Ethnic Differences in the Prevalence of Inherited Thrombophilic Polymorphisms in an Asymptomatic Australian Prenatal Population

JOANNE M. SAID,[1] SHAUN P. BRENNECKE,[2] ERIC K. MOSES,[3] SUSAN P. WALKER,[4] ANTHONY J. BORG,[3] JEFF T. WILLIAMS,[5] AND JOHN R. HIGGINS[6]

Abstract Differences in the prevalence of thrombophilias in different ethnic populations have been demonstrated. Because the Australian population includes many different ethnic groups, we sought to assess the effect of ethnicity in our Australian prenatal population on the prevalence of thrombophilic polymorphisms. Asymptomatic, nulliparous women ($n = 1{,}129$) recruited for a large prospective study were included in this analysis. These women had no personal or family history of venous thromboembolism and were not known to be carrying an inherited or acquired thrombophilia. Ethnicity was determined at recruitment, and women were categorized as being of Northern European, Southern European, Middle Eastern, Asian, or Other ethnicity. These women underwent genotyping for the following polymorphisms: factor V Leiden G1691A, prothrombin gene A20210G mutation, methylenetetrahydrofolate reductase (*MTHFR*) C677T and A1298C, and thrombomodulin C1418T. The factor V Leiden allele was seen significantly more frequently in patients of Middle Eastern background compared to those of Northern European and Asian ethnicity ($p < 0.05$). The prothrombin gene mutation was seen significantly more frequently in patients of Southern European ethnicity compared to those of Northern European or Asian ethnicity ($p < 0.05$). The *MTHFR* C677T allele (mutant) was significantly less common in those of Asian ethnicity compared to patients of Northern European

KEY WORDS: THROMBOPHILIA, FACTOR V LEIDEN, PROTHROMBIN GENE, METHYLENETETRAHYDROFOLATE REDUCTASE (*MTHFR*), THROMBOMODULIN, AUSTRALIA, PRENATAL POPULATION.

and Southern European ethnicity ($p < 0.0005$). There were no significant differences seen with the *MTHFR* A1298C polymorphism. The mutant thrombomodulin allele was seen significantly more frequently in Asian women compared to Northern European, Southern European, or Middle Eastern women ($p < 0.005$). There are important ethnic differences in the prevalence of thrombophilic polymorphisms in the Australian prenatal population.

Australia is a melting pot of diverse ethnicities. As a relatively new country, Australia has a history of different migration patterns, ranging from the early days of Anglo-Celtic colonization to the more recent patterns of Southern European, Southeast Asian, African, and Middle Eastern migration. Several studies have already demonstrated significant differences in the prevalence of a number of genetic thrombophilias (Rees et al. 1995; Herrmann et al. 1997; Gudnason et al. 1998; Rosendaal et al. 1998), but there are limited data for the Australian population.

Inherited thrombophilias predispose carriers to venous thromboembolism (Gerhardt et al. 2000), yet most of the carriers remain asymptomatic. Recent associations between thrombophilias and adverse pregnancy outcomes (Alfirevic et al. 2002; Rey et al. 2003; Said and Dekker 2003) have prompted calls for screening and institution of anticoagulant therapy in high-risk populations (Bates et al. 2004). To fully consider the merits of such propositions, we need a more detailed assessment of the prevalence of these conditions in prenatal populations. Furthermore, not all studies have confirmed an association between adverse pregnancy outcomes and inherited thrombophilias (Livingston et al. 2001; Infante-Rivard et al. 2002). It is possible that differences in the prevalence of inherited thrombophilias in different ethnic groups may contribute to apparent contradictions between studies.

We sought to assess the effect of ethnicity on the prevalence of five common thrombophilic polymorphisms in our Australian prenatal population: factor V Leiden polymorphism, which has been well described as the most common thrombophilia predisposing carriers to venous thrombosis in Caucasian populations (Dahlback 1997); the prothrombin gene mutation A20210G, which is associated with elevated circulating prothrombin levels (Poort et al. 1996); two polymorphisms (C677T and A1298C) in the methylenetetrahydrofolate reductase gene (*MTHFR*), which contribute to the development of hyperhomocysteinemia (Frosst et al. 1995; van der Put et al. 1998); and a common polymorphism in the thrombomodulin gene (C1418T), which interferes with thrombin binding on the endothelial surface and results in impaired activation of the naturally occurring anticoagulant protein C (Dittman and Majeurs 1990).

Methods

Nulliparous women were recruited for this study from the prenatal clinics at the Royal Women's Hospital and the Mercy Hospital for Women, in Melbourne,

Australia, as part of a study designed to assess the overall prevalence of thrombophilias in asymptomatic women and evaluate the risk of adverse pregnancy outcomes in thrombophilic women. Patients were recruited before they reached 22 weeks' gestation, and written consent for participation in the study was obtained. Ethnicity was determined at the time of recruitment by asking a series of questions about the patient's ethnicity as well as that of their parents, grandparents, and ancestors. This project was approved by the Institutional Ethics Committees at both hospitals. To obtain a truly asymptomatic population, which would not otherwise be suspected of carrying a thrombophilia, women were excluded from recruitment if they were known to be carrying a thrombophilia, had a family history of thrombophilia, had a past history or family history of venous thromboembolism, or had more than two previous miscarriages or a previous midtrimester miscarriage.

Because of the detailed nature of the consent process required, it was not possible to recruit non-English-speaking women.

Venous blood was obtained from the participants in vials containing EDTA, and a buffy coat layer was prepared from whole blood. Genomic DNA was then extracted from peripheral blood leukocytes using a commercially available kit (Puregene Whole Blood Kit, Gentra Systems, Minneapolis, Minnesota). Genotyping for the five polymorphisms was performed using Taqman assays in an ABI Prism 7700 Sequencer, using primers and fluorescent MGB probes designed using Primer Express Software and validated in the Pregnancy Research Centre at the Royal Women's Hospital. (Primer and probe sequences are given in Table 1.) Each PCR reaction was performed in a 10-μl volume using 2 μl genomic DNA (concentration 10 ng/μl), 5 μl Thermo-Start Q-PCR MasterMix (ABgene, Applied Biosystems, Foster City, California), 0.09 μl of the forward and reverse primers, 0.02 μl FAM and VIC labeled fluorescent probes, 0.03 μl Rox, and 2.75 μl H_2O, with the following PCR thermocycler conditions: initial activation step at 95°C followed by PCR amplification of 40 cycles (denaturation at 95°C for 15 s, primer annealing at 62°C, extension at 72°C for 30 s) and a final extension step at 72°C for 5 min. Fluorescence detection of PCR products was carried out in the 7700 Sequence Detector according to the manufacturer's recommendations.

Statistical Analysis. The prevalence and 95% confidence interval of each polymorphism was derived using Stata 7.0.

Differences between the prevalence in each ethnic subgroup were analyzed using the two-sample test of proportion for independent proportions. A p value less than 0.05 was regarded as significant, indicating that the difference in prevalence between the two ethnic groups was significant.

Results

This study included 1,129 women of known ethnicity. These women had all five polymorphisms successfully genotyped.

Most of the women were of Northern European descent (64%). Southern European and Asian women represented 15% and 13% of the population, respectively, and 6% of the women were from Middle Eastern countries (Lebanon, Israel, and Turkey predominantly). A further 2% of women (25 women) had other ethnic backgrounds, including African ($n = 15$) and Australian Aboriginal ($n = 1$), or were of mixed ethnicity ($n = 9$). Because this last group represented an extremely heterogeneous group and because the numbers in each individual group were too small to provide meaningful results, they were excluded from further analysis, leaving 1,104 women in this study.

The allele frequency of the mutant genes in each ethnic subgroup is shown in Table 2.

Factor V Leiden. We identified 60 women as heterozygous carriers of factor V Leiden. No women were homozygous for this mutation. The allele frequency for each ethnic group is shown in Table 2. The factor V Leiden mutation was least common in patients of Asian background compared to all other ethnic groups ($p < 0.05$). Middle Eastern women were more likely to carry this mutation than

a. NE, Northern European; SE, Southern European; A, Asian; ME, Middle Eastern.
b. Significant frequency of the mutant allele between the two ethnic groups indicated.

Northern European women ($p < 0.05$) or Asian women ($p < 0.0005$). No significant differences were seen between Northern and Southern European women.

Prothrombin Gene Mutation. Twenty-five of the 1,104 women were heterozygous carriers of the prothrombin gene mutation. This mutant allele was significantly more common in Southern European women than in Northern European or Asian women ($p < 0.05$). No statistically significant differences were observed in the frequency of the mutant allele in the Middle Eastern population compared to any other ethnic groups.

***MTHFR* C677T.** One hundred thirty-one women were homozygous for the *MTHFR* C677T polymorphism, which is associated with hyperhomocysteinemia. The mutant allele was seen significantly less frequently in Asian women compared to Northern European and Southern European women ($p < 0.0001$) and Middle Eastern women ($p < 0.05$).

***MTHFR* A1298C.** Homozygosity for the *MTHFR* A1298C polymorphism was seen in 111 women, and 451 women were heterozygous for this polymorphism. No statistically significant differences were seen among any of the ethnic groups.

Significant linkage disequilibrium was observed between the two *MTHFR* loci within each ethnic subgroup.

Thrombomodulin Polymorphism. Thirty-eight women were homozygous for the thrombomodulin polymorphism. The mutant allele was significantly more common in Asian women than in all other ethnic groups ($p < 0.005$). In addition, significant differences in the frequency of the mutant allele were also seen between Northern and Southern European women and between Northern European and Middle Eastern women ($p < 0.005$).

All five polymorphisms were in Hardy-Weinberg equilibrium within each ethnic subgroup.

Discussion

These data confirm the findings of previous studies, which have suggested a high prevalence of the factor V Leiden mutation in Middle Eastern subjects (Awidi et al. 1999; Irani-Hakime et al. 2000) and a virtual absence of this polymorphism in Asian populations (Rees et al. 1995; Angchaisuksiri et al. 2000). The prevalence of this polymorphism in our Northern European population is similar to that seen in other Caucasian populations (Lee et al. 1996; Ridker et al. 1997; Livingstone et al. 2000). These differences in the prevalence support the theory that the Factor V Leiden mutation arose in a single common ancestor 21,000 to 34,000 years ago (after the separation of Africans and Asians from Caucasian populations) (Zivelin et al. 1997).

Likewise, the prothrombin gene mutation is rarely seen in Asian populations (Angchaisuksiri et al. 2000; Chan et al. 2000) but is slightly more prevalent in Southern European populations than in Northern European populations (Rosendaal et al. 1998).

The *MTHFR* C677T polymorphism is more prevalent in Caucasian populations than in Asian (Esfahani et al. 2003) or African populations (Conroy et al. 2000; Esfahani et al. 2003). In contrast to the findings of Esfahani et al. (2003), we did not find any significant differences in the prevalence of the *MTHFR* A1298C polymorphism among the different ethnic groups. Significant linkage disequilibrium was observed between the two *MTHFR* loci among all four ethnic groups. This finding is consistent with the previous study by van der Put et al. (1998) but contrasts with the findings of Isotalo et al. (2000), who described the presence of triple and quadruple mutations in fetal samples, which could arise only if linkage disequilibrium were incomplete.

The significantly higher prevalence of the thrombomodulin polymorphism in Asian women is an important finding and requires further investigation of the possible role of this polymorphism in contributing to both venous thromboembolism and adverse pregnancy outcomes in these populations. To our knowledge, this is the largest population in whom the prevalence of this polymorphism has been examined.

We aimed to assess the prevalence of these thrombophilic polymorphisms in a population that would not otherwise be suspected of carrying thrombophilias. As such, we excluded women who had a personal or family history of thromboembolism, women who were known to carry or to have a family history of thrombophilia, and women who had had more than two previous miscarriages or a previous midtrimester miscarriage. There is no doubt that, according to these strict criteria, we will be underestimating the true population prevalence of thrombophilia—this is better achieved using random population-based samples (Gibson et al. 2005). Nevertheless, we have demonstrated that inherited thrombophilias are indeed prevalent in an asymptomatic prenatal population.

As illustrated in Table 2, we performed 30 separate statistical analyses. We acknowledge that this type of multiple analysis may result in the detection of a statistical difference simply by chance alone. Using a Bonferroni adjustment, statistical comparisons resulting in $p < 0.0017$ would still be regarded as significant. Table 2 highlights a number of highly significant differences in the prevalence of thrombophilias between ethnic groups. Significance for a number of these analyses is retained even when the Bonferroni adjustment is applied.

The prevalence of a particular thrombophilia will have a direct effect on the sample size required to study the association between inherited thrombophilias and adverse pregnancy outcomes. As this study and previous studies have demonstrated, the prevalence of thrombophilias varies significantly among different ethnic groups. These differences may contribute to the apparent contradictions seen in studies that examine the relationship between thrombophilias and adverse pregnancy outcomes.

Acknowledgments We gratefully acknowledge the work of the clinical research midwives, pathology collection staff, and laboratory specimen handlers at both the Mercy Hospital for Women and the Royal Women's Hospital for their invaluable assistance in the recruitment of subjects and sample collection. This project was supported by grants from the Kings Jubilee Fund (City of Melbourne), the Royal Women's Hospital, and the University of Melbourne (Australian Postgraduate Award and Felix Meyer Scholarship).

Received 19 December 2005; revision received 8 June 2006.
