

# The ‘Trendiness’ of Sleep: An Empirical Investigation into the Cyclical Nature of Sleep Time

Pierre Brochu\*    Catherine Deri Armstrong†    Louis-Philippe Morin‡

October, 2009§

## Abstract

Using Canadian time use data, we exploit exogenous variation in local unemployment rates to investigate the cyclical nature of sleep time and show that for both men and women, sleep time decreases when the economy is doing relatively better. Our results suggest that in a recession Canadians sleep an average of 2 hours and 34 minutes more per week, or 22 minutes more per day. Given the importance of even small changes in sleep time on measures of cognitive functioning such as reaction time and concentration, our findings may help explain the countercyclical nature of mortality. Further, as we find that sleep is affected by the same economic variables (notably the unemployment rate) that affect market work time, our results also contribute to the limited literature that shows that sleep time should not be treated as exogenously determined, but, like any other resource, determined by its relative cost.

**Keywords:** business cycles, sleep.

All errors are our own.

# 1 Introduction

Inadequate sleep time has been shown to affect many dimensions of cognitive functioning (reaction time, memory, and concentration in particular), and greatly inhibit our bodies' ability to defend against illness and disease. In short, adequate sleep time is essential for maximizing ones' productivity when awake.

Particularly striking is the impact of sleep on decision making and productivity. A randomized study of medical students in residency training found that those working a 'traditional schedule' made 36 percent more serious medical errors in comparison to the students working the 'intervention schedule' that allowed more time for sleep (Landrigan et al. 2004). Even small changes in quantity of sleep have been found to generate measurable effects. Kamstra et al. (2000) find that the two weekends involved with daylight savings time changes have negative effects on the functioning of financial markets which they attribute to sleep desynchronization.<sup>1</sup> These daylight savings effects are estimated to be 200 to 500 percent of the usual weekend effect, a one day loss equivalent of \$31 billion in the US markets alone.

The effect of sleep on accidents is equally remarkable. Police reports indicate that drowsiness or fatigue is responsible for over 56,000 crashes annually and approximately four percent of crash fatalities on US highways (Knippling & Wang 1994).<sup>2</sup> Powell et al. (2001) find that the potential risks of driving deprived of one night's sleep or driving short two hours of sleep each night for one week is not significantly different from driving with a blood alcohol level above the legal limit with respect to the 11 indices of driving performance considered. And again, even small changes in sleep generate measurable effects: increased motor vehicle accidents are documented following both weekends involved with the one hour daylight savings time changes (Monk 1980, Hicks et al. 1983, Coren 1996).

Using Canadian time use data, we exploit exogenous variation in local unemployment rates to show that sleep is a resource, like any other, that gets sacrificed when the value of one's time becomes more attractive; when the economy is doing relatively better as measured by lower unemployment rates. Our findings contribute to two distinct literatures.

The first is the literature that examines the relationship between health and the business cycle. While wealthier people/countries are in general healthier people/countries, it is not the case that health improves in 'good times'. In a series of papers (Gerdtham & Ruhm (2006), and Ruhm (2000, 2003, 2007)) Ruhm demonstrates that health (as measured by mortality in particular as well as various measures of general health) improve during recessionary periods.

---

<sup>1</sup>Sleep desynchronization is the disruption of the 'dark/light' cycle of the body's circadian rhythms, the 24 hour cycle of the body's biochemical, physiological and behavioural processes.

<sup>2</sup>These figures are argued to be conservative due in part to reporting differences across states and lack of evidence regarding the cause of the crashes (Knippling & Wang 1994).

The most significant fluctuations in mortality are found for those of prime-age and for causes of death disproportionately experienced by this age group: motor vehicle and other accidents (Ruhm 2000).

Three hypotheses are proposed for this countercyclical relationship (Ruhm 2003). First, leisure time becomes more costly during economic upturns, making time intensive, but health enhancing activities like exercise and medical visits relatively more expensive. Using American micro data, he demonstrates that lifestyles do become unhealthier during economic expansions as measured by increased smoking, decreased physical activity and increased obesity (Ruhm 2000). Second, workers' health may be inputs in the production process of goods and services. Increased hours of work associated with economic expansions increase exposure to hazardous working conditions and increase job related stress; both of which have been shown to have deleterious effects on health. This is particularly relevant to cyclically sensitive sectors such as construction, where accident rates are higher. Third, risky activities such as drinking and driving may be normal goods. As such, in times of economic expansion, the incidence of motor vehicle fatalities should increase.<sup>3</sup>

We show that sleep is another time intensive/health enhancing behaviour that responds to economic conditions. The associated decrease in cognitive functioning (concentration and reaction time in particular) due to lower sleep times might help explain the increased accidents in 'good times' – in particular in accident-prone and cyclically sensitive sectors like construction. Similarly, decreased sleep time may exacerbate the effects of increased drinking and driving in 'good times' with respect to motor vehicle accidents and fatalities.

This work also contributes to the literature which questions the assumption of exogeneity of sleep time found in most economic models. In the seminal work of Gary Becker (1965) on the theory of the allocation of time, utility yielding commodities are produced using combinations of market goods and time. The cost of these commodities thus includes both the costs of the market goods and the costs of one's time, including non-monetary costs such as the costs associated with raising children. Consumers allocate their time between work, leisure and sleep to maximize utility.

While this theory is no longer new, economic models most often consider sleep time to be exogenously determined, and question only the allocation of the remaining two thirds of our days between market and non-market (leisure) activities (Biddle & Hamermesh 1990). Most models thus exclude the possibility that sleep may generate utility, that sleep may be affected by other factors in the model (for example earnings potential), and that sleep may

---

<sup>3</sup>Ruhm & Black (2002) verify that alcohol consumption is in fact procyclical. While stress induced drinking may increase during recessionary periods, it is found to be offset by reduced consumption due to lower incomes and other economic factors.

also directly affect such factors (through say productivity). The authors show that such omissions bias estimates of labour supply elasticities.<sup>4</sup>

Two economic studies empirically examine this assumption of exogeneity of sleep time. Biddle & Hamermesh (1990) develop a utility based demand model for the allocation of time across three uses: market work, sleep and leisure time, in which sleep is a choice variable that enhances both productivity and utility. Using 1975-76 American time use data, they confirm that sleep is in fact a choice variable affected by the same economic variables (namely wages and household income) affecting market work and leisure time. Szalontai (2006) replicates the analysis of Biddle & Hamermesh using South African time use data and finds robust evidence that wages and education have negative effects on sleep, suggesting again that sleep time is a resource like any other that gets sacrificed when the value of one's time becomes more attractive.

We find that sleep is a choice variable affected by the same economic variables (here, the UR) that affect market work time. Thus our results also contribute to the works of Biddle & Hamermesh (1990) and Szalontai (2006) who show that the quantity of sleep time should not be treated as exogenously determined as is the norm in standard economic models, but, like any other resource, determined by its relative cost.

In sum, we find that sleep time is countercyclical. Our results suggest that in a recession Canadians will sleep an average of 2 hours and 34 minutes more per week, or 22 minutes more per day.<sup>5</sup> The effect is strongest for those of prime-age and is present for both men and women, but is experienced through different channels. The change in sleep time for women appears to be driven by movements in and out of the labour force, but for men it is also driven by changes (voluntary and/or involuntary changes) in the amount of time spent working.

As the literature clearly demonstrates that sleep time affects both productivity and accident risk, evidence of the countercyclical nature of sleep time can help employers encourage behaviours that promote healthy and productive workforces. Regulations limiting overall hours for employees operating heavy machinery, the provision of taxi chits for employees working well into the night or extra 'off time' for employees during economic expansions are simple, albeit not costless, ways to reduce the risks of accidents and illness.

---

<sup>4</sup>Gronau (1986) provides a good overview of the theoretical literature that examines the optimal allocation of non-market, non-sleep time.

<sup>5</sup>Following Oreopoulos et al. (2006), we assume that the unemployment rate increases by five percentage points in a recession.

## 2 Data and Basic Patterns

Our main source of data is three time use cycles of Statistics Canada’s General Social Surveys (GSS) corresponding to the years 1992, 1998, and 2005.<sup>6</sup> The data are based on telephone interviews which inquire about activities during the previous day in a diary format, reflecting a 24 hour period from 4am to 4am. Information on activities done on one’s own and with others, as well as socio-demographic characteristics of the household are recorded. These data are particularly useful in that they cover an expansionary period (2005) and a recessionary period (1992).<sup>7,8,9</sup>

While each respondent is interviewed only once (reflecting one 24 hour window), the sample is evenly distributed over each month of the survey year and across each day of the week so as to be capture seasonal and day-of-the-week variation in time use. This paper explores how sleep varies with the business cycle, as proxied by monthly, provincial unemployment rates. Unlike most surveys which collect data over a short period of time, monthly data provides us with additional variation (i.e. variation across months) when identifying the effect of the unemployment rate on time spent sleeping.

The provincial unemployment rates are estimated using the public use Labour Force Survey (LFS) files. The LFS is a large monthly household survey that gathers information on the labour market activities of Canadians. The LFS is used by Canada’s statistical agency to compute official labour force statistics (e.g. unemployment rate).

We restrict our sample to the working age population, individuals 20 to 69 years of age. We replicate the analysis in age ranges to investigate whether the UR has stronger effects for those of prime working age, those most likely to be affected by economic conditions due to their higher rates of labour force participation. Students and observations with missing

---

<sup>6</sup>Statistics Canada’s General Social Surveys are annual telephone surveys that “gather data on social trends in order to monitor changes in the living conditions and well-being of Canadians over time... and provide immediate information on specific social policy issues of current or emerging interest” (Statistics Canada 2006). Each year a different topic is considered. Time use has been the topic at regular intervals since the inception of the GSS program in 1985.

<sup>7</sup>This is an advantage over the new American Time Use Survey, which began only in 2003 which to date does not include any recessionary periods.

<sup>8</sup>There is a 1986 GSS time-use survey, but two key data limitations prevent us from using it. First, the only measure of health status available in the surveys is measured very differently in the 1986 survey. As health is theoretically one of the most important determinants of sleep time, we felt it was important to be controlled for in the regressions. But as only the later surveys allow for comparable measures of health, the 1986 survey is excluded from the analysis herein. Second, the 1986 survey was carried out over a six week period - unlike later time-use surveys which were carried out throughout the survey year. As such, the inclusion of the 1986 adds little variation for identifying the key unemployment rate effect. We have verified that the exclusion of the 1986 survey (N=7,429) does not drive our results in models excluding controls for health. These regressions are available from the authors upon request.

<sup>9</sup>Comparing different sources of information on time use, Juster & Stafford (1991) conclude that time diaries, like the GSS, provide the most valid measures of time use.

information are excluded from the analysis.<sup>10</sup> A detailed description of the sample restrictions is provided in Appendix A.

Figure 1 shows the periods for which we have time use data (vertical bars) – superimposed over provincial unemployment rates for a few select provinces (i.e. Ontario, Alberta and British Columbia). Figure 1 demonstrates considerable variation in unemployment rates over time and across provinces. This variation is used to identify the effect of UR on sleep, as explained in the next section.

Basic summary statistics for the three time-use surveys can be found in Table 1. The sleep variable is defined to include only essential sleep. The GSS codebook defines essential sleep as “the longest sleep of the day (usually at night); including “in bed” but not asleep, trying to sleep”.<sup>11</sup> We re-normalize activity time in terms of hours per week. This is done as to more easily compare our results with the labour time-use literature (e.g. Biddle & Hamermesh (1990)).<sup>12</sup> Table 1 shows that on average, women sleep more than men; sleep time tends to decrease with education level; and finally, individuals that work or have young children also sleep less.

### 3 Empirical Strategy

We estimate the impact of the unemployment rate on time spent on different activities using the following model

$$act\_time_{ipt} = \beta_0 + \beta_1 UR_{pt} + X_{ipt}\gamma + \delta_p + \phi_t + \epsilon_{ipt} \quad (1)$$

where  $act\_time_{ipt}$  is the hours spent per week on a particular activity (sleep, work or leisure) for individual  $i$  in province  $p$ , and at time  $t$ . The unit of time is the month/year. As such,

---

<sup>10</sup>We recognize that excluding students may bias our sample as in recessionary times, when job opportunities become relatively scarce, people may exit the labour force to go to school. Our findings are robust to the inclusion of students.

<sup>11</sup>The variable ‘essential sleep’ reflects the relevant sleep time in the 24 hour window. Recall that the data are constructed from individual recollections about a 4am to 4am period. There are three alternative measures of sleep available in the GSS. ‘Incidental sleep’ includes time lying down, napping and resting. We do not use this as our preferred measure of sleep as napping, resting etc. are more akin to leisure time. Next, individuals asleep at the beginning of the reference day (4am) were asked at what time they fell asleep the night before. Individuals asleep at the end of the reference day (4am) were asked at what time they woke up the next morning. These are also not our preferred measures of sleep as they are available only for respondents who were asleep at the beginning and end of the reference day. For example, we would lose from our sample anyone working shift work on the reference day. In addition, one cannot be sure these two measures account for the full sleeping time as sleep interruptions (for example, waking up to take care of children, use the bathroom or other reasons for night wakings) cannot be inferred from the two measures. Our main results remain essentially unchanged when any of these alternative measures are used.

<sup>12</sup>The time diaries cover a 24 hour period - where each activity is measured in minutes. We convert the activity time into hours per week by multiplying by 7 and dividing by 60.

individuals whose time diaries were held in the same month and year will have the same  $t$  in our regression analysis. The key explanatory variable of interest,  $UR_{pt}$ , is the unemployment rate for province  $p$  in period  $t$ .

The vector of controls ( $X_{ipt}$ ) in our main specification includes controls for gender, age, education, marital status, the presence of young children in the household (number of children four and under, and 18 and under), self-reported poor health, reference diary day of the week and a dichotomous variable taking the value one if the individual’s main activity is paid work but he did not work on the reference day (day off). The day off variable will help control for the likely higher amount of sleep time on non-work days (primarily weekends) and days taken off from work due to illness.

Finally we include both provincial and time (month/year) dummies.<sup>13</sup> The provincial and month/year dummies in Equation (1) control for systematic differences in sleep time across provinces and time. Specifically, the month/year dummies allow us to remove any seasonal effects (e.g. increased sleep time during the winter months) and any common long-term trends (e.g. changing social norms regarding sleep) from our estimated labour market condition effect. Our specification thus relies on movements within each province relative to a common time trend to identify the UR effect, a commonly used differences-in-differences strategy.

UR is thought as being exogenous in the *economic* sense (i.e. determined outside the model) as in Ruhm (2000, 2003, 2007), Ruhm & Black (2002), Oreopoulos et al. (2006), and Miller et al. (2009). However, health is probably an outcome variable (i.e. it may be affected by *sleep\_time*). This reverse causality issue combined with a potential correlation between UR and health, may introduce a correlation between UR and the error term ( $\epsilon_{ipt}$ ), making UR endogenous in the *econometric* sense.<sup>14</sup> In the Appendix, we use a simple simultaneous equation model to get some insight into the potential biases of 1) including a potentially endogenous health variable, and 2) omitting it from Equation (1).<sup>15</sup> Both scenarios suggest that, if health is positively affected by UR (as suggested by the Ruhm papers cited above), the estimator of the UR coefficient will be downward biased.<sup>16</sup>

Finally, the analysis in this paper relies on normalized GSS weights. The sample weights

---

<sup>13</sup>That is, each month of each year has its own dummy variable.

<sup>14</sup>For example, this reverse causality may arise if having difficulties sleeping affects self-perceived health. We investigate the potential effect of sleeping difficulties in Section 4.1.

<sup>15</sup>Many authors (e.g. Angrist & Pischke (2009)) favor not including an endogenous control when there is no appropriate instrument. In our case, the UR coefficient estimator will capture both the direct and indirect (through health) effects of UR on sleep.

<sup>16</sup>Although health is the most obvious candidate for being endogenous, other regressors could in principle also be seen as outcome variables (e.g. *dayoff*). We use the same inclusion/exclusion strategy for these other regressors to investigate the robustness of the UR estimate across specifications.

sum to unity within each survey, giving each of the three surveys equal weight.<sup>17</sup> In addition, we cluster our standard errors (by province, month and year) in all our regression specifications.

## 4 Results

We start by estimating Equation (1) with essential sleep as the dependent variable. Table 2 shows the impact of the UR when we introduce controls sequentially. Specification (1) controls for day, month-year, and province only. In Specification (2), we add gender, age and education controls. Specification (3) adds controls for marital status and the presence of children, and whether the diary is a day is a day off (if employed). Finally, Specification (4) adds a control for health status to investigate whether the impact of unemployment on sleep is mainly due to changes in health status.

The unemployment rate effect is robust to the inclusion of controls. The unemployment rate coefficient varies insignificantly (0.493 to 0.513) across specifications; implying that a 1 percentage point increase in the unemployment rate will increase sleep time by approximately half an hour per week.<sup>18</sup> If the unemployment rate increases by 5 percentage points in a typical recession, we can interpret the coefficient of 0.512 in Specification (4) as implying that in a typical recession, Canadians sleep on average 2 hours and 34 minutes more per week.<sup>19</sup> Based on our discussion in Section 3, we are confident that that the UR coefficient can be interpreted as conservative, if health is truly endogenous.

Results from Table 2 suggest that the labour market conditions have an impact on sleep time for the general adult population (aged 20 to 69). Next we verify whether the effect of economic conditions is larger for those with stronger ties to the labour market, those with the higher labour force participation rates. Table 3 replicates the sequential addition of controls (as shown in Table 2), but for a more restricted sample: individuals aged 30

---

<sup>17</sup>Our results are robust to the choice of normalization. We repeated our analysis using weights which were normalized to sum to one across all surveys, thus putting considerably more weight on the larger survey (2005). This did not materially affect our findings. As a final robustness check, we repeated our analysis without weights. Again our conclusions remain unchanged.

<sup>18</sup>A coefficient of 0.5 represents half an hour.

<sup>19</sup>As a robustness check we tried ways to control for the common unobserved time effect. We tried month and year dummies (instead of a fully flexible time trend); we also tried region specific (linear) time trend, i.e. each of the three regions in Canada had their own time trend. The three regions were West (B.C. Alberta, Saskatchewan and Manitoba), Central (Ontario and Quebec) and East (The Maritimes and Newfoundland). Finally, we tried province specific time trends. The standard errors do, however, becoming larger because we are removing more variation. In all these cases, the UR coefficient is essentially the same as in our preferred specification (i.e. using month/year dummies).

to 49.<sup>20</sup> The unemployment rate findings are again very stable across specifications. More importantly, these results indicate that prime-aged individuals respond more to changes in unemployment rate. A regression of the sub-sample of retired individuals, or the sub-sample of older respondents (e.g. 60 to 69 years of age) generate a statistically insignificant UR effect.

With respect to covariates, Tables 2 and 3 suggest that females sleep on average two hours more per week than males. Not surprisingly, these tables also suggest that the presence of children, decreases sleep time and poor health significantly increases sleep time. By construction, the child 4 and under and child 18 and under variables both take on the value 1 if an individual has a young child (i.e. 4 and under). The estimated effect on sleep time of having a young child is thus the sum of both coefficients. For example, Specification (3) in Table 2 shows that individuals with children 4 or under sleep 1.388 ( $0.531 + 0.857$ ) hours less than individuals without children 18 or under.

In Table 4, we re-estimate the full model (Specification (4) in Table 3) by gender. This table shows some differences between males and females. The UR coefficient of 0.741 implies that in a typical recession men aged 30 to 49 years of age sleep on average three hours and forty two minutes more per week. It would appear that women are less affected by a recession than males, although the difference is not statistically significant.<sup>21</sup>

## 4.1 Channels

Labour market conditions may affect individuals' sleep time through multiple channels. First, as documented in Ruhm (2003), labour market conditions may affect people's health and consequently, their sleep. Second, increased stress due to economic downturns may lead to increased difficulties falling asleep or staying asleep and thus longer periods of 'essential sleep'.<sup>22</sup> Note that while health and stress are related, the health and stress channels affect sleep in opposite directions. An increase in UR is found to improve health which is associated with lower sleep requirements, while an increase in UR generally increases stress which is associated with increased difficulties falling and staying asleep. Third, some employees will be laid off as the economic conditions deteriorate thereby increasing the amount of time available for other activities such as leisure and sleep. Lastly, employees who are not laid off

---

<sup>20</sup>Ruhm (2003) finds that the effect of the unemployment rate on general health is larger for individuals aged 30 to 55.

<sup>21</sup>We tested for whether the male-female difference was statistically different from zero by including a full set of gender interaction terms. We could not reject the null hypothesis that the unemployment rate effect was the same across gender.

<sup>22</sup>Recall that our dependent variable 'essential sleep' includes time sleeping and time lying down and trying to sleep.

may also see their amount of time spent working decrease as a consequence of an intentional choice (as the marginal benefit of working may decrease) or as a consequence of unintentional (imposed) changes in work schedules. We will refer to these mechanisms as the ‘health’, ‘stress’, ‘layoff’ and ‘hour adjustment’ channels, respectively.<sup>23</sup>

Table 5 investigates the importance of these potential channels by comparing the estimates of the effect of UR on sleep under different specifications switching on and off controls for these potential channels (health, stress, and employment). Regressions are reported for the prime age sub-sample and for men and women separately. Specifications 1 are reference regressions from Table 4.

We investigate the importance of the health channel by estimating models where we include/exclude individuals that are in poor health. For both men and women, the estimated UR coefficients remain significant (and relatively unchanged) whether we use the full sample with or without a health control (Specifications 1 and 3), or focus only on healthy individuals (Specification 2). These findings suggest that the ‘health channel’ is not driving our results.<sup>24</sup>

To investigate the stress channel we consider two alternative specifications.<sup>25</sup> First we add a dichotomous indicator for self-reported difficulty sleeping (Specification 4). To the extent that this variable captures the negative effects of cyclically induced stress, the UR coefficient should be void of the stress channel. Having difficulties sleeping is found to be significantly associated with reduced sleep time. The UR effect is dampened slightly but remains statistically and economically significant suggesting that the ‘stress channel’ may be influencing our results but not driving them.<sup>26</sup> Next, we rerun the analysis using an

---

<sup>23</sup>While we use the term ‘layoff’ adjustment to refer to unintentional movements out of the labour force, we recognize the possibility that some workers might rationally choose to leave the labour market, as for example due to decreased wages in bad times.

<sup>24</sup>That the UR coefficient essentially does not change going from a regression excluding health as control to one including health as a control would seem to suggest that the Ruhm story - that health improves during recessions - does not hold. However, the literature indicates that mortality (from motor vehicle or other accidents) is the main measure of health affected, and not general health as in our paper. Finally, it should be noted that one cannot state with certainty that UR does not affect health (other than through accidents). Our health measure is self-assessed, and as such, may not accurately measure a person’s general health. If this is the case, there could be a link between general health and UR (which we not be able to pick up). This would result in an endogeneity problem. The simple two equation model that is presented in the appendix provides guidance. If we do not control for health in the regression, we know that our estimate of the UR effect is in fact a conservative estimate.

<sup>25</sup>Although stress and health are clearly related, one must pay particular attention to the stress link because of the way our essential sleep variable is defined - it includes in bed but not asleep, trying to go to sleep. As such, it is important to see whether our measure of sleep increases with UR because people are actually sleeping more or because they simply spend more time trying to fall sleep.

<sup>26</sup>We also run a probit model with difficulty sleeping as the dependent variable and the same set of covariates. We find that the probability of reporting difficulty sleeping is negatively correlated with the UR as opposed to positively as the ‘stress channel’ would predict. The UR point estimate is statistically significant but small in magnitude. This again points to the insignificance of the ‘stress channel’ in explaining our findings.

alternative measure of sleep as the dependent variable: sleep duration from the time the individual fell asleep the night before the reference day and the time she woke up on the reference day, provided it was after 4am (Specification 5). Recall this is not our preferred measure of sleep as it is only defined for anyone who was asleep at 4am when the 24 time diary began, excluding for example shift workers (see footnote 12). If the stress channel is driving our results then this pure sleep duration specification should find no effect of UR on sleep time. For both men and women the UR effect remains in large and statistically significant.

Specification 6 and Tables 6 and 7 provide a series of exercises in which we explore the ‘layoff’ and hours’ channels. In Specifications (6) we shut down the UR ‘layoff effect’ channel by excluding unemployed respondents. The results suggest that the roles of these channels differ for males and females.

For males, the UR estimate found when restricting the sample to employed individuals is smaller but still statistically and economically significant. This suggests that the effect of unemployment on males’ sleep time goes through both the ‘layoff’ and the ‘hour adjustment’ channels.

On the other hand, for females the effect of unemployment rate on sleep seems to go solely through changes in employment situation (i.e. the ‘layoff’ channel). The UR coefficient in the reference Specification (1) is significant but becomes small and statistically insignificant once we restrict the sample to employed women (Specification 6).<sup>27</sup>

These findings are further corroborated by examination of the impact of UR on time spent working (Table 6).<sup>28</sup> In Panel A, we restrict our attention to workers only. In Panel B, we use the full sample (workers and non-workers).

Similar to the effect of UR on sleep, the magnitude of the effect of UR on work for males is larger for the full sample than for workers only. These findings again support the conjecture that, for males, the effect of the UR on sleep goes through both the ‘hours adjustment’ and ‘layoff’ channels. Recall that the full sample coefficient captures the effects of both channels while the workers only sub-sample captures the ‘hours adjustment’ channel only.

For females, the UR coefficient in the work regression is not significant in either regression (full sample or workers only). That the UR coefficient is not significant in the workers only regression supports our story that the adjustment does not occur through adjustment in

---

<sup>27</sup>Although the estimated coefficients for ‘children 4 or under’ and ‘children 18 or under’ are usually not individually statistically significant at the 95% level, the sum of these coefficients is in almost all cases significant, meaning that women with children 4 and under sleep more than women without children 18 and under.

<sup>28</sup>The work variable is broadly defined to include all time spent at work (including breaks). It does not, however, include time spent traveling to and from work. The reported coefficients are obtained from separate regressions.

hours. However, in the full sample regression where the UR coefficient should pick up both channels we might have expected the effect to be more significant.<sup>29</sup> While finding different results for men and women is commonplace in labor economic analysis, we are unable to precisely determine where the differences are coming from.

Table 7 further explores the ‘hour’ and ‘layoff’ adjustment channels. Changes in the UR lead to changes in wages - the most commonly used measure of individuals’ opportunity cost of time. If all the changes in sleep we observe over the business cycle reflect intentional responses to changes in wages - then we are capturing nothing more than the same ‘opportunity cost of time’ story as in Biddle & Hamermesh (1990) and Szalontai (2006). In this case, the estimated effect of the UR should fall to zero when wages are included in the regression. If, including wage does not fully explain away the UR effect, then there is evidence of some unintentional effects (layoffs or reduced hours) on sleep time.

In this table we include personal income as a proxy for opportunity cost of time (wages) in the regressions.<sup>30</sup> We find that for males the income effect is both economically and statistically significant, and of the expected sign. This is further evidence that sleep time is a function of one’s opportunity cost of time as shown in Biddle & Hamermesh (1990) and Szalontai (2006). The UR effect is dampened but remains economically significant. We again conclude that for men both the intentional (opportunity cost argument) and the unintentional (layoffs and reduced hours brought about by recessionary times) effects matter. For females, the statistical insignificance of the log income variable confirms our earlier findings that the impact of unemployment rate on sleep goes through (unintentional) movements in and out of employment. As a falsification test, we looked at the effect of UR on older respondents (60 to 69 years of age) that are retired. By the very fact that they are retired, we should

---

<sup>29</sup>As females tend to work less in general, in particular during child-bearing years, there is a significant amount of zero hours worked. We have run a tobit model and found that the UR coefficient is more negative but remain insignificant.

<sup>30</sup>Respondents’ wages are the main measures of opportunity cost of time used in Biddle & Hamermesh (1990) and Szalontai (2006). To replicate the results of their studies we would want to include the same measure. Unfortunately, wage data is not available in the Canadian GSS. We thus rely on total personal income as a proxy. Personal income is likely correlated with wages but includes all sources of income including for example: social assistance, rental and interest income. Income is not measured continuously but only in ranges, and has a 22% non-response rate. Following Phipps et al. (2001) we create a continuous measure of income using the midpoints of the ranges and inflating the 1992 and 1995 values to 2005 dollars, and control for missing income using a dummy variable. To deal with top-coding, we use 1.5 times the highest bracket (ie. for incomes in excess of \$80,000, we input \$120,000). As a robustness exercise we use the fact that we can identify the main source of income in the 1998 and 2005 surveys to more precisely estimate the effect of ‘wages’ on sleep time. We replicate our analysis using only the 1998 and 2005 surveys, for two different samples: the base group of workers, and the group of workers whose main source of income comes from wages and salaries. The log income and UR coefficients were not found to be materially different.

not observe any hours adjustment or layoff effect. The UR coefficient was both economically and statistically insignificant.<sup>31</sup>

## 5 Discussion and Conclusion

Using Canadian time use data, we exploit exogenous variation in local unemployment rates to investigate the cyclical nature of sleep time and show that for both men and women, sleep time decreases when the economy is doing relatively better. A five percentage point increase in unemployment rate (equivalent to the average change in unemployment rate during a recession) is associated with 2 hours, 34 minutes more sleep per week. The effect is present for both males and females, though is experienced through different channels. The change in sleep time for women appears to be driven by movement in and out of the labour force, but for men it is also driven by changes (voluntary and/or involuntary changes) in the amount of time spent working.

The statistical significance of the effect of economic conditions on sleep time is clear. But how should we interpret a two and a half hour change in sleep time over the course of a week with respect to mental and physical functioning? While the majority of research examines the effects of larger changes in sleep time on various cognitive outcomes, some studies do examine smaller changes. As discussed in the introduction, the one hour changes associated with daylight savings time have been associated with negative effects on the functioning of financial markets as well as increased motor vehicle accidents. An Israeli study of 5th grade students examined the effect of school starting hour on sleep duration and measures of fatigue and attention/concentration problems. Students with the earlier start times (7:10am as compared to 8:00am) slept on average 24 minutes less on school days and were 50 percent (21% vs. 14% respectively) more likely to report being tired throughout the day and 71% percent (12% vs. 7% respectively) more likely to report attention or concentration problems (Epstein et al. 1998). There is also evidence of negative effects of accumulated sleep loss. In a review article on the effects of chronic sleep restrictions on neurobehavioral and physiological functioning, Banks & Dinges (2007) summarize that existing experimental evidence suggests that restricting sleep to below 7 hours per night over a period of time leads to significant daytime cognitive dysfunction equivalent to that found after severe acute sleep deprivation.

---

<sup>31</sup>We acknowledge that the relationship between hours, stress, employment and health is likely complex and that by looking at subgroups or adding key controls to separately identify specific channels, we are assuming these channels to be additively separable. In the end however, patterns emerge that provide a consistent story that some channels are driving our results more than others. For example, the results from tables 2 through 7 all point to the fact that the employment channel and the hours channel matter, and that stress and poor health do not drive our results.

In sum, our finding of 20 minutes less sleep per day during an economic expansion is likely large enough to have economically significant effects on individual health, productivity and safety.

Our findings contribute to two distinct literatures. First, given the importance of even small changes in sleep time on such measures of cognitive functioning as reaction time and concentration, our findings can help explain the countercyclical nature of mortality found in the works of Ruhm (2000, 2007) and Gerdtham & Ruhm (2006). In particular Ruhm shows that overall and cause specific mortality increases as economic conditions improve - and the effect is largest for fatalities disproportionately experienced by younger adults: motor vehicle accidents and other accidents. Accidents of all kinds are more likely to occur and perhaps be more severe when sleep times are lower.

Second, we show that part of the effect of UR on sleep for males occurs through the effect of UR on personal income - through changes in individual's opportunity cost of time. Our results thus also contribute to the works of Biddle & Hamermesh (1990) and Szalontai (2006) who show that the quantity of sleep time should not be treated as exogenously determined as is the norm, but, like any other resource, determined by its relative cost.

These results are also consistent with the recent work of Miller et al. (2009) who use American mortality data from 1972 to 2004 to investigate possible mechanisms to help explain the pro-cyclicality of mortality.<sup>32</sup> The authors hypothesize that procyclical motor vehicle fatalities may be due to either changes in individual behaviour or externalities such as the increased number of vehicles on the road in good times. They report that the estimated effect of the UR on motor vehicle fatalities is of similar magnitude across all age groups, and take this to suggest that the externalities explanation is the more reasonable. However, because accidents often involve other vehicles, it is plausible that even if the increase in dangerous driving in good times is primarily experienced by those of prime age - a situation possibly exacerbated by increased number of vehicles on the road - adverse affects on all motorists would still be expected. The increase in the number of motor vehicle fatalities would be expected to be highest for prime aged individuals (which they predict) but be affecting all age groups (which they predict as well).

As the literature clearly demonstrates that sleep time affects both productivity and accident risk, evidence of the countercyclical nature of sleep time can help employers encourage behaviours that promote healthy and productive workforces. Regulations limiting overall hours for employees operating heavy machinery, the provision of taxi cabs for employees

---

<sup>32</sup>They find, like in the Ruhm papers, that the estimated effect of business cycles is largest in magnitude for motor vehicle fatalities as compared to 11 other causes of death. The largest decline in motor vehicle fatalities, resulting from a one percentage point increase in the UR, is predicted for individuals 18-54 years of age and accounts for 73 percent of the overall decrease.

working well into the night or extra 'off time' for employees during economic expansions are simple, albeit not costless, ways to reduce the risks of accidents and illness.

## Appendix A – Sample Restrictions

Beginning from the sample of 31,995 20 to 69 year olds, we exclude:

1. Anyone who reports being a student as their main activity the previous week;
2. Anyone with missing information for age, gender, marital status, education, student status, the presence of children 4 years and under, province of residence, or the day of the time diary, or;
3. Anyone whose unaccounted time exceeds 15 minutes, or;
4. Anyone whose phone interview day is more than two days after the diary day. One would expect greater recall problems the further apart the interview is from the diary day.

Following these sample restrictions, we are left with a sample of 28,380 individual observations.

## Appendix B - Reverse Causality and Omitted Variable Problems

Assume the following simple model:

$$sleep_i = \alpha_0 + \alpha_1 UR_i + \alpha_2 phealth_i + \varepsilon_i \quad (2)$$

$$phealth_i = \beta_0 + \beta_1 UR_i + \beta_2 sleep_i + \nu_i \quad (3)$$

If we were to regress

$$s\tilde{leep}_i = \alpha_1 \tilde{U}R_i + \alpha_2 p\tilde{he\grave{a}lth}_i + \tilde{\varepsilon}_i \quad (4)$$

$$s\tilde{leep} = \tilde{\mathbf{X}}\alpha + \tilde{\varepsilon}$$

where  $\tilde{z}_i = z_i - \bar{z}$ , and

$$\tilde{\mathbf{X}} = \begin{bmatrix} \vdots & \vdots \\ \tilde{U}R_i & p\tilde{he\grave{a}lth}_i \\ \vdots & \vdots \end{bmatrix},$$

the OLS estimator for  $\alpha$  would be defined as

$$\begin{aligned} \hat{\alpha} &= (\tilde{\mathbf{X}}' \tilde{\mathbf{X}})^{-1} \tilde{\mathbf{X}}' s\tilde{leep} \\ &= \alpha + (\tilde{\mathbf{X}}' \tilde{\mathbf{X}})^{-1} \tilde{\mathbf{X}}' \tilde{\varepsilon} \end{aligned}$$

Then,

$$\begin{aligned} plim \hat{\alpha} &= \alpha + plim \left( \frac{\tilde{\mathbf{X}}' \tilde{\mathbf{X}}}{n} \right)^{-1} plim \left( \frac{\tilde{\mathbf{X}}' \tilde{\varepsilon}}{n} \right) \\ &= \alpha + Q^{-1} plim \left( \frac{\tilde{\mathbf{X}}' \tilde{\varepsilon}}{n} \right) \end{aligned}$$

Since

$$\frac{\tilde{\mathbf{X}}' \tilde{\varepsilon}}{n} = \begin{bmatrix} \sum(\tilde{U}R_i \tilde{\varepsilon}_i)/n \\ \sum(p\tilde{he\grave{a}lth}_i \tilde{\varepsilon}_i)/n \end{bmatrix},$$

then

$$plim \left( \frac{\tilde{\mathbf{X}}' \tilde{\varepsilon}}{n} \right) = \begin{bmatrix} 0 \\ cov(p\tilde{he\grave{a}lth}_i, \varepsilon_i) \end{bmatrix}.$$

Therefore

$$plim \hat{\alpha} = \alpha + Q^{-1} \begin{bmatrix} 0 \\ cov(p\tilde{he\grave{a}lth}_i, \varepsilon_i) \end{bmatrix}$$

Now,

$$\tilde{\mathbf{X}}' \tilde{\mathbf{X}} = \begin{bmatrix} \sum \tilde{U}R_i^2 & \sum \tilde{U}R_i p\tilde{he\grave{a}lth}_i \\ \sum \tilde{U}R_i p\tilde{he\grave{a}lth}_i & \sum p\tilde{he\grave{a}lth}_i^2 \end{bmatrix}$$

$$(\tilde{\mathbf{X}}'\tilde{\mathbf{X}})^{-1} = \frac{1}{\sum \tilde{U}R_i^2 \sum p\text{health}_i^2 - (\sum \tilde{U}R_i p\text{health}_i)^2} \begin{bmatrix} \sum p\text{health}_i^2 & -\sum \tilde{U}R_i p\text{health}_i \\ -\sum \tilde{U}R_i p\text{health}_i & \sum \tilde{U}R_i^2 \end{bmatrix}$$

$$\text{plim} \left( \frac{\tilde{\mathbf{X}}'\tilde{\mathbf{X}}}{n} \right)^{-1} = \begin{bmatrix} \left[ \text{var}(UR_i) - \frac{(\text{cov}(UR_i, p\text{health}_i))^2}{\text{var}(p\text{health}_i)} \right]^{-1} & \left[ \text{cov}(UR_i, p\text{health}_i) - \frac{\text{var}(p\text{health}_i)\text{var}(UR_i)}{\text{cov}(UR_i, p\text{health}_i)} \right]^{-1} \\ \left[ \text{cov}(UR_i, p\text{health}_i) - \frac{\text{var}(p\text{health}_i)\text{var}(UR_i)}{\text{cov}(UR_i, p\text{health}_i)} \right]^{-1} & \left[ \text{var}(p\text{health}_i) - \frac{(\text{cov}(UR_i, p\text{health}_i))^2}{\text{var}(UR_i)} \right]^{-1} \end{bmatrix}$$

Finally, we get

$$\text{plim} \hat{\alpha} = \alpha + \begin{bmatrix} \left[ \text{cov}(UR_i, p\text{health}_i)(1 - 1/\rho^2) \right]^{-1} \text{cov}(p\text{health}_i, \varepsilon_i) \\ \left[ \text{var}(p\text{health}_i)(1 - \rho^2) \right]^{-1} \text{cov}(p\text{health}_i, \varepsilon_i) \end{bmatrix} \quad (5)$$

where  $\rho = \text{corr}(UR_i, p\text{health}_i)$ . We care about the top element of the vector in equation (5). If we believe Ruhm's findings, then we'd expect to have

$$\left[ \text{cov}(UR_i, p\text{health}_i)(1 - 1/\rho^2) \right]^{-1} \geq 0$$

Now if we plug equation (2) in equation (3), we get

$$p\text{health}_i = \left( \frac{\beta_0 + \beta_2\alpha_0}{1 - \beta_2\alpha_2} \right) + \left( \frac{\beta_1 + \beta_2\alpha_1}{1 - \beta_2\alpha_2} \right) UR_i + \left( \frac{\beta_2\varepsilon_i + \nu_i}{1 - \beta_2\alpha_2} \right) \quad (6)$$

Hence,

$$\text{cov}(p\text{health}_i, \varepsilon_i) = \text{cov} \left( \frac{\beta_2\varepsilon_i + \nu_i}{1 - \beta_2\alpha_2}, \varepsilon_i \right)$$

if we assume  $\text{cov}(UR_i, \varepsilon_i) = 0$ . We get

$$\text{cov}(p\text{health}_i, \varepsilon_i) = \frac{\beta_2}{1 - \beta_2\alpha_2} \text{var}(\varepsilon_i) + \frac{1}{1 - \beta_2\alpha_2} \text{cov}(\varepsilon_i, \nu_i)$$

We expect  $\beta_2 < 0$  and  $\alpha_2 > 0$ . Then  $1 - \beta_2\alpha_2 > 0$ . Let

$$\begin{aligned} \phi_1 &= \frac{\beta_2}{1 - \beta_2\alpha_2} \\ \phi_2 &= \frac{1}{1 - \beta_2\alpha_2} \end{aligned}$$

Then,

$$\begin{aligned} \text{cov}(p\text{health}_i, \varepsilon_i) &= \phi_1 \text{var}(\varepsilon_i) + \phi_2 \text{cov}(\varepsilon_i, \nu_i) \\ &= (-)(+) + (+)(?) \end{aligned}$$

If  $\text{cov}(\varepsilon_i, \nu_i) \leq 0$ , then  $\text{plim}\hat{\alpha} < \alpha$ . Also, if  $\text{cov}(\varepsilon_i, \nu_i) > 0$  but  $|\phi_1 \text{var}(\varepsilon_i)| > \phi_2 \text{cov}(\varepsilon_i, \nu_i)$  (i.e. the reverse causality problem dominates the omitted variable problem), then  $\text{plim}\hat{\alpha} < \alpha$ . The only problematic case is when  $|\phi_1 \text{var}(\varepsilon_i)| < \phi_2 \text{cov}(\varepsilon_i, \nu_i)$  (i.e. when the omitted variable problem dominates the reverse causality problem).

If instead of estimating equation (4) we estimated the reduced form equation

$$sleep_i = \omega_0 + \omega_1 UR_i + u_i \tag{7}$$

where

$$\begin{aligned} \omega_0 &= \frac{\alpha_0 + \alpha_2 \beta_0}{1 - \beta_2 \alpha_2} \\ \omega_1 &= \frac{\alpha_1 + \alpha_2 \beta_1}{1 - \beta_2 \alpha_2} \\ u_i &= \frac{\alpha_2 \nu_i + \varepsilon_i}{1 - \beta_2 \alpha_2} \end{aligned}$$

and again assume that  $cov(UR_i, \varepsilon_i) = cov(UR_i, \nu_i) = 0$ , then we would expect to have  $plim \hat{\omega}_1 = \omega_1$ . Of course, except under very special circumstances (e.g.  $\alpha_2 = 0$ ), we should have  $\omega_1 \neq \alpha_1$ . We can still say something about  $\alpha_1$  if we are willing to make some common sense assumptions about some parameters. First, we have to assume, as we did above, that sleep is good for your health (i.e.  $\beta_2 < 0$ ) and that illness forces you to sleep more (i.e.  $\alpha_2 > 0$ ). We also assume that the Ruhm (2000) findings are correct; bad economic outcomes are good for your health (i.e.  $\beta_1 < 0$ ). Then, we can see that

$$plim \hat{\omega}_1 = \omega_1 < \alpha_1$$

Hence, OLS estimates of  $\omega_1$  in the reduced form equation (7) should give us a conservative estimate of  $\alpha_1$  regardless of the correlation between the error terms  $\varepsilon_i$  and  $\nu_i$ .

Dependent variable: Weekly Hours of Sleep. For Specification (5) we use an alternative measure of sleep						
All specifications includes education, age, day, province and month-year controls						
Specification (2) excludes individuals in poor health; Specification (6) excludes those that are unemployed.						
Standard errors in parentheses. The standard errors are clustered at the province-month-year level.						
* significant at 10%; ** significant at 5%; *** significant at 1%						

Table 6: Sleep, Work, and Leisure - 30 to 49 years of age

Dependant Variable	Men		Women	
	Sleep	Work	Sleep	Work
A. Workers Only				
Unemployment Rate	0.518** (0.206)	-0.581* (0.311)	0.169 (0.194)	0.218 (0.303)
