + \beta_7\Delta(\text{CDS}^{\text{Sovereign}})_t + \varepsilon_t$$

## **Chapter 7**

### **Conclusions and Future Research**

This project has examined the basis between CDS and corporate yield spreads and how CDS relates with those spreads. Even though significant deviations between the two measures are documented, especially during the crisis period, the analysis confirms the theoretical equilibrium predicted by theory. CDS and corporate bond yields should be on average equal. The error correction analysis performed suggests that cointegration between the two markets broadly holds and indicates that CDS prices do indeed lead corporate yield spreads.

During the analysis period, market conditions significantly affected the basis, as reported in the final regression analysis, both for CDS-Bond basis and for CDS-i-Spread basis, which are reported to be, on average, negative (-21,8 bp) in the first case and close to zero (6,49 bp) in the second between March 2007 and March 2011.

There is evidence that counterparty and funding risks significantly affected the basis, with negative impact in CDS prices and then in the basis, (particularly in the CDS-Bond basis). Liquidity proxies were found to be significant in more than 50% of the cases in the changes of bond basis spreads.

This project mainly focused in the effects of counterparty and liquidity risks in the basis and used *Engle-Granger 2-step method* to analyse cointegration and lead-lag relationship between CDS and bond markets. One of the problems in assessing cointegration in this framework is the lack of power in unit root testing and the impossibility to perform any hypothesis tests on the cointegrating relationship estimated in step 1. One step further would be to use more advanced techniques in this respect, namely the *Johansen method* to study cointegration and *Vector Error Correction Model* and *Granger Causality* to study lead-lag relationship between CDS and bond markets.

Future research could focus in more detailed analysis of differences between the four periods above mentioned in respect to cointegration and basis drivers, or extend the analysis to speculative-graded corporate entities. Different variables could also be used to proxy the basis drivers above discussed, namely the so called *TED spread* as proxy for counterparty risk, and more advanced econometric models, such as the fixed effects framework, could be used to yield better insights regarding the relative importance of the different factors in the basis.

*Counterparty and Liquidity Risk: an analysis of the negative basis*

**Table A. 5 - Regression of CDS-i-Spread basis on counterparty and funding risks, liquidity and broad market conditions Proxies**

This table reports the results from regressing the CDS-i-Spread basis, in basis points, for 5 year maturity, on proxies of counterparty and funding risks, liquidity and broad market conditions. Included observations from 20/03/2007 to 18/03/2011.

$$\Delta(\text{CDS-i-Spread\_Basis})_t = \beta_1\Delta(\text{CDS-i-Spread\_Basis})_{t-1} + \beta_2\Delta(\text{EES})_t + \beta_3\Delta(\text{BAS}^{\text{CDS}})_t + \beta_4\Delta(\text{BAS}^{\text{Bond}})_t + \beta_5\Delta(\text{VDAX})_t + \beta_6\Delta\log(\text{Equity\_Index})_t + \beta_7\Delta(\text{CDS}^{\text{Sovereign}})_t + \varepsilon_t$$
