

Sintra Vegetation and Landscape

Sandra Mesquita*, Pedro Arsénio**, Mário Lousã*, Tiago Monteiro Henriques* & José Carlos Costa*

Fig. 1 – Itinerary of the excursion

The field trip to Sintra region, as part of the 48th IAVS Symposium, aims to illustrate well-preserved and representative plant communities of Sintra municipality. It consists of two short field stops and a 3 km walk (Fig.1).

From a geological point of view, the study area has a matrix of sedimentary rocks, cut by intrusive and extrusive magmatic outcrops.

The older sedimentary rocks of the territory were formed during Superior Jurassic, in marine environment. They correspond mostly to limestone, sometimes with marly levels or dolomite. The Cretaceous deposition environment changed cyclically from marine to fluvial and lacustrine. Thus, there are several limestones, marls, clays and sandstones from this period.

Sintra mountain range is the result of

* Departamento de Protecção de Plantas e de Fitoecologia. Instituto Superior de Agronomia. Tapada da Ajuda 1349-017 Lisboa. Portugal. mesquita.sandra@sapo.pt; mariolousa@isa.utl.pt; tmh@isa.utl.pt; jccosta@isa..utl.pt.

** Secção Autónoma de Arquitectura Paisagista. Instituto Superior de Agronomia. Tapada da Ajuda 1349-017 Lisboa. Portugal. arseniop@isa.utl.pt.

an intrusive event occurred about 80 million years ago, called “Maciço Eruptivo de Sintra” (MES), i.e. Sintra Eruptive Massif. It consists of a syenite nucleus surrounded by a long granite ring, occasionally separated by a band of gabbros and diorite. By means of contact with rocks dating from the Jurassic period, the MES originated a border of contact metamorphism, forming glassy limestone, calcareous schist, etc.

The landscape of the westernmost half of the District is dominated by several small volcanoes of the “Complexo Vulcânico de Lisboa” (CVL) — Lisbon Volcanic Complex. These were formed during the Superior Cretaceous and the beginning of the Tertiary periods, expelling lava flows and pyroclastic materials in alternate fashion. The resulting basalt complex sits on top of the limestone of the Upper Cretaceous period (Turonian).

Also dating from the Tertiary period, some sites of conglomerates with elements of variable nature and size, and also limestone and clays of deposition in marine environment can be found.

Finally, there are some areas of sand and shingle of ancient beaches and fossil dunes from the Pleistocene, as well as mobile dunes from the Holocene.

The meteorological stations located in Sintra municipality are classified as Oceanic Pluviserotinal Mediterranean Macrobioclimate. Most of the region falls into Upper Thermomediterranean thermotype, with the exception of the Sintra mountain range, which is classified in the Upper Mesomediterranean thermotype. As for the ombrotype, the majority of this territory is Lower Sub-humid, with the exception, once again, of the Sintra mountain, which belongs to the Upper sub-humid ombrotype, and of a small northern coastal area, which belongs to Dry Upper ombrotype.

Sintra municipality has been under intense human influence since historical times – which is shown by the countless roman, visigothic and medieval remains currently exhibited in the Museum of “São Miguel de Odriñhas”. This area was essentially rural until mid 20th century, with exception of the mountain, which has been for long a summer leisure destination for nobleman and the bourgeoisie. Parks and gardens with exotic ornamental vegetation, palaces and glass-houses are abundant in the mountain range. The Palace and the Park of Pena, built in the 19th century by D. Fernando II, dominate the mountain landscape and are an example of romantic architecture of Sintra.

During the second half of the 20th century, Sintra suffered an intense urban development as a result of the expansion of Lisbon suburbs.

Due to this development, natural vegetation was fragmented and confined to marginal positions in hedges, rocky grounds not suitable for agriculture and inaccessible areas.

Recently, agricultural set aside allowed natural vegetation to re-occupy some of areas formerly ploughed. Therefore, the lower stages of vegetation succession recover nowadays in significant areas. The mature stages – mainly climatophilous woodlands – are very rare and only small nuclei in areas less favorable to the urban expansion remain. As well as coastal areas, which still have well preserved natural vegetation.

This field trip is divided in two parts. In the morning we will visit an example of the most common vegetation series in the area, developing on limestone substrata. The places visited are included in the Olissiponean Super-District (Dividing Portuguese Sector) and Upper Thermomediterranean Lower Subhumid bioclimatic belts.

This vegetation mosaic corresponds to the potential and seral stages of the series *Arisaro clusii-Querco broteroi sigmetum* (figure 3). It is a characteristic and endemic series of limestone territories of the Center West of mainland Portugal. The mature stage is a Portuguese oak woodland — *Arisaro clusii-Quercetum boteroi*.

This woodland frequently exhibits an herbaceous border, the community *Leucanthemo sylvatici-Cheirolophetum sempervirentis*, which also occupies small clearings in the woods where the sunlight is able to penetrate, as opposed to under closed crown cover where is shady and few plants thrive.

This series also includes a wild plum prickly high shrub hedge, *Rubo ulmifolii-Prunetum insititoidis*, an endemic community. Nowadays, well preserved *Quercus faginea* subsp. *broteroi* woodlands are rare and, therefore, it is uncommon to find wild plum hedges in their typical seral position. These communities have, however, a huge development as separation fences of agricultural fields, and therefore are very common in this territory.

In wetter and deeper soils, the wild plum community is replaced by a laurel hedge — *Vinco difformis-Lauretum nobilis*. This laurel thicket is not very common, appearing typically in hedges close to streams or near rocky and North faced rock walls, shady and often with small water springs.

The first seral stage of this oak woodland is a high scrub, also endemic to the Center West of Portugal, *Bupleuro fruticosae-Arbutetum unedonis*, dominated by strawberry trees and other tall shrubs, such as *Phillyrea latifolia*, *Viburnum tinus* and *Phillyrea angustifolia*.

The second substitution stage is a kermes oak thicket, *Melico arrectae-Quercetum cocciferae*, a dense high shrub community dominated by kermes oak. This is a very common community in the study area. When the anthropic successional pressure (usually cutting or fire) in dry and rocky places ceases for enough time, this community may not evolve again to the terminal stage of the ecological succession, but instead to a wild olive tree woodland (*Olea europaea* var. *sylvestris*). This is a version of the kermes oak thicket, co-dominated by tall wild olive trees, forming part of secondary woodland. This woodland may eventually evolve to the following stages of succession or become permanent.

The next seral stage is a meadow of perennial grass dominated by *Brachypodium phoenicoides* — *Phlomido lycnitidis-Brachypodietum phoenicoides*. Tall grasses dominate this community, allowing a complete covering of the soil all year round.

Finally, the endemic gorse thicket *Salvio sclareoides-Ulicetum densi* stands for the last perennial stage in the successional process in thin soils. This gorse thicket occurs frequently in a mosaic pattern with the two stages described above, associated to recurring but not very intense wildfires.

This series includes an annual plant community of *Helianthemetea guttati* vegetation class, as an extreme regression stage.

In the afternoon, a walk over sea-cliffs is planned. We will pass through several types of coastal vegetation, firstly on limestone cliffs, then on granite cliffs (figure 2). This walk begins in the Olissiponean Superdistrict and enters the Sintranean Superdistrict (both in the Dividing Portuguese Sector). The frontier between the Upper Thermomediterranean Lower Sub-humid belt and the Lower Mesomediterranean Upper Sub-humid belt will be crossed later in the day.

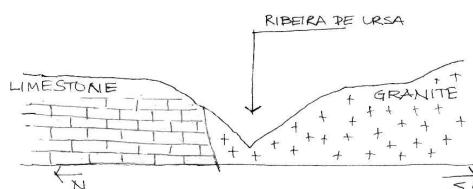

Fig. 2 – Schematic lithological profile of the local coastal cliffs

one series, of which the only climactic stage is a juniper *cocciferae-Juniperetum turbinatae*.

The microgeoseries is formed by a community of herbaceous perennial plants adapted to the extreme habitat conditions in the steep sea cliffs. This community develops on rocks, under the influence of strong salty winds (i.e. splashed by marine salt spray). On limestone (or sandstone) cliffs occurs a community of *Limonium* spp. — *Limonietum multiflori-virgati* (figure 4). On substrata other than limestone, namely syenite, granite or basalt, appears a community of roman carnations (*Armeria pseudarmeria*) and rock carrots (*Daucus halophilus*) — *Diantho cintrani-Daucetum halophili*, endemic to Sintra (figure 5).

On the other hand, in the cliff platform, over thin soils, thrives the juniper / kermes oak series - *Querco cocciferae-Juniperetum turbinatae sigmetum* that presents two successional facies. In limestone substrata, this series has as serial stages the gorse thicket *Salvio sclareoidis-Ulicetum densi*, variant of *Daphne maritima*, and a *Brachypodietum* meadow, *Phlomido lychnitidis-Brachypodietum phoenicoides* (figure 3). In non-calcareous substrates a different successional facies is present, which has as first serial stage a maritime gorse thicket of *Ulex jussiaei*, *Daphno maritimi-Ulicetum congesti*, followed by a perennial grassland of *Stipa gigantea*, *Avenulo sulcatae-Stipetum giganteae* (figure 5).

Both successional facies have as regressive stages extreme communities, which are annual pioneers of the class *Saginetea maritimae*.

Sintra municipality exhibits two types of maritime cliffs, according to the type of rock in which they are cut. This fact is paramount to differentiate distinct complexes of plant communities.

However, the vegetation structure is similar in both cases. It is a fairly simple geo-complex formed by a microgeoseries with only one community and a geoseries with only

1st Stop: Cabeceiras da Ribeira de Cabrela (Alcolombal)

This place has one of the few *Quercus faginea* subsp. *broteroi* woodland that can still be found in the District of Sintra (*Arisaro clusii-Quercetum boteroi*). The understory of oak woodland is nevertheless poorly preserved since it has been used for grazing. However, one can find the species associated to this mediterranean oak woodland, namely climbers — *Smilax aspera*, *Hedera maderensis* subsp. *iberica*, *Rubia peregrina*, *Rosa sempervirens*, *Lonicera implexa* — and shade-loving herbs or shrubs — *Viburnum tinus*, *Coronilla valentina* subsp. *glaucia*, *Ruscus aculeatus*, *Iris foetidissima*, *Vinca difformis*.

It is also possible to observe some hedge communities, in mosaic pattern with the oak woodland: a laurel thicket (*Vinco difformis-Lauretum nobilis*), like the one next to the rock wall that limits the woodland, and a tall-forb community (*Leucanthemo silvatici-Cheirolophetum sempervirentis*).

Some of the seral stages of the oak woodland can also be found in a slope that was most likely burnt down a few years ago. Namely a perennial grassland — *Phlomido lychitidis-Brachypodietum phoenicoides* — can be seen in the lower portion of the slope, which nowadays is used for grazing. Also a dense kermes oak woodland — *Melico arrectae-Quercetum cocciferae* — in the upper part,

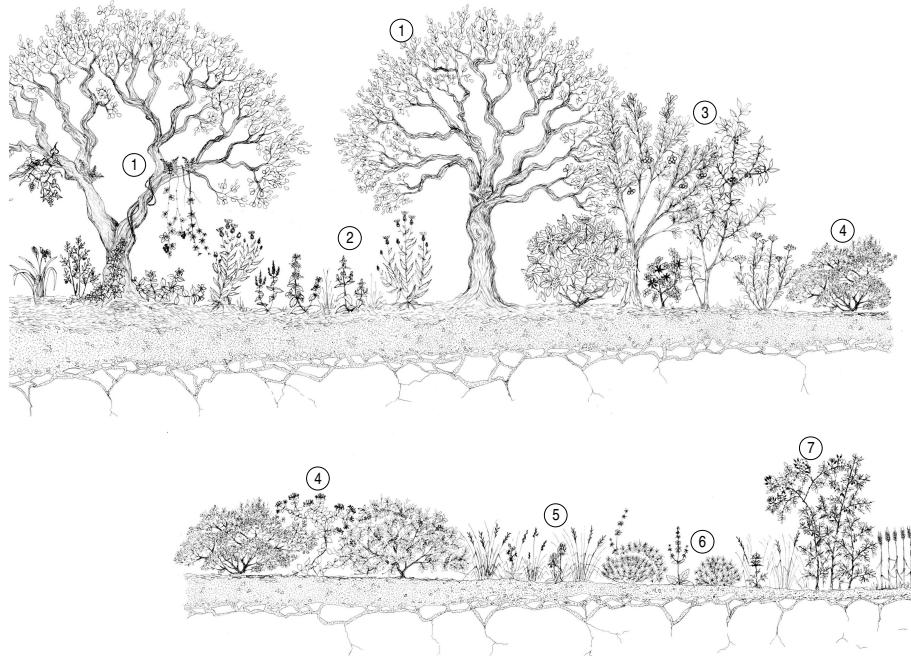

Fig. 3 – *Arisaro clusii-Querco broteroi sigmetum*: 1 *Arisaro clusii-Quercetum broteroi*; 2 *Bupleuro ruticosae-Arbutetum unedonis*; 3 *Leucanthemo silvatici-Cheirolophetum sempervirentis*; 4 *Melico arrectae-Quercetum cocciferae*; 5 *Phlomido lychitidis-Brachypodietum phoenicoides*; 6 *Salvio sclareoides-Ulicetum densi*; 7 *Rubo ulmifolii-Prunetum insititiodis*

Mesquita & al.

dominated by *Quercus coccifera* and *Pistacia lentiscus* is present.

The path crosses a small stream with rocky banks and bed with some riverside vegetation, although poorly preserved. A community of tamarisk (*Polygono equisetiformis-Tamaricetum africanae*) develops in the rocky banks, where the characteristic habitat conditions of temporary streams of the driest Mediterranean territories are partially reproduced. Contacts with the alluvial terrace — in which the natural vegetation was destroyed and replaced by agricultural fields — traces of ash tree woodlands (*Ficario ranunculoidis-Fraxinetum angustifoliae*) or its most common seral stage — hygrophilous bramble thicket (*Lonicero hispanicae-Rubetum ulmifoli*) can be observed.

2nd Stop: Moinhos da Torre

In this site, a community of *Salvio sclareoidis-Ulicetum densi*, gorse thicket dominated by *Ulex densus* — species endemic to Portugal — can be observed. The potential distribution area of these gorse thickets is limited to the limestone soils of the Dividing Portuguese Sector, but the majority of its current occurrence area is in Sintra region. This gorse thicket forms a mosaic pattern with the perennial grassland *Phlomido lychnitis-Brachypodietum phoenicoides*.

3rd Stop: Walk between Adraga Beach and Roca Cape

This walk begins in the limestone cliff next to Adraga beach, stretching through the abrasion platform, amongst communities of *Querco cocciferae-Juniperetum turbinatae* dominated by *Juniperus turbinata*, *Quercus coccifera* and *Phillyrea angustifolia*. In the steep cliffs over the sea, communities of *Limonietum multiflori-virgati* can be observed.

Further ahead, a mosaic pattern of juniper community with gorse thicket of *Ulex densus* — *Salvio sclareoidis-Ulicetum densi*, variant of *Daphne maritima*, pillow-shaped communities few centimeters high, can be observed. Occasionally, in small patches of sand, one can also see communities of *Armerio welwitschii-Crucianellietum maritimae*, with *Helichrysum picardi*, *Armeria welwitschii* and *Ononis ramosissima*.

Nearly halfway through the walk, we start the descent to Ribeira da Ursa valley. This is a very small valley with steep slopes, cut in the cliff by a stream. Half way through the descent, the limestone changes into granite and correlative vegetation change also follows.

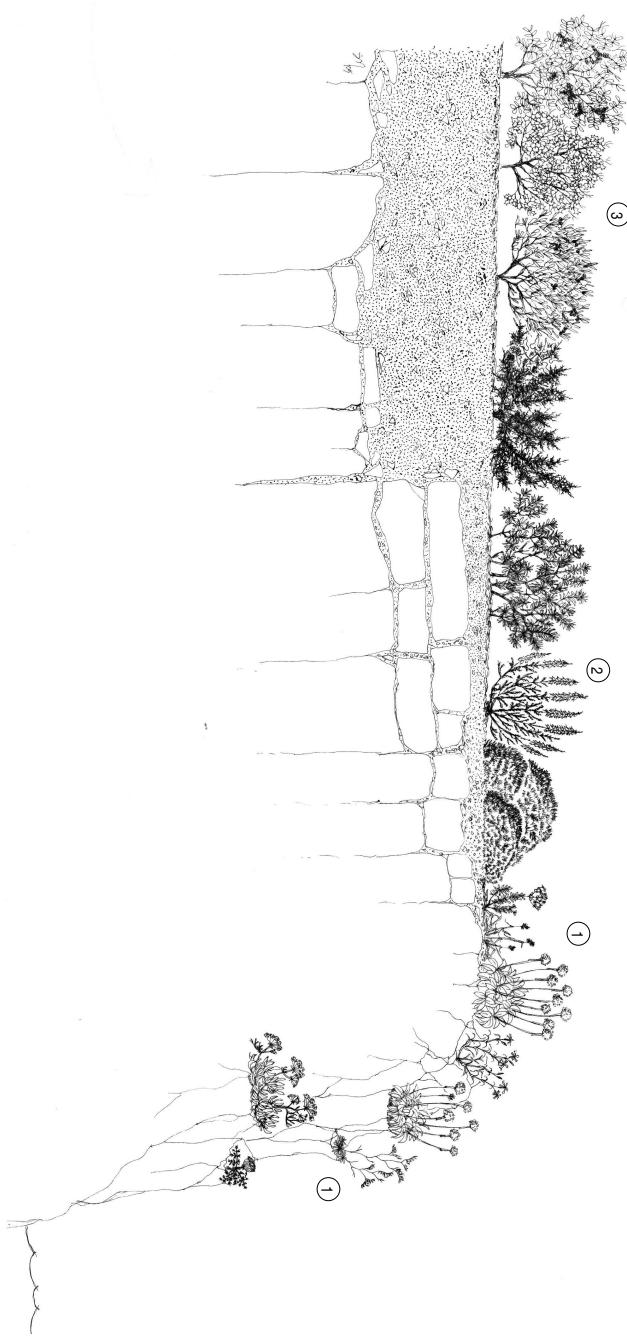

On the slope above the beach, one can see the communities *Diantho cintrani-Daucetum halophilii*, local endemic vegetation — i.e., from the seacoast Sintranean Superdistrict. We emphasize the presence of *Dianthus cinranus* subsp. *cinranus*, *Armeria pseudarmeria*, *Limonium virgatum* and *Daucus halophilus*.

Climbing to Roca Cape, the seral stages of the juniper community in acid plutonic substrata can be observed: the gorse thicket of *Ulex jussiaei* — *Daphno maritimi-Ulicetum congesti* — and the perennial grassland *Avenulo sulcatae-Stipetum giganteae*.

Fig. 4 – Adraga limestone cliff: 1 *Limonietum multiflori-virgati*; 2 *Armerio welwitschii-Crucianellietum maritimae*; 3 *Salvio sclareoidis-Ulicetum densi* variant of *Daphne maritimae*; 4 *Querco cocciferae-Juniperetum turbinatae*

Fig. 5 – Ursa granitic cliff. 1 *Diantho cinnamomei-Daucetum halophilii*; 2 *Daphno maritimi-Ulicetum congesti*; 3 *Querco cocciferae-Juniperetum turbinatae*

In the last stretch of the route, already on syenites, this vegetation is enriched by the presence of shrubby individuals of pyrenean oak (*Quercus pyrenaica*).

The walk ends close to Roca Cape, an outstanding 142 meter high headland above the Atlantic Ocean, in the most westerly place of Continental Europe.

Synthetic tables and relevees of the most representative communities are presented below:

Synthetic table of *Arisaro clusii-Quercetum broteroi* Br.-Bl., P. Silva & Rozeira 1956 (*Quercetea ilicis, Quercetalia ilicis, Quercion broteroi, Quercenion broteroi*) from LOUSA et al. (1994), 11 relevees:
