I dedicate this work to my
father who hasn't had the
chance to see me finish it.

Acknowledgments

This is the final step from a journey that I choose to be my life. During this journey, many people positively interfered, so here is my acknowledgment to all of them.

Firstly, to my parents that always encouraged me to follow my dream and made everything possible for me to achieve it. I need to make a special reference to my father that made me the man I am today and always wanted me to be successful, so this is for you.

Secondly, to Doctor Turlough Mc Nally, my co-supervisor, for accepting me at Anglesey Lodge Equine Hospital and for setting a great example of professionalism. I am really grateful for all the help with this work. It was an honor.

To Prof. Doctor José Paulo Pacheco Sales Luís, my supervisor, for supervising my work and for creating the enthusiasm that I have now for surgery.

To all my family, for supporting me along the way and gave me the strength that was decisive to finish this work.

To Carolina Temtem (a.k.a Mamã Coirão) for supporting my decisions and for being there as a true friend helping me every time I needed.

To all my friends at Almeirim, especially Inês and “Toon” for all the good advices along these six years.

To Doctor Paula Tilley for all the knowledge transmitted during my training period at Equine Hospital, Faculty of Veterinary Medicine, University of Lisbon (FMV-ULisboa) and along the degree.

To Dr. Joana Simões and Dr. Adriana Alberto for welcoming me at Equine Hospital, Faculty of Veterinary Medicine, University of Lisbon (FMV-ULisboa) and made me feel part of the team.

To all the remaining staff at Anglesey Lodge Equine Hospital, especially to Kirsty who received me at her home and made me feel at home in Ireland during the training period.

Also to Dr. Telmo Nunes for all the patience and help during the statistical analysis of this work. Without your help the results of this work would never be possible.

Abstract

Performance evaluation in Irish racehorses with dorsal displacement of the soft palate following the laryngeal tie-forward procedure

The horse races are a very important money income in Ireland, being required that the racehorses show the full potential at the races. The dorsal displacement of the soft palate (DDSP) is a common cause of poor performance and exercise intolerance in racehorses being the laryngeal tie-forward procedure the surgical technique with the highest success rate on the correction of this condition. A performance evaluation study was performed to evaluate the significance of the laryngeal tie-forward procedure for correction of DDSP in racehorses.

The race performance data was collected for the horses ($n = 16$) and the effect of surgery on racing performance, the effect of recovery time in earnings and the difference of the earnings by sex and age were analyzed.

The racing performance improves after surgery ($P = 0,0138$), with an increase in the earnings three times the baseline value four races after surgery.

The laryngeal tie-forward procedure corrects DDSP, increasing the race performance above the baseline value.

Key words: racehorses, DDSP, race performance, laryngeal tie-forward, earnings.

Resumo

Avaliação da performance desportiva em cavalos de corrida irlandeses com deslocamento dorsal do palato mole após a realização de cirurgia para movimento rostral da laringe

As corridas de cavalos são uma grande fonte de riqueza na Irlanda, sendo importante que os cavalos de corrida apresentem o potencial máximo durante as corridas. O deslocamento dorsal do palato (DDP) é uma causa comum de diminuição da performance e de intolerância ao exercício em cavalos de corrida, sendo a cirurgia para movimento rostral da laringe a técnica cirúrgica com maior taxa de sucesso no tratamento desta condição. Foi realizado um estudo para avaliar a significância da cirurgia para movimento rostral da laringe para correção de DDP na performance desportiva.

Os dados da performance desportiva foram recolhidos para todos os cavalos ($n = 16$) e foi analisado o efeito da cirurgia na performance desportiva, o efeito do tempo de recuperação nos ganhos monetários e a diferença dos ganhos monetários por género e idade.

A performance desportiva melhora após a cirurgia ($P = 0,0138$), aumentando os ganhos monetários três vezes o valor base, quatro corridas após a cirurgia.

A cirurgia para movimento rostral da laringe corrige o DDP, aumentando a performance desportiva para valores superiores ao valor base.

Palavras-chave: cavalos de corrida, DDP, performance desportiva, movimento rostral da laringe, ganhos monetários.

Training period activities

In the last year of the integrated masters in veterinary medicine, the author took a training period of approximately six months in two different locations – at the Equine Hospital, Faculty of Veterinary Medicine, University of Lisbon (FMV-ULisboa) from 20th October to 21st December 2013; and at Anglesey Lodge Equine Hospital – Ireland, the latter under the LLP/Erasmus Program, between 6th January to 20th April 2014. The training period was supervised by Prof. Doctor José Paulo Pacheco Sales Luís (FMV-ULisboa) and co-supervised by Doctor Turlough Mc Nally (Anglesey Lodge Equine Hospital).

During the first part of the training period, held in Lisbon, the author followed two veterinarians in the routine activities of the Equine Hospital. In this period, it was possible to help with the diagnosis/evaluation of osteoarthritis lesions in Lusitano horses of the Portuguese School of Equestrian Art, doing lameness examination to establish what was the affected limb or to evaluate if the horse was improving with the treatment. The lesions were evaluated using radiography and ultrasonography.

In the Equine Hospital it was possible to follow a case of a donkey with a bite from a dog (Figure 1).

Figure 1: A: Joint lavage of the carpal joint (original); B: Abscess drainage on the left thoracic limb (original); C: Penrose drain placed at the abscess site (original); D: Canine tooth fragment removed from the left thoracic limb (original).

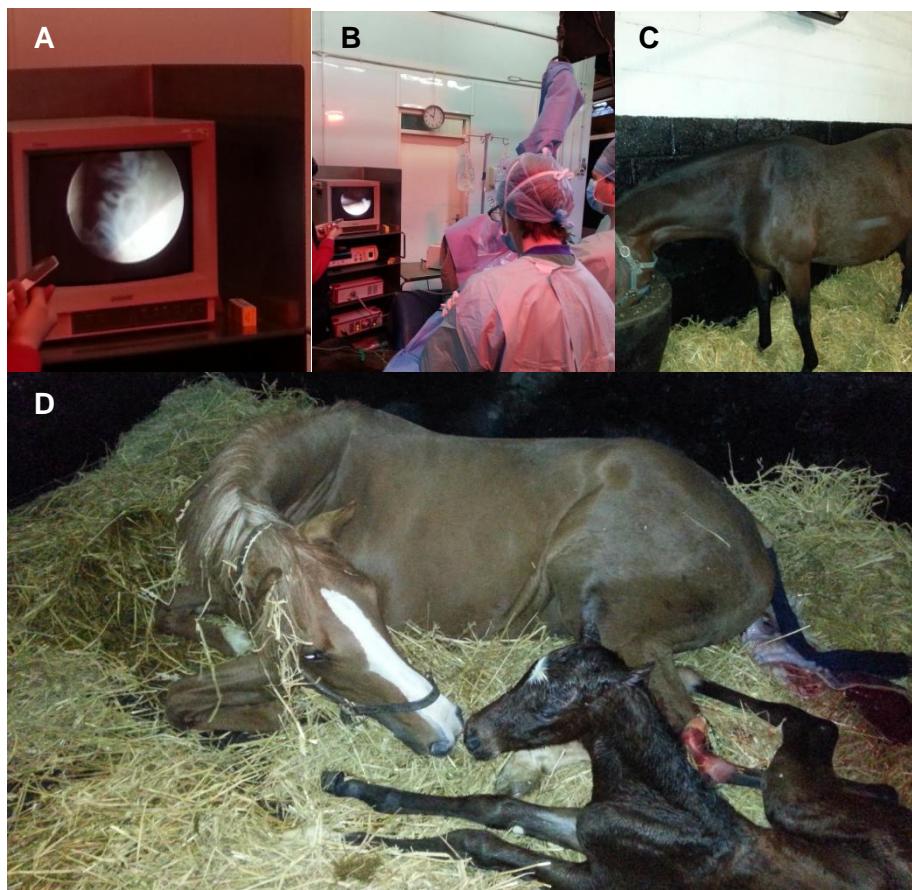

The author also followed a case of a filly with a fracture of the second phalanx of the left pelvic limb, being the evolution of the fracture line evaluated using radiography. Twice a day was made a cooling bath in the hoof and fetlock to decrease the temperature of the affected limb, managing the inflammatory process in the fracture site.

Another case followed by the author at the Equine Hospital was a corneal ulceration in a male horse probably caused by a foreign body. Antifungal, antimicrobial, anti-inflammatory and atropine eye drops were done to help with the healing of the ulcer. For a better adherence of the corneal epithelium during the healing process, a grid was made in the corneal stroma.

In Anglesey Lodge Equine Hospital, the author gathered all the cases that were used in the work presented in this document. In the first weeks, the author was introduced to the routine procedures done in the hospital and integrated in the staff schedule for the daily rotations between surgery, imaging and hospitalized horses. The training period was during the foal season, so most of the medicine cases that the author was exposed to were pregnant mares with placentitis and neonatology cases of prenatal asphyxia and the surgery cases were mostly upper airway laser surgery and joint lavages with arthroscopy (Figure 2).

Figure 2: A: Sinovial cartilage image during arthroscopy (original); B: Joint lavage with arthroscopy (original); C: Pregnant mare with placentitis (original); D: Newborn foal from a mare with placentitis (original)

The author also had to do night rotations following one of the interns of the Anglesey Lodge Equine Hospital.

During the hospitalized horses rotation, the author had the opportunity to follow a case of thromboembolism in the external iliac artery, confirmed by rectal ultrasonography. Also had the opportunity to follow one foal with one abscess in the left eye, being treated with antimicrobial collyrium twice a day.

During the surgery rotation, the area to which the author was more exposed was the upper respiratory surgery, being the most common pathologies the DDSP and laryngeal hemiplegia. The author also had the opportunity to follow two cesareans of which only one foal survived, being necessary to do cardiopulmonary resuscitation to the survival foal. In the orthopedic area, the most common pathology that the author was exposed to was osteochondral fragments that were removed with arthroscopy.

The foaling season made that the majority of the medicine cases were foals and pregnant mares needing intensive care also during the night. The author, during the night rotations, was exposed to neonatal intensive care in foals with prenatal asphyxia syndrome, being necessary to give parenteral nutrition and to control the glicemic value, being necessary in some foals to start the administration of insulin. During the night rotations, the author also had the opportunity to help in a dystocic foaling.

1. Introduction

The horse races are a very important money income in Ireland, being the racehorses very valuable. Therefore, is very important that the racehorses show the full potential at the races, being the performance evaluation a key point for the veterinarians (UCD Dublin - School of Agriculture and Food Science, 2012).

The sports performance is the result of the interaction of several physiologic systems, being the dysfunction of one that decreases the sportive capacity of the horses (Franklin S. & Allen K., 2008).

The respiratory system is fundamental for the horse's performance, once a good oxygen supply is essential for a proper muscular function (Marlin D. & Nankervis K., 2002).

The limiting factors for the sports performance vary with the type of exercise done by the horse, being a small obstruction of the upper airways a major problem in racehorses (Hinchcliff & Geor, 2008).

The dorsal displacement of the soft palate (DDSP) is a common cause of poor performance and exercise intolerance in racehorses (Ainsworth & Cheetham, 2010), being this the main reason for choosing the theme of this dissertation.

There are numerous surgical options for correction of DDSP. The success rates vary for each surgical option, being the laryngeal tie-forward procedure the surgical option with the higher success rate (Woodie, Ducharme, Kanter, Hackett, & Erb, 2005).

This dissertation aims to evaluate the response in sports performance after the laryngeal tie-forward procedure for the correction of DDSP in racehorses.

In the first part of the first chapter of this document the anatomical description of the pharynx, focused on the functional anatomy will be presented. The second part of the first chapter refers to DDSP, and the etiology, clinical signs, diagnose techniques and non-surgical and surgical treatment are described.

The second chapter addresses the study developed, including material and methods, results, discussion and conclusion of all the research performed.

2. Literature Review

2.1. Pharynx

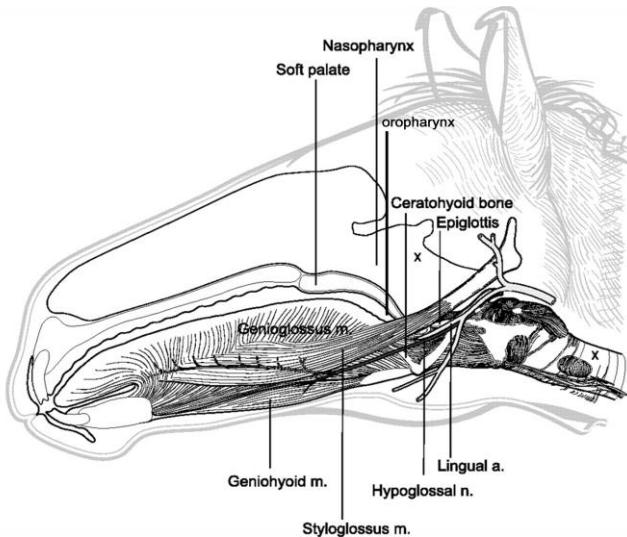

2.1.1. Functional anatomy of the pharynx

The pharynx is a musculomembranous tubular structure not directly supported by bone or cartilaginous matrix that represents both a part of the digestive and respiratory tract. It has a funnel shape, being wider and larger rostrally than caudally and its long axis is directed obliquely in a ventral and caudal direction measuring about 15 cm (Hare, 1975). The pharyngeal cavity has seven openings: two choanae, two pharyngeal openings of the eustachian tubes, the oral opening, the laryngeal opening and the esophageal opening (Rush & Mair, 2004). The two choanae allow the communication between the oral and nasal cavities. The two pharyngeal openings of the eustachian tubes are located on the lateral wall of the pharynx, caudally to the choanae and at the same level of the ventral nasal meatus. These openings look like clefts and are directed ventral and caudal and have about 3 cm of length (Dyce, Sack & Wensing, 2004). Caudal to the openings of the eustachian tubes are the pharyngeal recess (Rush & Mair, 2004). The oral opening is limited dorsally by the soft palate, ventrally by the base of the tongue and laterally by the palatoglossal arches of the soft palate. It is not a wide opening and is closed by the soft palate in normal conditions, except during deglutition. The laryngeal opening occupies most of the ventral wall of the pharynx, being closed only during deglutition. The esophageal opening is caudal to the laryngeal opening (Hare, 1975).

The anatomic references of the pharynx are the base of the cranium and the guttural pouches dorsally, the larynx ventrally and the medium pterygoid muscle, the stylohyoid bone, the extern carotid artery and the lingual trunk, the glossopharyngeal, rostral laryngeal and hypoglossal nerves, the mandibular salivary gland and the retropharyngeus lymph nodes laterally. The pharynx extends from the caudal aspect of the nasal and oral cavities and connects these cavities to the larynx and esophagus (Holcombe & Ducharme, 2004).

The pharynx is composed of 1) the nasopharynx, 2) the oropharynx and 3) the laryngopharynx. The soft palate forms the division of the pharynx into nasopharynx dorsally and oropharynx ventrally (DerkSEN, 2012) (Figure 3).

Figure 3: Equine upper airway anatomy (adapted from Cheetham *et al.* 2009)

Legend: m = muscle; n = nerve; a = artery

The soft palate is a musculomembranous velum and inserts on the hard palate, leaning ventrally and cranially. The oral surface is ventral and is covered by a mucous membrane that continues from the hard palate and has a rounded medial ridge that usually is flanked by a sagittal fold from each side. On this surface, the soft palate contains the palatine glands and their ducts (Holcombe & Ducharme, 2004). From each side of the oral surface of the soft palate, there is a short and thick fold that crosses on the lateral board of the tongue originating the palatoglossal arch of the soft palate. The dorsal surface of the soft palate is the pharyngeal surface and is lined by nasal mucous membrane (Sisson, 1975). During breathing the epiglottis lies dorsal to the soft palate and the caudal free margin of the soft palate is in intimate contact with the subepiglottic tissue (Derksen, 2012). During swallowing, contraction of the muscles at the base of the tongue and walls of the pharynx pushes ingesta to the caudal portion of the oropharynx causing dorsal elevation of the soft palate and retroversion of the epiglottis (Barakzai, 2007). It continues caudally by two folds that flank the larynx and originate the palatopharyngeal arch, caudal to the esophageal opening. The space between the palatoglossal and palatopharyngeal arches, the tonsillar fossa, is occupied by the tonsils (Holcombe & Ducharme, 2004). In the horse, there are no compact tonsils like in other mammals like the human or the dog, so the tonsil is an extension of lymphoid masses from the base of the tongue, with a caudal path of 10 cm. Because the tonsil is not a compact structure, between the lymphoid masses there are crypts, and that's where the ducts of the tonsil open (Hare, 1975). The soft palate of the horse is well developed, being the median length 15 cm. The length and the intimate contact with the epiglottis could explain the fact that the horse is an obligate nasal breather (Holcombe &

Ducharme, 2004). The pharyngeal aponeurosis is located on the dorsal surface of the soft palate, being formed by the expansion of the tendon of the tensor veli palatini muscle and attaches to the caudal margin of the hard palate. This structure is thicker cranially and very thin caudally where the soft palate is more muscular. The blood supply to the soft palate is derived from the linguofacial trunk and maxillary artery and venous drainage is by the accompanying veins. The lymphatic drainage is toward the retropharyngeal lymph nodes. The afferent innervation from branches of the trigeminal, glossopharyngeal, and vagus nerves arises from pressure, mechanical, and temperature receptors lining the mucous membrane of the nasopharynx, including the soft palate (Derksen, 2012). The position of the soft palate is partially determined by the coordinated function of four muscles that are included in the intrinsic muscles of the nasopharynx: tensor veli palatini, levator veli palatini, palatinus and palatopharyngeus (Holcombe & Ducharme, 2004).

The laryngopharynx, which is lined by stratified squamous epithelium (Rush & Mair, 2004), begins at the base of the epiglottis and extends caudally to the arch of the cricoid cartilage (Derksen, 2012).

Positioned ventrally, the oropharynx is located caudal to the 6th cheek teeth, is limited by the soft palate dorsally and by the epiglottis caudally (Barakzai, 2007).

The nasopharynx is attached to the pterygoid, palatine and hyoid bones and to the cricoid and thyroid cartilages of the larynx by muscles that cause dilation and constriction of this structure (Hare, 1975). Although the nasopharynx is not directly supported by bone or cartilage, it must withstand large changes in intraluminal pressures, that vary from 24 to 50 cm H₂O, that occur at varying airflow velocities with minimal changes in diameter in the normal horse. It does this through muscular contraction, whose sensory drive is not well understood in horses (Holcombe & Ducharme, 2004). The blood supply to the nasopharynx is provided by the common and external carotid arteries and the linguofacial trunk and venous drainage is by the accompanying veins. The lymphatic drainage is toward the retropharyngeal and cranial cervical lymph nodes. The afferent sensory innervation of the nasopharynx is derived from the trigeminal, glossopharyngeal and vagus nerves (Sisson, 1975).

The musculature that is involved with the nasopharynx can be classified as intrinsic or extrinsic to this structure. The intrinsic group includes the muscles of the soft palate and pharynx, and the extrinsic group includes the muscles of the larynx and hyoid apparatus (Derksen, 2012).

2.1.1.1. Intrinsic muscles of the nasopharynx

The intrinsic muscles of the nasopharynx are composed of: tensor veli palatini, levator veli palatini, palatinus, palatopharyngeus and stylopharyngeus (Holcombe & Ducharme, 2004).

The tensor veli palatini muscle is innervated by the mandibular branch of the trigeminal nerve (Derksen, 2012) and is a fusiform and flattened muscle that originates at the muscular process of the petrous part of the temporal bone, pterygoid bone and lateral lamina of the auditory tube and travels rostroventrally along the lateral wall of the nasopharynx. The tendon of this muscle courses around the hamulus of the pterygoid bone and ramifies in the palatine aponeurosis (Sisson, 1975). This tensor veli palatini muscle acts in the rostral aspect of the soft palate tensing it and depressing this aspect of the soft palate toward the tongue using the hamulus of the pterygoid bone as a pulley, retracting the palate away from the dorsal pharyngeal wall, expanding the nasopharynx and lightly depressing it ventrally during inspiration (Rush & Mair, 2004).

The levator veli palatini muscle is innervated by the pharyngeal branch of the vagus nerve (Derksen, 2012) and arises from the muscular process of the petrous part of the temporal bone and the lateral lamina of the auditory tube and passes along the lateral wall of the nasopharynx, medial to the tensor veli palatini, to insert within the soft palate, dorsal to the glandular layer. This muscle elevates the soft palate during swallowing closing the choanae (Sisson, 1975), and also seems to have some responsibility in the vocalization (Rush & Mair, 2004).

The palatinus muscle is also innervated by the pharyngeal branch of the vagus nerve and consists of a paired fusiform muscle that originates from the caudal aspect of the palatine aponeurosis. This muscle courses through the middle of the soft palate, just beneath the nasal mucosa, to ramify in the caudal free margin of the soft palate (Sisson, 1975).

The palatopharyngeus muscle arises from the palatine aponeurosis, laterally to the palatinus muscle attachment, and from the palatine and pterygoid bones. The fibers continue caudally on the lateral wall of the pharynx and partially insert in the upper edge of the thyroid cartilage. The remaining portion of this muscle continues dorsally and inserts at the median fibrous raphe (Sisson, 1975). Its innervation is from the pharyngeal branch of the vagus nerve (Holcombe & Ducharme, 2004).

The combined contractions of the palatinus and palatopharyngeus muscles depress the caudal part of the soft palate toward the tongue shortening it, controlling the position of this structure (Rush & Mair, 2004).

The last muscle of the intrinsic group is the stylopharyngeus, which is divided into two parts, one rostral and the other caudal. The rostral stylopharyngeus originates from the medial surface of the rostral end of the stylohyoid bone and inserts on the pharyngeal raphe. This muscle is a pharyngeal constrictor that is not known to be stimulated during exercise, so it will not be discussed. The caudal stylopharyngeus is a pharyngeal dilator that originates from

the medial aspect of the caudal third of the stylohyoid bone and courses ventrally and rostrally to attach on the dorsolateral wall of the pharynx. The caudal part is responsible for tensing the roof of the nasopharynx and helps to prevent pharyngeal collapse with inspiratory pressure. It is innervated by the glossopharyngeal nerve (Derksen, 2012).

This group of muscles contributes to the stability by contractions that tense and dilate the walls of the pharynx (Derksen, 2012).

2.1.1.2. Extrinsic muscles of the nasopharynx

The extrinsic muscles of the nasopharynx are composed of: genioglossus, geniohyoideus, styloglossus, hyoglossus, sternohyoideus and sternothyroideus, hyoepiglotticus and thyrohyoideus (Derksen, 2012).

The genioglossus muscle is a paired funnel shaped extrinsic tongue muscle that originates within the median plane of the tongue and attaches to the medial surface of the mandible, caudal to the symphysis. This muscle is separated from the muscle of the opposite side by a fatty layer and connective tissue (Sisson, 1975). It is innervated by the medial branch of the hypoglossal nerve (Holcombe & Ducharme, 2004). The contraction of the fibers of this muscle has varied actions, depending on the fibers that are contracted. The contraction of the rostral fibers of the geniglossus muscles retracts the tip of the tongue and the contraction of the medial fibers pull the tongue down, but the most important action of this muscle is made by the contraction of the caudal fibers, protracting the tongue and pulling the basihyoid bone rostrally (Sisson, 1975). This activity can be simulated by using a tongue-tie (Derksen, 2012).

The geniohyoideus muscle is a paired wide and fusiform rostrohyoid muscle that originates in conjunction with the genioglossus, on the medial surface of the molar portion of the mandible, and inserts on the basihyoid bone. It is innervated by the main branch of the hypoglossus nerve and the facial nerve and irrigated by the sublingual artery. The geniohyoideus protrudes the tongue and pulls the hyoid apparatus rostrally (Sisson, 1975).

The styloglossus muscle is a thin and wide paired muscle that lies on the lateral aspect of the tongue which originates on the lateral surface of the stylohyoid bone, next to the joint with the ceratohyoid bone and inserts on the tip of the tongue (Sisson, 1975). It is innervated by the lateral branch of the hypoglossal nerve (Holcombe & Ducharme, 2004). Contraction of this muscle retracts the tongue, but if only one side of the muscle contracts, it make the tongue turn towards the side that the muscle contracts on (Sisson, 1975).

The hyoglossus muscle originates in the lingual process of the hyoid apparatus and stylohyoid and thyrohyoid bones and inserts on the median plane of the dorsal surface of the tongue and is positioned medial to the styloglossus muscle. It is innervated by the lateral branch of the hypoglossal nerve. The action of the hyoglossus muscle is retraction and depression of the base of the tongue (Derksen, 2012).

The sternohyoideus muscle and the sternothyroideus muscle, also known as the sternothyrohyoideus, are caudothyroid muscles that originate on the sternal manubrium and extend cranially. The sternohyoideus inserts on the basihyoid bone and lingual process of the hyoid apparatus, and the sternothyroideus inserts on the caudal edge of the thyroid cartilage lamina of the larynx (Sisson, 1975). Both of these muscles receive motor innervation from the ventral branch of the first and second cervical nerves and irrigation from the common carotid artery. The action of the sternothyrohyoideus muscle is retraction of the hyoid apparatus, base of the tongue and larynx (Holcombe & Ducharme, 2004).

The hyoepiglotticus muscle is a small muscle that can be simple or bifid and originates on the basihyoid bone, inserting on the basal portion of the rostral surface of the epiglottis, being the only muscle that are inserted on this cartilage. It is innervated by the main branch of the hypoglossal nerve. The contraction of the hyoepiglottic muscle pulls the basihyoid towards the epiglottis (Sisson, 1975), increasing the ventral dimension of the rima glottidis (Derksen, 2012).

The last muscle of the extrinsic group is the thyrohyoideus that is a squared muscle, extending from the lateral lamina of the thyroid cartilage of the larynx to the caudal edge of the thyrohyoid bone (Sisson, 1975). It is innervated by the thyrohyoid branch of the hypoglossal nerve, but one study in rabbits has shown that the innervation of this muscle could be achieved by the pharyngeal branch of the vagus nerve (Derksen, 2012). Contraction of the thyrohyoideus muscle increases the stability of the soft palate during exercise by moving the larynx rostrally, letting the thyroid cartilage rest more rostral and dorsal in relation to the basihyoid bone (Derksen, 2012).

This group of muscles contributes to the respiratory patency of the nasopharynx, increasing its diameter through change in size of the oropharynx or position of the larynx and increase the stability of the soft palate during exercise. The potential roles of these muscles have been identified in horses when interfering with their function, resulting in dorsal displacement of the soft palate during exercise (Holcombe & Ducharme, 2004).

2.2. Dorsal displacement of the soft palate (DDSP)

The soft palate of the horse provides an airtight seal around the larynx (Dowling, Hodgson, & Rose, 2000), not allowing for communication between the oropharynx and the nasopharynx during respiration (Radostits, Gay, Hinchcliff, & Constable, 2007). This makes it possible that the airflow during exercise is efficient (Dowling *et al.*, 2000). The position of the soft palate is subepiglottic (Rush & Mair, 2004) and only becomes dorsal to the epiglottis, in normal conditions, during deglutition (Radostits *et al.*, 2007). When it happens not during deglutition, it's called dorsal displacement of the soft palate (DDSP), and may be intermittent or persistent (Rush & Mair, 2004). In DDSP, the caudal free margin of the soft palate displaces dorsally and the epiglottis cannot be seen in the nasopharynx, being located in the oropharynx. The free edge of the soft palate goes across the rima glottidis during exhalation creating an airway obstruction during inspiration (Ducharme, 2012b).

Dorsal displacement of the soft palate is a common cause of poor performance and exercise intolerance in racehorses (Ainsworth & Cheetham, 2010). When intermittent, this occurs during exercise and it is usually associated with abnormal respiratory sounds (Rush & Mair, 2004), although some horses experience silent displacement (Ainsworth & Cheetham, 2010). Horses with intermittent DDSP are typically normal at rest and light exercise but will exhibit exercise intolerance during strenuous exercise (Ducharme & Hackett, 1997). This condition is commonly associated with other pharynx diseases, especially accompanied by pharynx inflammation (Rush & Mair, 2004).

Persistent DDSP is observed even with the horse at rest and is usually associated with dysphagia (Ducharme, 2012a). It is also possible to see signs of tracheal aspiration (Ducharme & Hackett, 1997) which may lead to infection of the lower respiratory tract (Ducharme, 2012a). This condition is usually the result of disruption of the nerve supply to the pharynx (Radostits *et al.*, 2007) or anatomic abnormalities (Ducharme & Hackett, 1997).

2.2.1. Etiology

The nasopharynx has to withstand large intraluminal pressure variations between 30 to 60 cm H₂O during respiration, without any support of bone or cartilage. In addition, this structure is exposed to a turbulent airflow with a maximum velocity of 90-100 L/sec, which can cause vibration of the soft tissues (Rush & Mair, 2004).

The stability of the nasopharynx is obtained through the muscular contraction of the intrinsic and extrinsic muscles of this structure (Rush & Mair, 2004).

The etiologic factors of DDSP are not well understood, but can be divided in intrinsic or extrinsic, depending on the muscles or structures that are affected (Ainsworth & Cheetham, 2010).

Intrinsic factors are associated with dysfunction of the intrinsic muscles of the soft palate, the most important ones being the palatines muscle and the palatopharyngeus muscle.

Dysfunction of these muscles may be associated with pharyngeal lymphoid hyperplasia in young horses. Dysfunction of the other muscles of the soft palate may result in respiratory obstruction, but not necessarily DDSP (Ainsworth & Cheetham, 2010).

Extrinsic factors are associated with the dysfunction of the muscles of the hyoid apparatus and larynx and alteration of the anatomy of the epiglottis and larynx (Ainsworth & Cheetham, 2010).

The first hypothesis for the occurrence of DDSP was paralysis of the palate muscles (Quinlan, Van Rensburg, & Starke, 1949) followed by elongation of the soft palate (Shappel, Caron, Stick, & Parks, 1989).

From the clinical perspective, mechanical factors seem to be associated with the etiopathogenesis of DDSP, once the correction of these factors promote the subepiglottic position of the soft palate to be reestablished. The mechanical factors include subepiglottic or palatal granulomas, cysts and masses. These factors predispose to DDSP either by mechanically interfering with the intimate contact between the caudal free edge of the soft palate and the subepiglottic tissue or by provoking irritation or pain that stimulates DDSP (Ducharme, 2012b).

Other hypothesis for the occurrence of DDSP is the association with epiglottic hypoplasia. It was thought that inadequate length or rigidity of the epiglottic cartilage could not hold the soft palate in its subepiglottic position (Linford, O'Brien, Wheat, & Meagher, 1983; Tulleners & Hamir, 1991). During exercise alteration of the position of the larynx occurs prior to DDSP, with this structure being retracted caudally, and the soft palate lifted against the ventral surface of the epiglottic cartilage, showing palatal instability (PI). Caudal retraction of the larynx causes an apparent flaccidity of the epiglottis (Ducharme, 2012b). A swallow seems to move the larynx rostrally, correcting its position. In horses with diagnosed intermittent DDSP it was showed that the incidence of swallowing increases in the minute prior to the occurrence of DDSP, supporting the hypothesis that the horses with DDSP are trying to stabilize an unstable palate by swallowing (Pigott, Ducharme, Mitchell, Soderholm, & Cheetham, 2010). The flaccidity of the epiglottis should be seen as a result of the movement of the larynx and not as a cause of DDSP. The role of the epiglottis as an initiating factor of DDSP is questionable because DDSP does not occur when epiglottic retroversion is experimentally induced, not being the epiglottic cartilage in position to hold the soft palate in its normal subepiglottic position (Holcombe, Derksen, Stick, & Robinson, 1998).

Another factor that was thought to cause DDSP is the retraction of the tongue, which was hypothesized to lead to retraction of the larynx (Cook, 1981). When retraction of the tongue occurs, the base of the tongue may elevate and push the caudal edge of the soft palate dorsally, inducing DDSP. This idea led to the belief that the action of a tongue-tie, pulling the tongue cranially, would prevent this from happening. Several experimental investigations failed to identify a morphologic or physiologic effect from a tongue-tie (Beard, Holcombe, &

Hinchcliff, 2001; Cornelisse, Holcombe, Derksen, Berney, & Jackson, 2001; Cornelisse, Rosenstein, Derksen, & Holcombe, 2001), but an experimental investigation performed in 2012 with 12 normal horses (Chalmers, Farberman, Bermingham, Sears, & Viel, 2013) showed that the use of a tongue-tie on a standing horse, altered the position of the basihyoid. Although there is not a great amount of explanations about the effect of the use of a tongue-tie, clinical studies show that the use of a tongue-tie is beneficial. A clinical study performed with 6 horses, showed that in 2, DDSP was reversed with the use of a tongue-tie (Franklin, Naylor, & Lane, 2002) and a cohort study performed in the UK reported that the use of a tongue-tie appears to have a positive effect on racing performance (Barakzai, Finnegan, & Boden, 2009).

The clinical association of opening the mouth or swallowing during exercise and the occurrence of DDSP has led to the hypothesis that the air entering in the oropharynx when the horse opens the mouth disturbs the stabilizing effect of the sub atmospheric pressure on the ventral surface of the soft palate (Odeh, Schall, Gavriely, & Oliven, 1993). To prevent this occurrence, the use of dropped or figure-of-eight noseband was promoted, although there are no experimental data investigating the function of this piece of equipment (Ducharme, 2012b).

The position of the hyoid bone and of the larynx seems to be relevant to the occurrence of DDSP. Three studies that were recently realized show that the position of these structures is important predictive element in the occurrence of DDSP. In the first study was found that in horses with DDSP at exercise, the basihyoid is in a more ventral position (Chalmers, Yeager, & Ducharme, 2009), and in the same year, another study showed that a more dorsal position of the basihyoid and larynx after a laryngeal tie-forward procedure gives a better postoperative outcome (Cheetham, Pigott, Thorson, Mohammed, & Ducharme, 2008). The last study gave information about the position of the larynx of horses with permanent DDSP, with this structure being more caudal than in horses with intermittent DDSP (Ortved, Cheetham, Mitchell, & Ducharme, 2010). The position of the basihyoid and larynx could also be altered by the manipulation made by the rider at exercise, like changing the head position or the use of spurs in the thorax (Van Erck, 2011).

The studies presented before show structural conditions that could lead to DDSP, but DDSP also could be caused by functional disorders. From this point of view, there are three experimental cases that result in DDSP in horses.

The first experimental case showed that the blockade of the pharyngeal branch of the vagus nerve causes persistent but reversible DDSP, leading to the idea that the dysfunction of the palatinus and palatopharyngeus muscles could lead to DDSP (Holcombe *et al.*, 1998). A more recent study showed that the palatinus and palatopharyngeus muscles have respiratory related activity during exercise, strengthening the hypothesis that the dysfunction of these muscles could result in DDSP (Holcombe, Derksen, & Robinson, 2007).

The two other cases differ from the first one because in these two models the DDSP only occurs at exercise and in the first one it was permanent.

The second experimental case showed that the resection of the thyrohyoideus muscles causes DDSP, and the reconstruction of the action of these muscles corrects the DDSP. The findings in this study support the idea that these muscles are important to the stability of the nasopharynx and the dysfunction of these structures could result in DDSP (Ducharme *et al.*, 2003). Another study shows that the thyrohyoideus muscle activity decreases prior to the occurrence of DDSP (Ducharme, 2001).

The third experimental case showed that the blockade of the hypoglossal nerve results in intermittent DDSP at exercise, confirming that this nerve is responsible for the stability of the nasopharynx in horses. Although the blockade shows that this nerve is important, the experimental case doesn't differentiate between intrinsic and extrinsic muscles of the tongue (Cheetham *et al.*, 2009).

2.2.2. History and clinical signs

Racehorses with intermittent DDSP usually have a history of poor performance and could be associated with a gurgling noise during exhalation (Cook, 1981) and it has been suggested that up to 30% of horses with DDSP make no audible abnormal respiratory sounds at exercise (Martin, Reef, Parente, & Sage, 2000). The poor performance generally is an acute problem that could be described by the trainer or owner as "choking down" or "swallowing the tongue", and the horse could also exhibit open-mouth breathing, because airflow is directed through the oropharynx during exhalation (Ducharme, 2012b). Horses used for show or pleasure could exhibit only the respiratory noise that could be exacerbated by head flexion (Van Erck, 2011).

2.2.3 Diagnosis

Resting endoscopic examination of the nasopharynx in horses that are presented for investigation of respiratory noise and/or poor performance during exercise are performed to try to identify major structural abnormalities that are apparent at rest and to try to use the appearance and function at rest of the structures to predict their function during exercise (Barakzai & Dixon, 2011). Some alterations that could point to the diagnosis of DDSP during exercise are dorsal displacement of the palatal arch at rest provoked by nasal occlusion (Beard, 1996) or induced by swallowing (Hobo, Matsuda, & Yoshida, 1995).

More recently, several studies reported a weak link between the diagnosis of DDSP made by resting endoscopic examination and the confirmation by high speed treadmill endoscopy (HSTE) (Barakzai & Dixon, 2011) or over ground endoscopy (Kelly, Reardon, Johnston, & Pollock, 2013).

The gold standard for the diagnosis of intermittent DDSP is a group of exams that include the history of poor performance associated or not with respiratory abnormal noise, physical examination to rule out other causes of exercise intolerance and endoscopic examination at rest and during exercise either over ground or HSTE (Ducharme, 2012b). Although both over ground and HSTE are good at diagnosing DDSP, the treadmill exam has a higher diagnostic rate. This could happen because the treadmill exam is a more strenuous exercise than the over ground exam that is usually performed on the trainer's gallops. The over ground exam should recreate the conditions encountered during races (Allen & Franklin, 2010) (Figure 4).

Figure 4: Endoscope in place for dynamic endoscopy (adapted from Desmaizieres *et al.*, 2009)

If none of the exercise endoscopic exams could be performed, the resting endoscopic exam immediately after the cessation of the exercise should be performed, since the observation of DDSP during this exam will support the diagnosis (Ducharme, 2012b).

If only the resting endoscopic exam is available, a suggestive evidence of the occurrence of DDSP is the ulceration of the caudal edge of the soft palate (Lane, Bladon, Litte, Naylor, & Franklin, 2006). The tracheoendoscopy allows assessing this area of the soft palate by introducing the endoscope in the proximal trachea and inducing the gag reflex, being possible to see the caudal free edge of the soft palate after withdrawing the endoscope. The exam of the free edge of the soft palate can also be performed under sedation and applying 50 to 100 ml of lidocaine hydrochloride on the soft palate and epiglottis, using an equine laryngeal forceps to elevate the epiglottic cartilage (Ducharme, 2012b).

2.2.4. Treatment

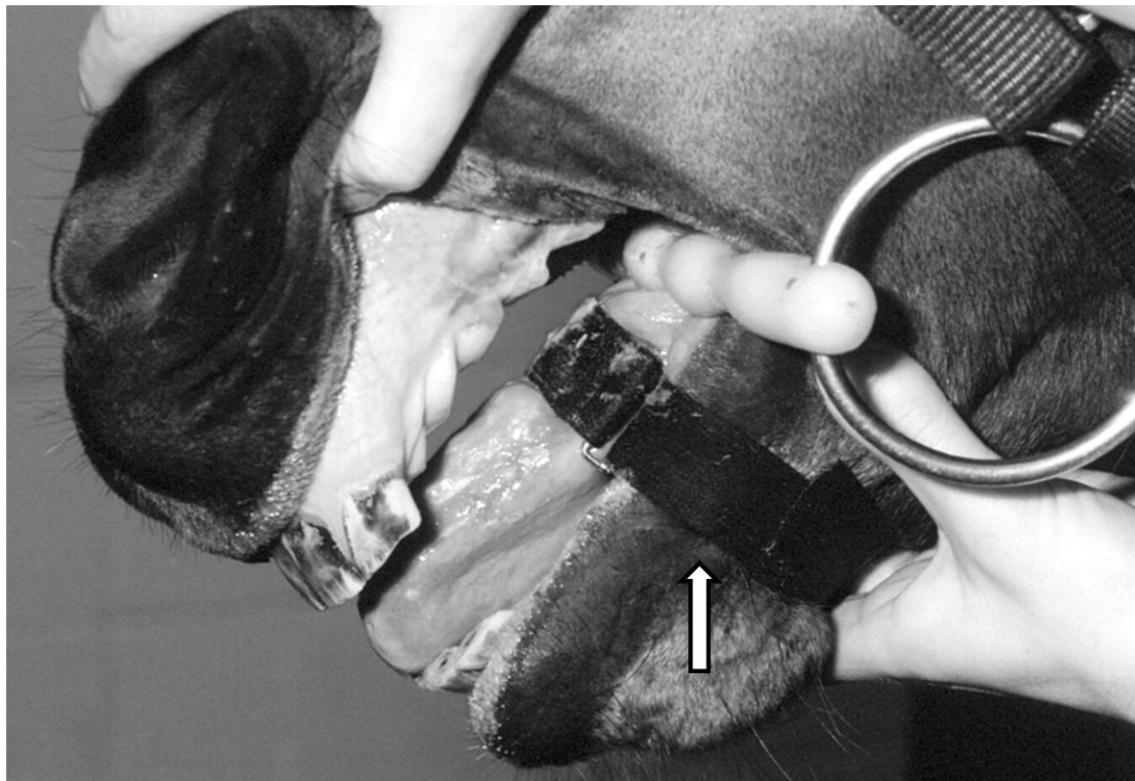

2.2.4.1. Non surgical management of DDSP

The dysfunction of the pharyngeal branch of the vagus nerve may be caused by inflammation in the nearby structures such as the guttural pouches and the nasopharyngeal wall, interfering with the tone of the palatinus and palatopharyngeus muscles, leading to DDSP (Holcombe *et al.*, 1998). It was also suggested that horses diagnosed with DDSP have a high prevalence of upper airway inflammatory diseases (Hobo *et al.*, 1995). If inflammation of the upper airways is diagnosed, treatment should include corticosteroid therapy with dexamethasone IV or PO, starting with 30 mg sid for 3 days, followed by 20 mg sid for 3 days, then 10 mg sid for 3 days ending with 10 mg qod for three treatments. Along with the corticosteroid therapy, throat spray, composed by 250 ml of glycerin, 250 ml of 90% DMSO, 500 ml of nitrofurazone and 50 ml of prednisolone 25 mg/ml may be used. Also unfitness and immaturity of the horse should be considered as a cause of DDSP (Ducharme, 2012b).

There are some tack changes that could help to prevent DDSP. The use of a dropped or figure-of-eight noseband may prevent DDSP by keeping the horse from opening its mouth, not letting the airflow to go into its oropharynx (Woodie, Ducharme, Hackett, *et al.*, 2005). It has also promoted the use of a bit that secures and/or restricts the caudal movement of the tongue, such as a W bit, a spoon bit or a "Serena song" bit, combined with the use of a tongue-tie (Ducharme, 2012b), but none of this bits have been statistically validated.

The tongue-tie is typically a piece of nylon or other elastic material used to tie the tongue rostrally and laterally through the diastema to the bridle or to the mandible (Chalmers *et al.*, 2013) (Figure 5). The use of the tongue-tie is controversial, as in some studies there are no positive out-come with the use of a tongue-tie, neither in the hyoid apparatus position and nasopharynx diameter (Cornelisse, Rosenstein, *et al.*, 2001) nor in the airway patency (Beard *et al.*, 2001; Cornelisse, Holcombe, *et al.*, 2001) and in others there are some positive out-comes, showing that the tongue-tie alters the position of the lingual process and the thyroid cartilage in the standing horse (Chalmers *et al.*, 2013) and showing a performance improvement (Barakzai *et al.*, 2009). The hypothesis that lead to the use of the tongue-tie is that it prevented the caudal retraction of the tongue and, almost certainly prevents the root of the tongue from applying dorsal pressure on the ventral surface of the soft palate or prevents the basihyoid or larynx from moving caudally (Franklin *et al.*, 2002).

Figure 5: Horse with a tongue-tie in place (arrow) (adapted from Franklin, Naylor & Lane, 2002)

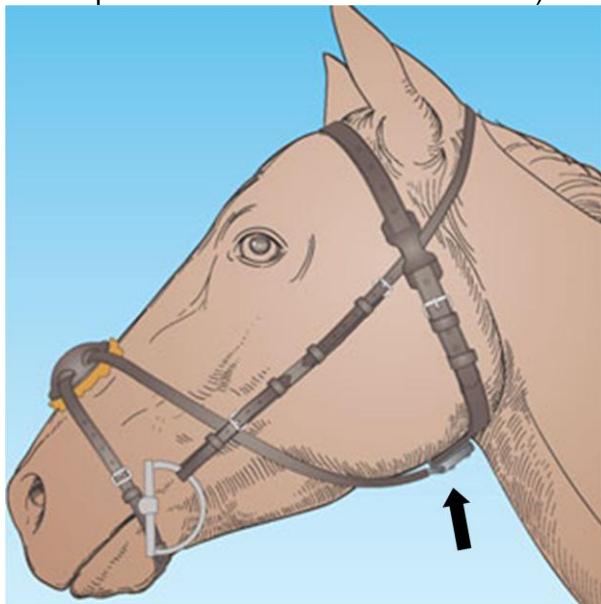

Another possible treatment to correct the position of the soft palate in horses with DDSP is the use of an external device that makes external pressure in the intermandibular space, moving the larynx dorsally and rostrally (Figure 6). This is possible by applying upward and forward pressure on the caudal aspect of the thyroid cartilage and on the caudal aspect of the basihyoid bone, respectively (Woodie, Ducharme, Hackett, *et al.*, 2005).

A study was made to test this device and it showed that the use of the throat support device correct DDSP in experimental cases. The results of the use of this device are similar to the results of the tie-forward surgery (Woodie, Ducharme, Hackett, *et al.*, 2005).

The device is now used in races to prevent DDSP and is used as a diagnostic tool (Ducharme, 2012b).

Figure 6: The laryngohyoid support device positioned on the horse (arrow) (adapted from <http://vet-aire.com/cornell-collar.html>)

The data supporting the nonsurgical options is not enough to draw clear conclusion about all the options, but these treatments may be used as a first approach when the horse doesn't have any anatomical abnormality (Ducharme, 2012b).

One study showed that the use of nonsurgical treatment alone has a 60% success rate, a similar result to the reports that use surgical treatment (Allen, Christley, Birchall, & Franklin, 2011).

2.2.4.2. Surgical management of DDSP

There are numerous surgical options for correction of DDSP. The success rates vary for each surgical option, with the laryngeal tie-forward procedure being the surgical option with the higher success rate, demonstrated to be 80-82% (Woodie, Ducharme, Kanter, *et al.*, 2005).

2.2.4.2.1. Laryngeal tie-forward procedure

This surgical procedure was hypothesized as a result of one study by Ducharme (2003) that reported that the resection of the thyrohyoideus muscles results in DDSP during exercise and it could be corrected by placement of sutures replacing the function of these muscles.

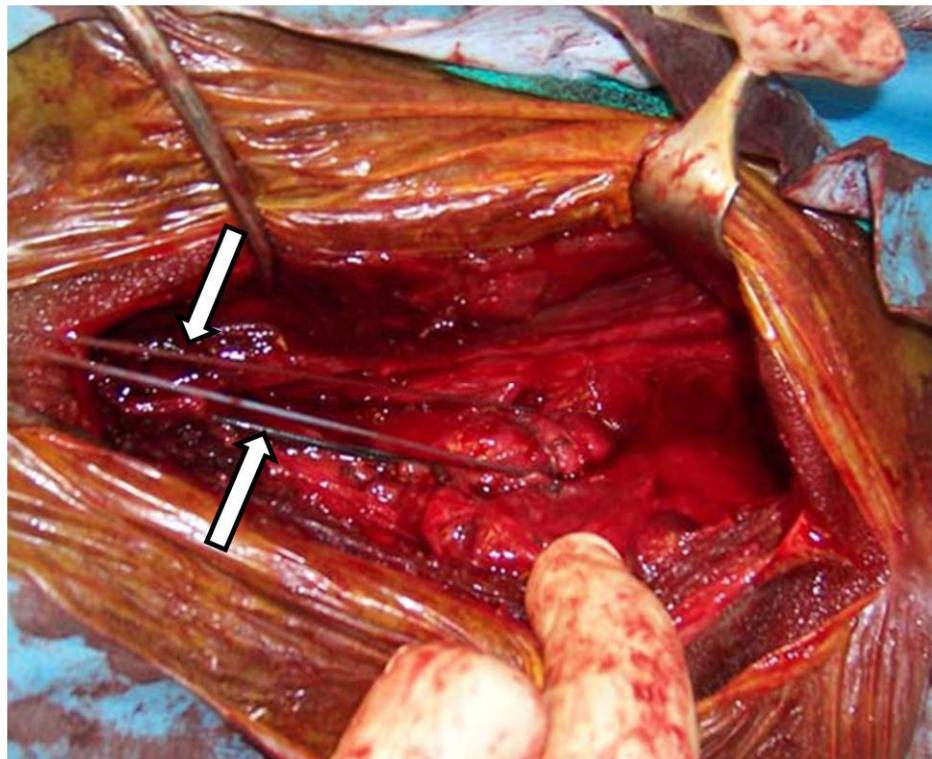

The surgery is performed with the horse under general anesthesia and in dorsal recumbency with the head in full extension (Rossignol, Ouachée, & Boening, 2012). After positioning, an endotracheal tube is placed (Ducharme, 2011). The ventral cervical and intermandibular areas extending 10 cm rostral to the basihyoid bone are prepared aseptically (Ducharme, 2012b) (Figure 7).

Figure 7: Ventral cervical and intermandibular areas clipped and prepared aseptically (original)

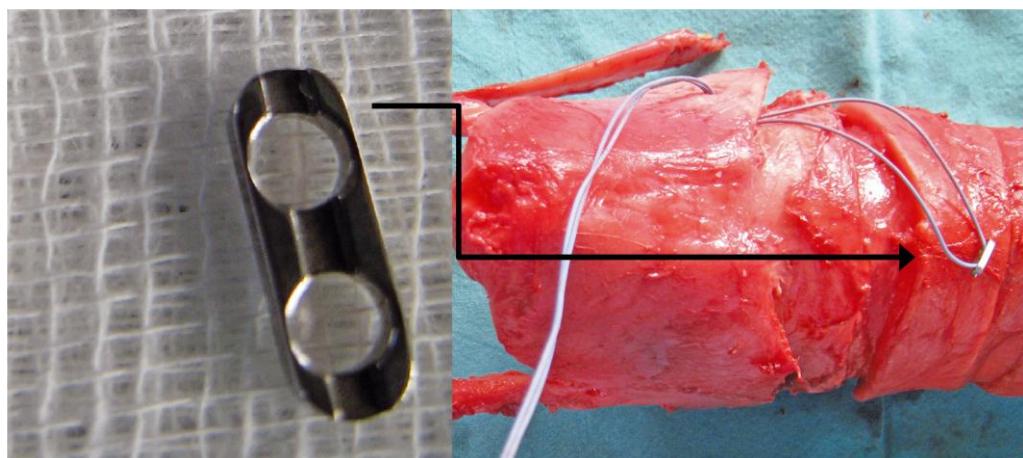

A ventral midline incision of 15 cm is made starting 1 cm caudal to the cricoid cartilage and extending 2 cm rostral to the caudal aspect of the basihyoid bone. After the incision, on the midline, the paired sternothyroideus and omohyoideus muscles (Rossignol *et al.*, 2012) are bluntly separated and dissected free of the dorsolateral aspect of the larynx lateral to the thyrohyoideus muscles. The sternothyroideus muscle tendon of insertion on the thyroid cartilage lamina is undermined and isolated, if not already transected in a prior surgery (Ducharme, 2011). The sutures are first passed in the thyroid cartilage, using size 5 polybend suture inserted at the ventral aspect of the right sternothyroideus tendon and exited from the lateral lamina of the thyroid cartilage. The suture is then passed through the thyrohyoideus muscle, 1 cm rostrally and slightly dorsal from its insertion point. After this, three more bites are placed in the right lamina of the thyroid cartilage, each bite more dorsal than the previous one forming a loop in the thyroid lamina, with each bite 4 mm apart (Ducharme, 2011) (Figure 8).

Figure 8: Surgery incision with the sutures in place (adapted from Ducharme, 2011)

An alternative method is threading through both holes of a 3,5 mm stainless steel button and the ends drawn through the eye of a 48 mm half circle trocar point needle. The needle is passed a single time through the thyroid cartilage, being inserted ventromedial to dorsolateral, 1 cm from the caudal border of this cartilage, at the level of the sternothyroideus tendon insertion. After placing the suture, traction should be applied to the suture strands to pull the metallic button against the medial surface of the caudal aspect of the thyroid cartilage (Rossignol *et al.*, 2012) (Figure 9).

Figure 9: Ventral view of the horse larynx showing placement of the first suture before pulling the metallic button (adapted from Rossignol, Ouachée & Boening, 2012)

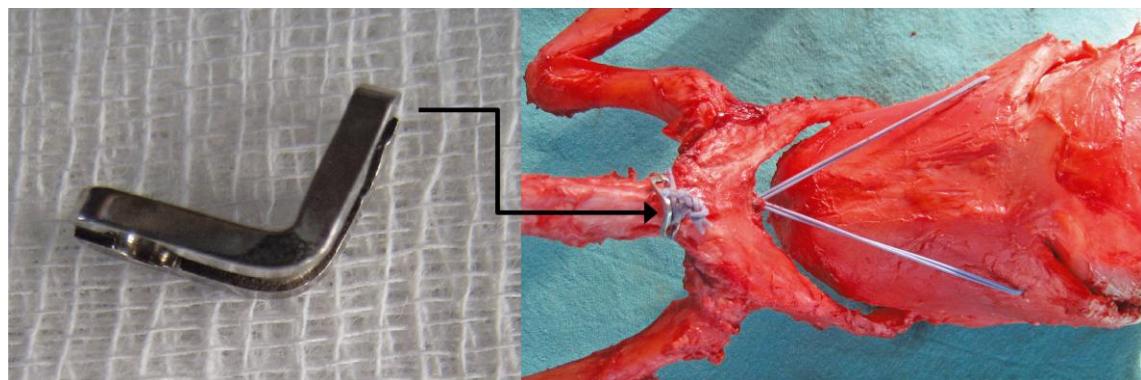

These steps are then repeated on the left side. The sternothyroideus tendon and 2 cm of muscle at its insertion on the thyroid cartilage are transected after the sutures are placed in the thyroid lamina (Ducharme, 2011). The sutures are then passed around the basihyoid using either a 2-0 suture (Rossignol *et al.*, 2012) or a wire passer (Ducharme, 2011). The most dorsal suture on the right side and the most ventral suture on the left are passed dorsal to the basihyoid to exit on the right side of the lingual process where they are tagged with separate hemostats. The most dorsal suture on the left and the most ventral on the right are similarly passed dorsal to the basihyoid, but this time to exit on the left side of the lingual process, and they are also tagged with separate hemostats (Ducharme, 2011). In the procedure described by Rossignol (2012), the 2-0 suture is drawn through the eye of a blunt Deschamps needle and it is inserted rostral to caudal, dorsal to the left side of the lingual process of the basihyoid and the 2-0 suture is used to pull the contralateral polybend suture dorsal to the basihyoid. All these procedures are repeated on the right side.

After the positioning of the sutures, they are tied to mobilize the larynx. To get a better positioning of the larynx and better tightening, the horse's nose is lifted so the head and neck are angled at approximately 90°.

The sutures on each side are tied using a square knot. The ventral sutures are tied so the rostral aspect of the thyroid cartilage is approximately 1 cm rostral to the caudal aspect of the basihyoid. After the sutures are tied, the head is replaced in its normal resting position. Using this procedure it's expected that the larynx moves approximately 2 cm dorsally and 4 cm rostrally (Ducharme, 2011). In the Rossignol (2012) procedure, after the first knot, a bent suture button is incorporated in the subsequent throws on the ventral surface of the lingual process of the basihyoid bone (Figure 10).

Figure 10: Ventral view of the horse larynx and hyoid apparatus showing placement of the bent suture button on the ventral surface of the lingual process of the basihyoid bone
(adapted from Rossignol, Ouachée & Boening, 2012)

After the first knot it's important to verify if the thyroid wings are symmetric and if not, the knot should be loosened and tied again (Rossignol *et al.*, 2012). After all the knots are tied, the surgical incision is closed with a 0 polyglactin suture reapposing the sternothyroideus muscles. The loose fascia overlying the larynx needs to be incorporated into that closure in order to prevent postoperative seromas. The subcutaneous tissues and skin are closed in a routine manner (Ducharme, 2012b).

In the first two weeks after surgery, the horse should be watered and fed at shoulder height to minimize the stress on the sutures. NSAIDs should be administered for 3 to 5 days. In the first two weeks, the horses are maintained in a box with handwalking once a day. The return to training is set after the two weeks rest (Ducharme, 2012b).

2.2.4.2.2. Staphylectomy

This procedure was first described for the treatment of an excessively long soft palate, but this condition seems to be present only in neonatal foals (Ahern, 1993). The staphylectomy should be used as a surgical procedure for the resection of a granuloma or cysts from the caudal free edge of the soft palate, but it's important to be careful, as when more than 0,75 cm of the soft palate is removed, the seal between oropharynx and nasopharynx can be disrupted and allow the passage of fluids and food into the nasopharynx (Ducharme, 2012b).

The procedure is performed with the horse under general anesthesia and in dorsal recumbency with the head and neck extended. The area is clipped and prepared aseptically for a laryngotomy (Smith & Embertson, 2005). A skin incision of 10-12 cm centered with the cricothyroid space is made and then the sternohyoideus muscles are separated using a curved Metzenbaum or Mayo scissors (Derksen, 1991). After the separation of these muscles, a self-retaining retractor is placed, exposing the cricothyroid membrane, which is incised with a scalpel along the midline, from the junction of the thyroid cartilages to the cricoid cartilage. It is important to cauterize the blood vessel that is incised at the level of the caudal two thirds of the membrane (Ducharme, 2012b). The self-retaining retractor is then placed within the cricothyroid space allowing identification of the caudal free margin of the soft palate rostral to the incision. The endotracheal tube is retracted and the mass or cyst is identified and the caudal free margin of the soft palate is secured with an Allis tissue forceps in the midline and another two forceps are used to secure the soft palate 2 to 2,5 cm lateral to the midline on each side. The caudal free margin of the soft palate is resected using curved Satinsky thoracic scissors. A crescent shaped piece of mucosa is resected, 3 to 4 cm long and 0,5 cm wide on the midline and tapered toward both ends. The laryngotomy incision could be left to heal by second intention or the cricothyroid membrane may be reapposed using 0 polyglactin 910 suture material. The complete closure of the laryngotomy incision is not recommended since it increases morbidity unnecessarily (McIlwraith & Robertson, 1998). The laryngotomy site should be cleaned twice a day for approximately 3 weeks and post-

operative systemic antibiotic and anti-inflammatory therapy should be continued for 7 and 3 days, respectively (Ducharme, 2012b).

For the treatment of DDSP, a laser-assisted staphylectomy is done after a laryngeal tie-forward procedure, when needed. The objective of this procedure after a laryngeal tie-forward is to remove the least amount of mucosa needed to let the epiglottis remain dorsal to the caudal free margin of the soft palate without loss of laryngopalatal seal. The dorsal displacement is corrected with the help of a laryngeal forceps, being possible to observe the redundant palate under the epiglottis that needs to be resected. The intended site of resection is marked prior to using the laser, as the soft palate is an elastic structure and excessive resection could occur. After this, the free margin of the soft palate is lifted and resected. The horse is then treated with broad-spectrum antibiotics and NSAIDs (Ducharme, 2012b).

2.2.4.2.3. Standard myectomy

This procedure consists on the partial resection of the sternohyoideu and sternothyroideus muscles, the procedure could also include the resection of the omohyoideus muscles, and is performed to control the caudal retraction of the larynx (Anderson, Tulleners, Johnston & Reeves, 1995).

The horse should be treated with NSAIDs and broad-spectrum antibiotics preoperatively. This procedure can be done with the horse standing or under general anesthesia. If the plan is to resect the omohyoideus muscle, the procedure needs to be done with the horse anesthetized and in dorsal recumbency as a more extended dissection is needed to reach this muscle (Ducharme, 2012b).

On the ventral surface of the neck, the hair is clipped and the area is prepared aseptically and local anesthesia is infiltrated along the midline at the junction of the proximal and the middle thirds of the neck (McIlwraith & Robertson, 1998).

The procedure starts with a 10 cm incision on the midline skin and it continues through the cutaneus colli muscles. After the incision, the sternohyoideus muscles are identified and with the help of a curved forceps the sternothyroideus and the sternohyoideus muscles are separated. Both muscles are elevated through the incision and clamped at the proximal and distal ends of the incision. The muscles are transected between the forceps and a section of 6 to 8 cm should be removed. After removing the transected section of the muscles, careful inspection is necessary to be sure that adequate sections of both muscles were removed (McIlwraith & Robertson, 1998).

Resection of the omohyoideus is not recommended, since the removal of a section of this muscle lead to a bigger dead space, causing a higher rate of incisional complications (Ducharme, 2012b).

The incision is closed routinely and a Penrose drain can be placed (Derksen, 1991). A firm bandage is placed around the neck and should be removed 24 hours later along with the drain if one was placed. NSAIDs and antibiotics should be continued after surgery for 3 and 5 to 7 days respectively.

The use of this procedure is decreasing and the use of similar but less invasive procedure is increasing (Ducharme, 2012b).

2.2.4.2.4. Minimally invasive myectomy

Also known as the Llewellyn procedure, the minimally invasive myectomy consists on the partial sternothyroidectomy and tenectomy. This procedure is one of the first choice procedures because it can be performed in the field and it is simpler than the standard myectomy (Ducharme, 2012b).

The procedure is performed with the horse under general anesthesia and a 5 to 7 cm skin incision is made centered on the cricoids cartilage. The subcutaneous tissue is also incised to expose the sternthyroideus muscles which are divided using a curved Mayo or Metzenbaum scissors and the dissection continues dorsally to the sternohyoideus muscle exposing the caudolateral border of the thyroid cartilage. The origin of the tendon of the sternothyroideus muscle on the thyroid cartilage is identified and transected 1 cm caudal to its attachment to avoid the caudal laryngeal artery. It is also necessary to be careful to not damage the cricothyroid muscle. With the help of one finger, the sternothyroideus muscle is separated from the surrounding fascia and resected more proximally and a 3 cm section of the muscle is removed. All these steps are repeated on the contralateral muscle (McIlwraith & Robertson, 1998).

The incision is closed reposing the sternothyroideus muscles and the skin is closed routinely. Postoperatively NSAIDs are given for 3 to 7 days (Ducharme, 2012b).

3. Study: Performance evaluation in Irish racehorses with dorsal displacement of the soft palate following the laryngeal tie-forward procedure

3.1. Introduction and Main Objective

DDSP occurs during exercise being a cause of poor performance and exercise intolerance. The laryngeal tie-forward procedure has the highest success rate on the correction of this condition (Woodie, Ducharme, Kanter, *et al.*, 2005), but only one study was performed in the USA to evaluate the significance of this procedure in horse's race performance (Cheetham *et al.*, 2008). This is the first study in Europe evaluating the effect of the laryngeal tie-forward procedure in racing performance. The main objective of this study is to compare the earnings won before and after surgery and evaluate if there's a positive income on racing performance after this procedure.

3.2. Material and Methods

3.2.1. Study design, population and eligibility criteria

All horses undergoing the laryngeal tie-forward procedure at Anglesey Lodge Equine Hospital between May 2012 and February 2014 were eligible for inclusion. Medical records of all horses were reviewed. Subject details (name, age, breed, sex, trainer), history and treatment information were obtained.

All horses were subjected to resting endoscopic examination and the definitive diagnosis was obtained by dynamic endoscopic examination showing displacement of the caudal portion of the soft palate dorsal to the epiglottis for at least 8 seconds during gallop. Horses that did not have dynamic endoscopic examination as a method of diagnosis were excluded.

3.2.2. Surgical technique

All the horses operated were treated with a modified technique of the tie-forward procedure (surgical advancement of the larynx) as described by Cheetham *et al.* (2008). In the original technique, was used a curette to remove the muscle insertion and expose the ventral aspect of the basihyoid bone and a hole was created in this bone through the use of a 3,2 mm drill. The sutures were passed through the hole in the basihyoid bone (Woodie, Ducharme, Kanter, *et al.*, 2005). In the modified technique, one size 5 metric Fiberwire suture is inserted at the ventral aspect of the left sternothyroid tendon insertion and exited from the lamina of the thyroid cartilage and through the thyrohyoideus muscle rostrally and slightly dorsal from its insertion point and the suture is placed three more times through the lamina of the thyroid cartilage, each bite more dorsal than the previous. This procedure is then repeated on the right side. After the placement of the sutures, the sternothyroideus tendon and 2 cm of the muscle at its insertion on the thyroid cartilage are transected. A graft passer is used to pass the dorsal suture on the right side and the ventral suture on the left side dorsal to the

basihyoid bone and exit on the right side of the lingual process and they are tagged with separate hemostats. The process is repeated on the left side. After the positioning of the sutures, the horse head is flexed to an angle of 90° relative to the neck, and the sutures are tied separately using a slip knot (Ducharme, 2011).

After surgery, an endoscopic examination is done to make sure that the soft palate and larynx are in a physiologic position.

3.2.3. Performance data

Race position and earnings by race data were obtained from www.racingpost.com for each horse. Every horse, to be included in the study, need to have at least data from three races before surgery, been preferable horses with data from four races before surgery when possible. Horses with less than three races before surgery were not included in the study.

Similarly to other study (Barakzai & Dixon, 2005), to distinguish the horses that run but did not win any prize money from the non-finishing horses was assigned a nominal 1 pound (GBP) and 0 GBP respectively.

To allow the comparison of the racing performance before and after surgery, a baseline earning was established. The baseline earning value was calculated using the mean earning of the races before surgery in the case horses.

3.2.4. Control selection

Controls were selected for each treated horse from the date of the third race before surgery, being selected from a different race from the one run by the treated horse. This was made to allow horses, case and control, to have the same position in the selected race.

Control horses were matched to the treated horse by sex, breed and age. The third race before surgery was reported by Cheetham *et al.* (2008) as the point from when the earnings start to decrease after a preliminary evaluation of the race data, being this the point chosen for the selection of the controls. Race data from these horses were aligned temporally with the treated horses in the third race before surgery.

The control horses allow the evaluation of the earnings by race in horses that were not under the laryngeal tie-forward procedure giving a point of comparison between treated horses and non-treated horses.

3.2.5. Statistical analysis and reporting

The performance comparison was made between the first race before surgery, been this race the one with the lowest mean earning, and the third race after surgery, since this is the point from when the horse should be showing a positive response to the surgery.

The effect of the surgery on race position and race earnings was determined using ANOVA with repeated measures, with horse identity as error, race number as factor, and race

position or earnings by race as variables. Differences between control and case horses were estimated by adding the interaction term for “case or control” x “race relative to surgery”.

To the importance of recovery time to racing performance after surgery was done a spearman correlation test, using the earnings of the fourth race after surgery as dependent variable and the time to first race after surgery in days as independent variable.

The differences of earnings by age and sex were evaluated using ANOVA with single measure.

The horses were then divided in two groups: horses aged between 3 and 5 years and horses aged between 6 and 8 years. It was evaluated the importance of recovery time to racing performance after surgery in the same way that it was done before the separation of the horses in the two groups.

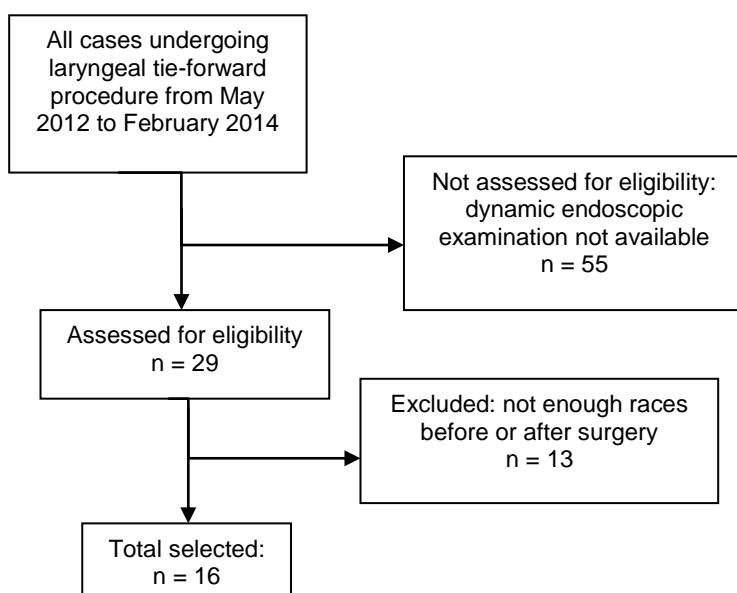

Statistical analysis was performed using R 3.1.2. The level of significance was set at $P<0,05$. All confidence levels were 95%.

3.3. Results

3.3.1. Population

The figure 11 gives a summary of the case selection process. 34,5% of the horses that underwent the laryngeal tie-forward procedure were assessed for eligibility and 16 of 29 horses were included. The population consisted of 16 thoroughbreds, 14 males and 2 females. The mean \pm s.d. age at the date of surgery was $5,7 \pm 2,7$ years. These consisted of 3 three-year-olds, 3 geldings and 1 mare, 4 five-year-olds geldings, 3 six-year-olds geldings, 4 seven-year-olds, 3 geldings and 1 mare, and 2 eight-year-olds geldings.

Figure 11: Flow diagram of case selection (original)

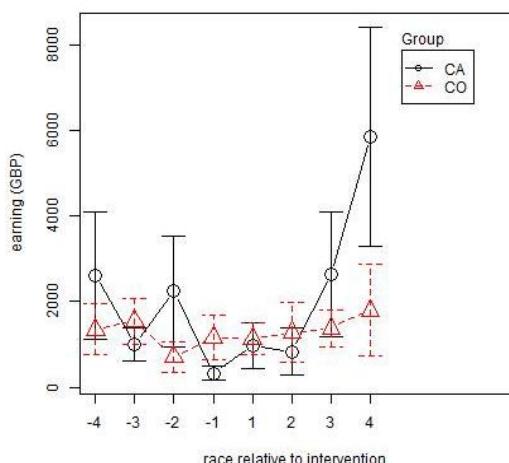

3.3.2. Effect of surgery on racing performance

The between groups test indicates that the difference between case and control in the first race before surgery and the third race after surgery is significant ($P = 0,016$). The earnings and race position change over time, showing that exists a time effect in the performance of the horses ($P = 0,0138$). The numerical summary of earnings by race for the treated horses is shown in table 1. In table 1 and in graphic 1 it's possible to see that the earnings baseline is slightly over the 2000 GBP in the cases, and the mean decreases to 333 GBP in the first race prior to surgery. After the recovery period and two races after surgery, the mean earnings are already at the baseline level, increasing to 5855 GBP in the fourth race. As seen in the graphics 1 and 2, the cases are improving differently from controls over time ($P = 0,0208$), once the controls stay more or less in the same range of results and the cases improve the race position to the same level of the controls and triple the baseline earnings.

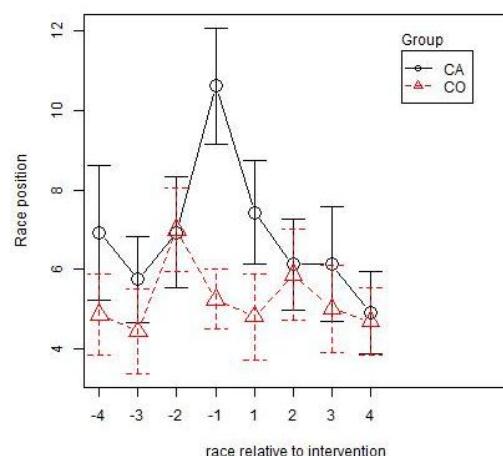

Table 1: Earning (GBP) data for the cases and controls for each race

Race		-4	-3	-2	-1	1	2	3	4
Cases	Minimum	0	1	0	0	0	0	1	0
	Mean	2609,64	999,28	2238,30	332,76	966,32	835,84	2639,09	5854,63
	s.d.	5548,53	1533,12	5156,00	647,53	2133,01	2215,36	5652,59	9582,28
	Median	699,19	299,28	1	1	1	1	583,33	950
	Maximum	20313	5610	19817	1951	7012	8913	21667	27083
Controls	Minimum	0	0	0	0	0	0	0	0
	Mean	1348,33	1542,32	709,56	1168,32	1139,13	1288,52	1378,96	1792,44
	s.d.	2309,62	2101,41	1431,65	2094,48	1462,95	2807,21	1730,56	3854,66
	Median	288,60	424,80	1	1	215,25	244,40	1001,58	1
	Maximum	6900	5610	4488	5890	4106	11196	6333	11792

Graphic 1 Comparison between mean earnings (GBP) for each race relative to surgery in cases (CA) and controls (CO) (original)

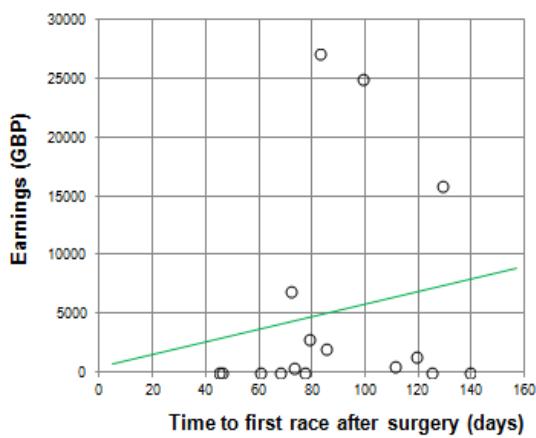

Graphic 2: Comparison between race position for each race relative to surgery in cases (CA) and controls (CO) (original)

3.3.3. Effect of recovery time in earnings

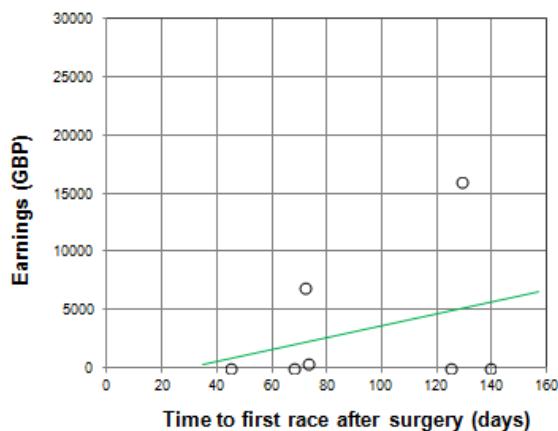

The graphic 3 shows the earnings achieved by each horse in the fourth race after surgery and the recovery time that the same horse needed until the first race after surgery. Although not significant ($P=0,32$), it's possible to see in graphic 3 that more time between surgery and first race after surgery is better than a short time of recovery period ($P=0,287$), once horses with a bigger recovery time have a better earnings. It is also possible to see that the better earnings in the fourth race after surgery are from horses that have a recovery period between 80-100 days.

Graphic 3: Spearman correlation test between earnings (GBP) and time to first race after surgery (days) with linear regression in case horses (original)

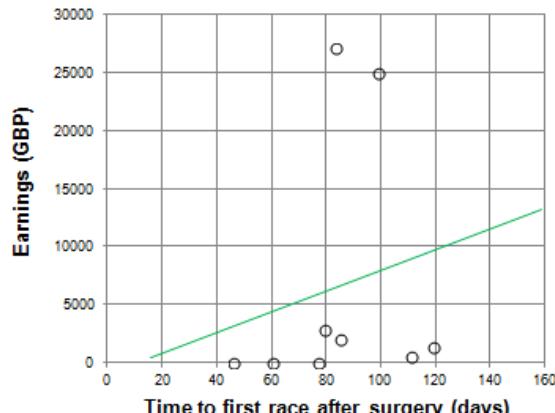

For a better understanding of the effect of recovery time in the racing performance, two groups were made, separating the younger horses from the older. In the group 1 are the horses whose age is between 3 and 5 years and in group 2 are the horses whose age is between 6 and 8 years.

Graphic 4: Spearman correlation test between earnings (GBP) and time to first race after surgery (days) with linear regression in group 1 horses (original)

Graphic 5: Spearman correlation test between earnings (GBP) and time to first race after surgery (days) with linear regression in group 2 horses (original)

As is possible to see in the graphic 4, group 1 has better results with longer recovery periods ($P=0,06$). In this group, the horse with the better earning in the fourth race after surgery has a recovery period between 120-140 days. The same is possible to see in graphic 5 for the group 2 ($P=0,299$). The horse with the better result in group 2 has a recovery period between 80-100 days.

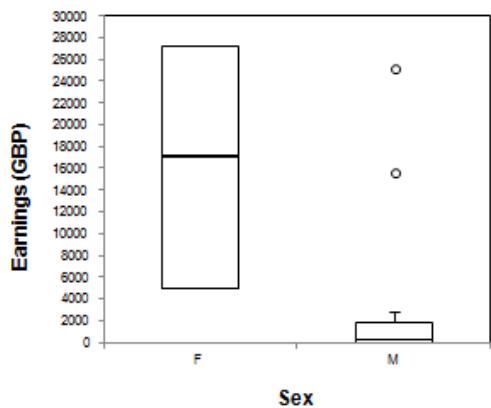

Observing both graphics 4 and 5, it's also possible to see that group 2 have better earnings than group 1.

The positive correlation in both group 1 ($P=0,913$) and group 2 ($P=0,471$) is not significant.

3.3.4. Earnings by sex

The difference between sexes is not significant ($P=0,07$), but it's possible to see in graphic 6 that the females have better results in the fourth race after surgery than males. The means of the earnings in the fourth race after surgery for each gender are shown in table 2. The difference for the controls is also not significant ($P=0,562$), but in the controls, the males have better results, as shown in graphic 7. Analyzing the means of cases and controls, it's possible to see that the males, in both cases and controls, have a similar mean earning in the fourth race after surgery. In the females the means are very different, being the cases much higher than controls.

Graphic 6: Comparison of mean earnings (GBP) at the fourth race after surgery between sexes in case horses (original)

Graphic 7: Comparison of mean earnings (GBP) at the fourth race after surgery between sexes in control horses (original)

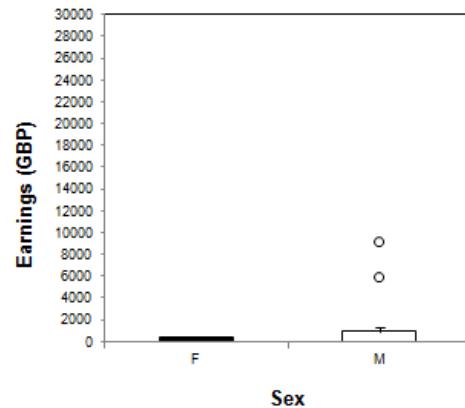

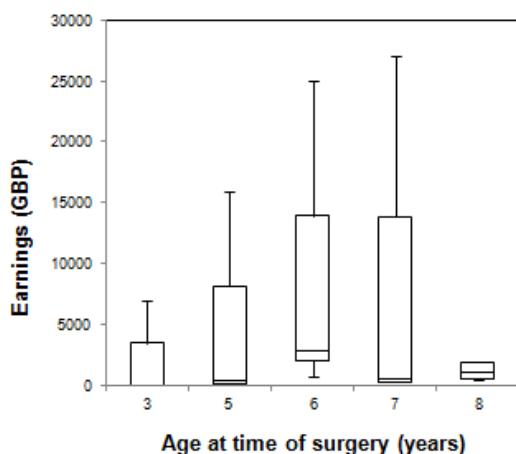

Table 2: Mean earning (GBP) data for the fourth race after surgery in case and control horses divided by sex

	Sex	Mean ± s.d.
Cases	Female	16991,67 ± 14271,77
	Male	3998,46 ± 7980,47
Controls	Female	250,50 ± 352,85
	Male	2072,79 ± 4153,00

3.3.5. Earnings by age

The difference between ages is not significant ($P=0,832$), but it's possible to see in graphic 8 that the horses that were under surgery at the age of 6 and 7 years old have better results than the horses in early and older ages. Observing the means by age of the earnings in the fourth race after surgery, the horses that have better results are the horses that were under surgery at the age of 6, as it's possible to see in table 3. The difference in controls, shown in graphic 9, is also not significant ($P=0,514$). Analyzing the means of the earnings in the fourth race after surgery by age in cases and controls is possible to see that the mean is higher in the cases at every age.

Graphic 8: Mean earnings (GBP) at the fourth race after surgery by age in case horses (original)

Graphic 9: Mean earnings (GBP) at the fourth race after surgery by age in control horses (original)

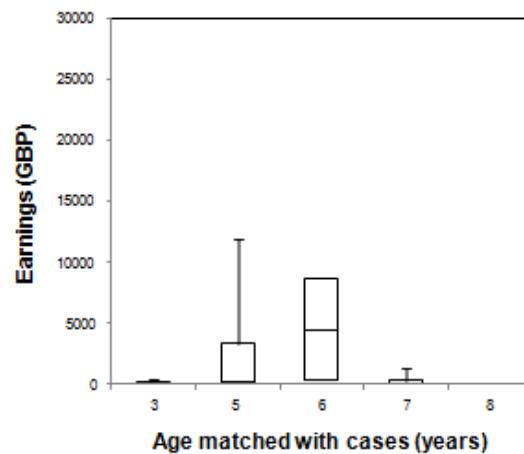

Table 3: Mean earning (GBP) data by age in case and control horses

	Age	Mean ± s.d.
Cases	3	2300,67 ± 3983,14
	5	5421,67 ± 9089,18
	6	9715,28 ± 13257,60
	7	9217,00 ± 15475,28
	8	1000,50 ± 1413,51
Controls	3	167,33 ± 288,10
	5	3117,98 ± 5907,29
	6	4512,50 ± 5815,95
	7	325,70 ± 650,07
	8	-

3.4. Discussion

It was referred that the laryngeal tie-forward procedure allows horses to return to a racing performance equal to preoperative baseline levels. These data support this hypothesis and also give the idea that the horses were not showing the total potential, once they triple the mean earning four races after surgery. Other study also demonstrates that the laryngeal tie-forward procedure returns racing performance to preoperative baseline (Cheetham *et al.*, 2008). This could be explained once the horses with DDSP could have PI prior to this condition, and this could limit the performance of the horse, placing them running in lower category races with lower associated earnings.

All the horses included in the study were Thoroughbreds. As shown in other studies, there were no significant anatomical differences in the distance between the caudal aspect of the basihyoid bone and the rostral and cranial aspects of the thyroid and cricoid cartilages, respectively, between Thoroughbreds and Standardbreds, and the surgery technique is the same for the two breeds (Woodie, Ducharme, Kanter, *et al.*, 2005) and there were some significant differences in the preoperative position of the thyrohyoid-thyroid cartilage articulation and in the ossification of the thyroid cartilage, being more caudal and dorsal, respectively, in Standardbreds (Ortved *et al.*, 2010). The differences in the earnings are not significant between these two breeds (Cheetham *et al.*, 2008).

Similarly to other study (Barakzai & Dixon, 2005), in this study the method for evaluating the racing performance was the earnings, because it takes into account the horse performance in a race relative to the other racing horses and also to the race itself. To distinguish the horses that ran but did not win any prize money from the non-finishing horses a nominal 1 GBP and 0 GBP were assigned respectively.

A beneficial point of this study is that all the surgeries were performed by the same surgeon, showing that the technique applied by this specific surgeon corrects DDSP, but for a better

analysis of this surgical procedure, surgeries done by other surgeons should be included in the study, allowing a better extrapolation of the results. A limitation of the study is that the percentage of recurrence of DDSP after surgery in these horses is not known. This recurrence is well known by equine surgeons although there are no published reports on the prevalence of this condition (Woodie, Ducharme, Kanter, et al., 2005). In one study done by Woodie *et al.* (2005), the percentage of recurrence is approximately 6%. One way to evaluate the recurrence of DDSP is to establish as a follow-up exam a dynamic endoscopic examination. This could be done 6 months after surgery and once a year after that.

The control selection is a main difficulty in this study, once the preferable controls are horses with a definitive diagnose of DDSP that were not undergoing the laryngeal tie-forward procedure, showing the evolution of the horses results without the correction of this condition, but this is a difficult goal to achieve in the racing industry, once the horses are raced to win.

As shown by Allen & Franklin (2013), prior to DDSP all horses showed some grade of PI, concluding that this condition could be an early stage of DDSP. This leads to the idea that the laryngeal tie-forward procedure could be done in an early stage, preventing the drop of performance showed in DDSP cases, allowing horses to achieve the full performance potential in an early age.

In this study ideal age to perform this surgical procedure was not investigated, but it was possible to see that the horses that were under surgery at the age of 6 had better results four races after surgery.

Another factor that was not investigated in this study was the recovery time. It is easy to understand that a longer recovery time is better than a too short recovery time, but the studies to define what is the ideal recovery time for this surgery were not done. Ducharme (2011) recommended that the return to training was 2 weeks after surgery. In this study, it's possible to see that the horses with better results had a recovery time between 80 – 100 days.

This is the first study in Europe investigating the significance of the laryngeal tie-forward procedure in horse's race performance and only one other study was done in the USA (Cheetham *et al.*, 2008). It demonstrates that the laryngeal tie-forward procedure is an appropriate technique for the correction of dorsal displacement of the soft palate in racehorses. In order to achieve a better understanding of the factors that influence the success of this procedure in racing performance, a study with more horses should be done, trying to evaluate the differences between horses with different recovery times and horses that were under surgery at different selected ages. Another thing that should be interesting to analyze is the response of horses that were under the laryngeal tie-forward procedure at different stages of DDSP and PI, trying to evaluate the best time to perform this surgery.
