Abstract

The stem cell microenvironment contains soluble factors, support cells, and components of the extracellular matrix (ECM) that combine to effect cellular behavior. Mass spectrometry based proteomics offers the opportunity to directly assay components of extracellular microenvironments, thereby providing a sensitive means for obtaining insight into the stem cell niche. In this study we present the generation and analysis of human embryonic stem cell (hESC) and human induced pluripotent stem cell (hiPSC) matrix microenvironments using an MS-based proteomics approach.

One of the primary limitations in the proteomics analysis of hESCs and hiPSCs is the reproducible generation of sufficient cell numbers amenable to experimentation. In Chapter 2 we develop reliable methods for the maintenance and proliferation of hESCs in metabolic labeling medium for use in stable isotope labeling with amino acids in cell culture (SILAC) experiments. Previously, the application of SILAC with hESCs was hindered by the use of medium insufficient for their reproducible culture and the problematic conversion of isotopically labeled arginine to proline. To address these issues, we demonstrate the culture of hESCs, hiPSCs, and mouse ESCs in SILAC conditions using a serum-replacement mixture and alternatively in defined medium. In these optimized conditions we show that the problematic conversion of arginine to proline can be eliminated through the simple addition of exogenous proline to the culture medium.

Within the *in vitro* microenvironment, the ECM plays a significant role in the maintenance and regulation of hESCs and hiPSCs. In order to better understand the

communication between hESCs and hiPSCs and the extracellular matrix, we focused our investigation on this portion of the microenvironment. To facilitate the proteomic analysis of complex ECM mixtures, in Chapter 3 we describe methods for the fractionation and MS-based proteomics analysis of these matrices. Application to a variety of cell-derived and recombinant growth matrices demonstrates not only the effectiveness of our methods, but also the utility of directly assaying matrices used in hESC culture for the determination of factors beneficial for the maintenance of self-renewal and pluripotency.

Through combination of the SILAC growth (Chapter 2) and matrix analysis (Chapter 3) methods, the protein compositions of conditioned matrices from multiple pluripotent stem cell lines are determined (Chapter 4). Within these matrices, numerous antagonists of core pluripotency pathways are identified, such as soluble frizzled related protein (sFRP) 1 and 2. In Chapter 5 we focus on characterizing the functions of sFRP1 and sFRP2 in hESC self-renewal and pluripotency. Taken together, the work presented here illustrates the utility of assaying interactions between stem cells and their matrix microenvironment for the determination of pathways involved in the regulation of the pluripotent phenotype.

Key Words: human embryonic stem cells, microenvironment, mass spectrometry, proteomics, extracellular matrix, protein digestion, peptide sequencing, pluripotency, differentiation, induced pluripotent stem cell

Co-Authorship Statement

Chapter 1

Hughes, C.S.*, Nuhn, A.*, Postovit, L.M., Lajoie, G.A.. (2011) "Proteomics of Human Embryonic Stem Cells". *Proteomics*. 11;4:675 – 690

CSH and AN contributed equally to this manuscript. Both authors along with GL and LMP were involved in the generation of concepts to be presented and the drafting and revisions of the manuscript. All authors contributed to revisions and discussion of concepts.

Hughes, C.S., Ma, B., Lajoie, G.A.. (2010) "De Novo Sequencing Methods in Proteomics". *Methods in Molecular Biology*. 604:105 - 121

CSH wrote the complete initial draft of the manuscript. Generation and discussion of concepts as well as revisions were completed by all authors.

Chapter 2

Bendall, S.C.*, Hughes, C.S.*, Stewart, M.H., Doble, B., Bhatia, M., Lajoie, G.A.. (2008) "Prevention of Amino Acid Conversion in SILAC Experiments with Embryonic Stem Cells". *Molecular and Cellular Proteomics*. 7:1587 – 1597

SCB and CSH contributed equally to this manuscript. SCB and CSH were involved in experimental design, data interpretation, and manuscript preparation. The remaining authors were involved with aspects of experimental design, manuscript revision, and discussion of concepts.

Chapter 3

Hughes, C.S., Postovit, L.M., Lajoie, G.A.. (2010) “Matrigel: A Complex Protein Mixture Required for Optimal Growth of Cell Culture”. *Proteomics*. 10;9:1886 – 1890

CSH designed and performed experiments, interpreted data, and prepared the manuscript. Revisions were completed by all authors, as well as generation and discussion of concepts.

Hughes, C.S., Radan, L., Betts, D., Postovit, L.M., Lajoie, G.A.. (2011) “Proteomic Analysis of Extracellular Matrices used in Stem Cell Culture”. *Proteomics*. 11;20:3983 – 3991

CSH designed and performed experiments, interpreted data, and prepared the manuscript. LR also contributed to experimental work. All authors were involved in revisions of the manuscript and the generation and discussion of concepts.

Chapters 4 & 5 & 6

Hughes, C.S., Radan, L., Stanford, W., Betts, D., Postovit, L.M., Lajoie, G.A.. (2012) “Mass Spectrometry-Based Proteomics Analysis of the Matrix Microenvironment in Pluripotent Stem Cell Culture”. (In Preparation)

CSH designed and performed experiments, interpreted data, and prepared the manuscript. LR also contributed to experimental design as well as work. All other authors were involved with manuscript revisions as well as generation and discussion of concepts. WS donated iPSC lines used in the experiments.

Dedication

I would like to dedicate this firstly to my family for always being supportive of my endeavors and especially of my never-ending schooling. You have always been there when I have needed you and for that you will always have my appreciation. You have given me everything I have needed to become who I am today, for which I hope one day I can repay you.

Secondly, I would like to give thanks to all of my friends who have stuck with me through thick and thin. Especially Ryan, Jerry, and Jesse, no one knows me like you guys do. Although we don't live as close as we used to, we will always be lifelong bros. Jonathan, although I've only known you for a few years now we have had some awesome times, and I'm sure that will continue. Thank you for always being there, even if I only required someone to kill grubs with. Last but not least, Lida. You have been a never-ending source of support and good-will to me and for that I will forever owe you thanks. There is not much I can put here because you and I both know that you know me better than I know myself.

Thanks to all of you. This would not have been possible without your support.

Acknowledgements

Firstly I would like to thank everyone from the Lajoie lab. Sean, you were my mentor when I arrived at the lab and taught me a great deal about research and how to be a good scientist before you left. Paula, you always fought the never ending instrument battle with me and kept me afloat on the Global for my entire time in the lab. I hope that one day you finally find that piece of data analysis software that just does what you want with a click of a button and works it every time. Lastly, thank you Gilles for your support and knowledge throughout my graduate degree. You always gave me the space to work in a very independent fashion but were always there when I needed your help. You taught me a lot during my time here and were instrumental in developing me into the scientist I have become today.

Thank you to all the members from the Postovit lab. Scott, Daniela, Guihua, Michael, Padmalaya, Krista, Alia, and Dylan, you always provided the answers to questions, experimental advice, or training I required to stay afloat in the molecular biology world whenever I needed it. Lynne, even though you were never officially my supervisor you certainly were an excellent mentor. Although I guzzled reagents like crazy, you were always available to me for the scientific advice I needed to get through my graduate work. I would not have accomplished what I did without your help.

Thank you to the Betts lab. You welcomed me into your lab as one of your own and did anything you could to facilitate my work. Lastly, thank you to Courtney Brooks from the lab of Dr. Cheryle Seguin. The never ending supply of MEFs, hESCs, and MEF-CM you provided me with was critical to my work.

Tyr	(Y)	tyrosine
Val	(V)	valine

Chapter 1

Introduction

1.0 Pluripotency and Stem Cells

Stem cells are broadly defined by two primary characteristics: (i) the ability to self-renew, generating daughter cells equal to the parent and (ii) the unique capacity to differentiate into an array of cellular sub-types. Stem cells can provide valuable insight into human development and disease, have exciting potential in regenerative medicine, and can be used as models for drug discovery and toxicity analyses (reviewed in [1]). These properties have prompted the initiation of numerous research studies using stem cells as a model system with the goal of potentially unlocking the molecular mechanisms behind the regulation of the stem cell phenotype.

This chapter contains excerpts with permission from the following papers:

Hughes, C.S.*, Nuhn, A.*, Postovit, L.M., Lajoie, G.A.. (2011) "Proteomics of Human Embryonic Stem Cells". *Proteomics*. 11;4:675 – 690

Hughes, C.S., Ma, B., Lajoie, G.A.. (2010) "De Novo Sequencing Methods in Proteomics". *Methods in Molecular Biology*. 604:105 - 121

*Denotes equal author contribution

Stem cells can be further characterized by their differentiation capabilities and tissue-type of origin. A variety of cell and tissue types can give rise to cells of varying developmental potential. In mammals, pioneering work with teratocarcinomas established the presence of an undifferentiated cell type within these germ-line tumors (reviewed in [2]). These embryonal carcinoma (EC) cells were later cultured in a pluripotent state *in vitro* [3]. EC cells were later observed to have the capacity to differentiate *in vitro* through the formation of embryoid bodies (EB) [4]. Similar work *in vivo* demonstrated the ability of EC cells to generate chimeras and populate the germline in mice [5]. Together these findings suggested the similarity of EC cells to those that populate the inner cell mass (ICM) and contributed towards the discovery of embryonic stem cells (ESC).

Utilizing many of the findings gained from the study of EC cells, the derivation of ESCs from mice was demonstrated by Evans and Martin [6, 7]. ESCs are classified as being pluripotent, meaning they have the ability to differentiate into derivatives of the three primary germ layers (Figure 1.1). *In vitro*, pluripotency is conventionally demonstrated using an EB formation assay as previously mentioned for EC cells. These EBs can be assayed for the presence of markers delineating the three primary germ layers as indicators of differentiation capacity. More stringent tests of pluripotency are carried out *in vivo* using teratoma, chimera, or tetraploid complementation assays. Using a chimera assay to illustrate the ability to contribute to the germ line of injected mice, the *in vivo* pluripotency of mESCs was later demonstrated [8, 9].

Figure 1.1. Derivation and distinction between stem cell types. Embryonic stem cells are the pluripotent derivatives of the inner cell mass of the blastocyst. Embryonic stem cells can be differentiated into any of the cells comprising the three primary germ layers. Adult somatic cells will contain tissue-specific populations of adult stem cells that are considered multipotent. Adult somatic cells derived from normal development can be reprogrammed using different combinations of transcription factors to generate induced pluripotent cells. These stem cells are also considered pluripotent and can mimic the differentiation capabilities of their embryonic counterparts. It is currently unknown whether embryonic and induced pluripotent cells are truly equivalent.

Soon after the work in mouse, derivation of pluripotent stem cells from the ICM of blastocyst stage embryos was demonstrated in humans (Figure 1.1) [10]. These hESCs shared the key properties of mESCs in that they could multiply indefinitely and generate cells of the three primary germ layers. Pluripotency could be assayed *in vitro* and *in vivo* using EB and teratoma formation respectively, but due to ethical concerns chimera and tetraploid complementation assays could not be undertaken. Since this time, alternative methods for the derivation of hESCs have been demonstrated, such as from biopsied blastomeres [11, 12].

Comparisons of mouse and human ESC lines have revealed several defining characteristics for each cell type. Identification of an undifferentiated colony is typically performed through the examination of intracellular and cell surface markers. mESCs and hESCs are both known to have strong expression for the nuclear cell markers Oct3/4 and Nanog [13]. On the cell surface, mESCs can be identified by the stage-specific embryonic antigen marker – 1 (SSEA-1) and the absence of SSEA-3 and -4. In hESCs, SSEA-3 and -4 mark undifferentiated cells whereas SSEA-1 is only present on those that have differentiated. Additional differences are observed when examining culture conditions for mESCs and hESCs. mESCs can be maintained in an undifferentiated and pluripotent state on a minimal matrix with supplementation of leukemic inhibitor factor (LIF) and bone morphogenic protein (BMP), whereas hESCs cannot [14, 15]. hESCs are typically grown on a layer of mitotically inactivated mouse feeder (MEF) cells in media supplemented with fibroblast growth factor 2 (FGF2 or basic FGF) [10]. Recent work has suggested that hESCs share several properties with mouse epiblast derived stem cells, whereas mESCs are indicative of a more naïve state

of the ICM [16, 17]. These findings have recently been advanced by the generation of naïve hESCs that share many of the defining properties of mESCs *in vitro* [18].

In contrast to embryonic, adult stem cells (ASC) are classified as being multipotent, meaning they can typically only generate differentiated cells that are a sub-type specific for the lineage to which they already belong (Figure 1.1). In addition to their limited differentiation capacity, ASCs are also have limited self-renewal capacity in culture, making their study difficult. Adult stem cells are thought to act as reservoirs of multipotent progenitors serving to regenerate cellular sub-types residing within specific tissues. This was originally validated in pioneering work with hematopoietic stem cells by Till and McCulloch where it was demonstrated that bone marrow cells could give rise to different types of blood cells [19, 20]. Since this time ASCs have been identified from heart, lung, skin, fat, and liver tissues (reviewed in [21]).

1.1 Inducing Pluripotency in Somatic Cells

The ability to reprogram somatic cells to induced pluripotent stem cells (iPSC) was first demonstrated in mice by Takahashi and Yamanaka [22]. The retroviral introduction of *POU5F1* (herein referred to as Oct3/4), Nanog, Sox 2, and c-Myc into mouse fibroblasts generated cells that shared the characteristic morphology of embryonic stem cells (Figure 1.1). However, due to deficiencies in their developmental potential, they were not classified as pluripotent. Reprogrammed fibroblasts that had the developmental potential of ESCs and were germline competent were later demonstrated in mouse [23, 24]. Shortly after the demonstration of mouse iPSCs, human fibroblasts were

reprogrammed by using different combinations of Oct3/4, Nanog, Sox 2, c-Myc, Lin28, and Klf4 [25-27]. These hiPSCs shared similar gene expression patterns and *in vitro* differentiation capabilities to their ESC counterparts.

Since these original discoveries, research on the reprogramming factors and methods for transgene introduction have been extensive (reviewed in [28]). Currently, the only factor that is verified to be absolutely essential for reprogramming is Oct3/4. Removal of unnecessary reprogramming factors, such as c-Myc, is deemed necessary for reducing the potential tumorigenicity of iPSCs to facilitate their use in therapeutic applications. Alternative methods for transgene introduction that have been demonstrated include: retroviral, adenoviral, lentiviral, Epstein-Barr Virus, piggyBAC transposase, recombinant protein, and synthetic RNA [28]. The main focus of these alternative methods is the generation of 'footprint' free iPSCs that do not contain any exogenous genetic material resulting from methods used for transgene expression. Using methods such as recombinant proteins and synthetic RNAs, fibroblasts can be efficiently reprogrammed to generate iPSCs free of exogenous genetic material [28].

The observation that somatic cells can be reprogrammed to an embryonic-like state was a groundbreaking step forward in the stem cell field. The ability to generate embryonic-like cells in the lab side-stepped many of the ethical concerns surrounding stem cell research, and brought the prospect of cell-based therapeutics closer to reality. Tissue specific material could now be generated using a patient's own cells, overcoming immunocompatibility concerns. However, the risk of tumor formation in humans has to be eliminated before any significant *in vivo* studies can be carried out. In addition to any

potential clinical applications, these cells also provide new avenues for the study of stem cells and significantly increase the accessibility to this research area. However, due to limited information on the equivalency of induced pluripotent and embryonic stem cells, iPSCs are currently not yet recognized as a suitable replacement for hESCs in research.

1.2 Genomic and Proteomic Characterization of hESCs

Since the establishment of the first hESC line in 1998 by Thomson *et al.*, a significant amount of research on hESC biology has been published [10]. In an effort to better characterize this cell type, many of these studies employed large screens directed at the identification of genes that regulate the pluripotent state [29-36]. Comparisons of gene expression patterns between hESCs, other pluripotent cells, or their differentiated derivatives, have led to the identification of growth and transcription factors that are hallmarks of hESC pluripotency, such as Oct 3/4, Nanog, and Sox 2 (Figure 1.2) [29, 32, 34-42]. The largest of these screens was undertaken by the International Stem Cell Initiative (ISCI). This group undertook characterization of 59 different hESC lines using a variety of analysis methods to identify hallmarks of pluripotency that are cell line independent [13, 43]. When global gene expression patterns were compared with that of the core pluripotency factor Nanog, a positive correlation was observed for many known hESC markers, such as Oct4, Nodal, LIN28, and DNMT3B. The findings of this global analysis led to the discovery of a set of genes that exhibited minimal variance across hESC lines that can be used as true markers of pluripotency. However, with the

Figure 1.2. Regulation of human embryonic stem cell self-renewal and pluripotency. The pathways shown represent those believed to play the most significant roles in the regulation of hESCs *in vitro* based on current knowledge. FGF and Activin/Nodal pathways are key regulators required for maintenance of an undifferentiated state and as such is commonly supplemented into culture medium. BMP signaling is known to promote mESC maintenance but induces hESC differentiation. Canonical Wnt signaling has been shown to promote both differentiation and the maintenance of pluripotency. Oct4/Sox2/Nanog are critical for hESC pluripotency, however little is known about their regulation outside of the nucleus or cell itself. The bulk of the knowledge concerning these key pathways has been derived from comparative genomic and proteomic screens of differentiated and undifferentiated stem cells.

rapid generation of new hESC and hiPSC lines, reconciling heterogeneity across populations remains a challenge, especially in proteomics (reviewed in [44]).

Since proteins are the effectors of cellular processes, it is important to investigate how stem cells are regulated by changes at the protein level in addition to genomic analyses. Post-translational modifications (PTM), such as phosphorylation, may influence the activity of pivotal proteins, and this information can only be determined by studying the proteome. The importance of the analysis of the proteome is further emphasized by the fact that changes in RNA abundance do not always correspond to those in their respective proteins. This discordance is the result of post-transcriptional factors, such as stability of mRNA and the rates of translation and protein degradation [45-49]. Discordance between RNA and protein abundance has been observed in the analysis of stem cell populations [45-49]. In one of the first studies to analyze both mRNA and protein abundance levels in stem cells, Fathi *et al.* utilized mass spectrometry (MS)-based proteomics and qRT-PCR genomics approaches to characterize differences between hESCs and EBs [50]. When the proteomic and genomic data were compared there was minimal correlation between the two sets. These findings highlight the necessity for complementary genomic and proteomic analyses in order to fully validate observations made when studying hESC populations.

Technological advances in protein and peptide fractionation techniques, mass spectrometers, and quantitative methods have greatly increased the capacity to analyze and extract biological information from complex cellular samples. With recent advances in the ability to proliferate hESCs to numbers amenable to proteomic experiments, there

have been a surge of proteomic studies looking at hESCs (reviewed in [51-53]). Initial efforts focused on the analysis of the cellular proteomes of hESCs using 2D-SDS-PAGE methods coupled with MS for protein identification [50, 54]. However, these studies were limited in the depth of proteome coverage due to the use of methods that hindered the detection of low abundance proteins. Since this time, multiple large-scale analyses of the proteomes of hESCs and hiPSCs have been completed through utilization of high-resolution MS platforms coupled to multi-dimensional fractionation chromatography [55-57]. Although these studies provide valuable resources, in order to extract greater biological significance from their data and facilitate comparative analysis of hESCs with their differentiated counterparts, researchers have turned to quantitative proteomic methods [58-63]. Quantitative studies have also been applied to the direct analysis of the hESC phosphoproteome during maintenance and differentiation [64-67]. The results of these studies have provided valuable information on the dynamic state of the proteome in hESCs. Collectively, the genomic and proteomic studies that have been completed on hESCs to date have revealed and characterized many of the intracellular pathways currently considered to be critical for pluripotency (Figure 1.2).

1.3 Mass Spectrometry-based Proteomics

The goal of proteomics is to study the entire protein complement of cells or tissues. This not only encompasses the quantitative and qualitative analysis of protein abundance and turnover, but also their PTMs. Reaching this goal has conventionally relied upon technologies such as two-dimensional gel electrophoresis and western blotting. However, these methods offer limited information on a global proteome scale.

Although techniques for obtaining high-resolution and throughput genomic data sets have been available for some time, methods for the acquisition of complementary proteome data have lagged behind.

1.3.1 Mass Spectrometry-based Proteomics - In the field of proteomics, MS has become a central technology for the analysis of protein and peptide samples. This is due to the ability of MS instrumentation to rapidly acquire high quality spectra for thousands of peptides from a single sample injection. MS-based proteomics experiments are typically done in a 'bottom-up' approach, in which proteins are enzymatically digested to peptides prior to fractionation and analysis. Analysis of these complex peptide mixtures can yield high resolution and sensitivity data on the protein composition of a sample of interest. Greater instrument capabilities and new software advancements have resulted in the emergence of "top-down" experiments, in which intact proteins are analyzed (reviewed in [68, 69]). Until very recently, top-down experiments had not been amenable to large-scale analyses [70].

1.3.2 Mass Spectrometry of Proteins and Peptides - A typical MS analysis takes place in three steps. First, the mass of the intact peptide ions entering an MS in a given time window is measured. In the second step, specific precursor ions are selected in the first mass analyzer (e.g., Quadrupole 1), typically based on their relative abundance to one another, and fragmented in a collision cell (Quadrupole 2). The mass, or more accurately the mass-to-charge ratio (m/z), of each fragment ion is detected in a second mass analyzer (e.g., Time of Flight, Linear Ion Trap, Orbitrap, Ion Cyclotron Resonance cell), for each of the previously selected precursors. This type of experiment is referred

to as a tandem MS, or MS/MS analysis. Detailed investigation of the product ion masses within an MS/MS spectrum provides information on the sequence of the peptide selected for fragmentation and, by inference, identification of the protein to which it belongs.

Early forms of MS were not amenable to the analysis of protein samples. Ionization techniques such as electron and chemical ionization would cause high levels of in-source fragmentation for biomolecules. The development of soft ionization techniques, such as matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI), revolutionized the analysis of biomolecules by MS [71-73]. Both of these ionization types are classified as 'soft' techniques because there is little in-source fragmentation of the ionized species, such that the mass of the intact molecular ion can be measured. ESI and MALDI sources can be interfaced to a variety of mass analyzers and instrument architectures compatible with proteomics experiments. The most frequently used designs in proteomics are hybrid instruments that contain a combination of mass analyzers, such as: time of flight (TOF) [74, 75], quadrupole (Q), ion trap (LIT) [76], Fourier transform ion cyclotron resonance (FT-ICR) [77], and Orbitrap [78]. All of these platforms have advantages and disadvantages, for a comprehensive review of instruments types and their characteristics see ([76, 79]).

1.3.3 Proteomic Analysis of Complex Mixtures - Even with advancements in instrument scan speed, mass spectrometers can only detect a limited number of ions in a given period of time. To spread the components of an injected sample across a wider time window, chromatographic methods of separation are used prior to MS (Figure 1.3). The

conventional method of fractionation utilized prior to MS analysis is separation with a reversed phase (RP) column that partitions based on the hydrophobic character of the sample components. It is becoming increasingly common for researchers to employ a secondary orthogonal fractionation method prior to RP, such as strong cation exchange (SCX) or 1D-SDS-PAGE. The decrease in fraction complexity and complementary nature of these methods aids in providing an increase in depth of proteome coverage [80, 81]. One distinct advantage of ESI is its compatibility with a number of these on-line separation techniques employed prior to MS analysis.

1.3.4 Peptide Identification from Mass Spectra - In order to obtain information on the amino acid series of ions that enter the MS, sequence ions can be generated through fragmentation of the peptide parent ion in an MS collision cell. Each peptide ion dissociates in one place along the backbone so that the difference in mass between the resulting fragment ions potentially corresponds to the mass of an amino acid (reviewed in [82]). The most common form of fragmentation found in MS instrumentation is collision induced dissociation (CID) [83-85]. In CID, peptide ions are induced to fragment through collisions with inert gas molecules. Aside from CID, electron capture (ECD) and electron transfer dissociation (ETD) have been implemented in more recent mass spectrometers [86-88]. The combination of CID and ETD is now available on instrument platforms such as Orbitrap and qFT-ICR mass spectrometers. This allows for the acquisition of spectra from the same sample using two fragmentation techniques generating complementary series of fragment ions [89].

The identification of peptides from fragment ion data relies on spectral interpretation software (Figure 1.3). Conventional search engines perform comparisons between observed and theoretical peptide spectra from an *in silico* digest of a sequence database (reviewed in [90]). Search engines will score peptide matches based on a variety of metrics designed to generate a score representative of the quality of match between the observed and theoretical spectra [90, 91]. However, there has been a recent emergence in software designed to search peptide spectra against a database of previously acquired MS/MS experimental spectra identification [92]. These search engines offer greater sensitivity and speed, but are limited by the content of the experimental spectral databases.

An alternative to the previously mentioned database-dependent approaches are *de novo* methods that make use of computerized methods for determining the sequences of peptides directly from MS/MS spectra [93]. *De novo* methods use the knowledge of the fragmentation methods employed in the MS and basic search parameters input by the user to rebuild the peptide ion series [94-101]. *De novo* sequencing approaches hold a lot of potential due to their ability to identify previously unknown peptide sequences and post-translational modifications. However, utilizing a combination of multiple search engine strategies has been shown to be beneficial to achieving greater depth of coverage in proteomics experiments [102-104].

1.3.5 Quantitative Proteomics - To increase the biological significance of their data, quantitative proteomic strategies are frequently used to compare different cellular states or conditions (Figure 1.3). Mass spectrometers are not strictly quantitative, so

quantitative labeling is often used; however, label-free techniques are becoming increasingly popular (reviewed in [105, 106]). Application of the quantitative label can be done at the protein or peptide level, prior to analysis on the MS (Figure 1.3).

Reagents that are applied at the peptide level normally target primary amines to obtain complete sample coverage. In methods such as isobaric tags for relative and absolute quantification (iTRAQ) and tandem mass tags (TMT), samples are tagged following proteolytic digestion [107] (Figure 1.3). Peptides in different experimental conditions can be distinguished and quantified in MS/MS spectra based on the label applied. Dimethyl labeling approaches for peptide tagging have also been employed successfully, with the added advantage of minimal reagent expense [108, 109].

The most common alternatives to peptide tagging approaches are based on metabolic incorporation of isotopically labeled amino acids. One such isotopic labeling method, termed stable isotope labeling with amino acids in cell culture (SILAC) involves metabolic incorporation of ^{13}C and ^{15}N containing amino acids into a cell's proteome [110, 111]. Other methods based on metabolic incorporation of ^{15}N have been widely applied both *in vitro* and *in vivo* [112]. Both methods rely on the depletion of native versions of the targeted amino acids or elements and re-supplementation of isotopically labeled versions that can be incorporated into newly synthesized proteins. Metabolic incorporation can also be achieved through the feeding of labeled populations of cells to higher organisms [113]. In all mentioned metabolic approaches, differentially labeled samples are mixed at a defined ratio, and the relative abundance of proteins can be compared quantitatively based on the relative intensities of the peptide forms in MS

Figure 1.3. Conventional methods used in proteomics analysis of *in vitro* cell populations. Comparison of multiple experimental conditions can be performed separately or together. Separate sample analysis is conventionally done using 2D-SDS-PAGE fractionation followed by quantification of spot intensity on the gel. Spots that exhibit changes in intensity can be extracted from the gel and subjected to enzymatic digestion and subsequent identification through MS analysis. Alternatively, separate samples can be quantified in a label-free manner based on peptide abundance in the mass spectrum. When an isotopic label is used, samples from separate experimental conditions can be combined for analysis. When metabolic labeling with SILAC is used samples can be combined prior to fractionation and digestion. Alternatively, if iTRAQ or TMT approaches are used samples must remain separate until after enzymatic digestion and labeling. In both cases, peptides are analyzed and quantified in the mass spectrometer in a single analysis. For SILAC, quantification is completed at the MS level, whereas iTRAQ and TMT are performed in the MS/MS spectrum.

spectra. Isotopic labeling using any of the previously mentioned methods offer powerful tools for researchers to directly compare minute changes between cellular states over time (Figure 1.3).

1.4 *In Vitro* Culture of hESCs

Many experiments and therapeutic applications of hESCs require the cells to be pluripotent and free of non-human contamination. A major limitation to the use of hESCs in medical research is that they can undergo spontaneous differentiation in culture if proper conditions for retaining pluripotency are not maintained. At present, there is limited information about which culture conditions effectively maintain differentiated hESCs *in vitro*, and this restricts the amount of suitable material that can be generated for analysis [114-116]. One reason for this is that many advances in culture conditions for mouse embryonic stem cells are not applicable to hESCs [117].

Since the correct mixture of factors that maintains hESC pluripotency is unknown, hESCs are often derived on a feeder layer of MEF cells (Figure 1.4). This layer provides a growth substrate and secretes various growth factors, cytokines, and adhesion related proteins that promote pluripotency [118, 119]. Other human fibroblasts have also been shown to be supportive of sustained pluripotent hESC growth [120-124]. Due to the potential variability that culture on feeder layers presents and the risk of xeno-transmission from non-human sources, there has been a shift in the field to feeder-free growth of hESCs on defined matrices (Figure 1.4). A significant step forward in hESC culture methods was the discovery by Xu *et al.* that hESCs can be maintained on a layer of basement membrane matrix called MatrigelTM, in medium

that has been conditioned by irradiated MEFs (MEF-CM) [125]. Matrigel™™, which is extracted from Englebreth-Holm-Swarm tumors in mice, is a complex mixture of extracellular matrix (ECM) proteins that is composed primarily of laminin, collagen-IV, and enactin [126-128]. Matrigel™ has proven to be effective as a growth matrix for a wide variety of hESC lines using a variety of media formulations [129]. However, concerns regarding the composition and complexity of Matrigel™ and its suitability in research applications have been raised [126, 128, 130-132]. To overcome these limitations, a variety of ECM proteins or synthetic matrices have been evaluated for their ability to support hESC proliferation [133-148].

In parallel to matrix development, there have been numerous advances towards the generation of defined culture medium for hESC growth [149, 150]. All formulations contain growth factors designed to promote the maintenance of pluripotent hESCs, such as bFGF and Activin. In order to elucidate factors essential for the maintenance of hESCs, analyses of the secretomes of supportive feeder layers have been performed [151-154]. Factors supportive of the maintenance of hESC pluripotency, such as pigment epithelium derived factor (PEDF), have been identified through examination of these datasets. It was later demonstrated that PEDF can maintain undifferentiated hESCs without the addition of other exogenous supplements [155]. Other factors, such as Activin A and TGF- β 1, were also identified in screens of conditioned media, both of which have been shown to promote the feeder-independent growth of hESCs in the absence of pre-conditioning with MEF layers [115, 156, 157]. Although these screens provide valuable information on extracellular regulation of hESC fate *in vitro*, our

Figure 1.4. Derivation and culture of human embryonic stem cells. hESCs derived from the inner cell mass of the blastocyst are conventionally cultured on a layer of mouse embryonic fibroblast feeder cells in medium supplemented with FGF2. Alternatively, hESCs can be derived in xeno-free conditions by culturing them on human derived feeders, such as foreskin fibroblasts. hESCs derived in either condition can be passaged to feeder-free conditions where a culture matrix is substituted as the growth surface. The most commonly employed matrix is Matrigel™ in combination with culture media that has been conditioned on a mouse or human feeder-cell layer. If xeno-free conditions are desired, human cell-derived or recombinant protein matrices can be substituted and used in combination with defined culture medium.

understanding of how these pathways exact this control, alone or in combination, remains inadequate.

1.5 *In Vitro* Microenvironment and hESC Cell Fate

Based on advances in our knowledge regarding the optimal conditions for hESC culture *in vitro*, it is clear that extracellular processes are critical for maintaining the delicate balance between self-renewal and differentiation. Control over these extracellular processes is governed by a dynamic interplay between the various contributors to the microenvironment. This supportive environment is often referred to as the 'niche' and consists of a combination of accessory support cells, extracellular structure, and autocrine/paracrine signals (Figure 1.5). In stem cells, the concept of the niche was first defined for the hematopoietic system in mammals [158]. Additional evidence from *Drosophila* and *C. elegans* contributed to the development of the understanding of the stem cell niche (reviewed in [159, 160]). Research in mouse has contributed to the bulk of our current insight into the stem cell niche in mammalian systems. An example of this is recent work where the ability of mESCs to interact to form local microenvironments within single colonies that regulate cell-fate decisions dependent on the presence or absence of exogenous factors was demonstrated [161]. Studies such as these provide detailed insight into niche control of stem cells *in vitro*.

Studies directed at the analysis of the hESC niche have been limited due to the complexity its analysis presents. However, as illustrated by the intricate requirements for efficient proliferation *in vitro*, proteomic characterization of the microenvironment

from human stem cells should be a fruitful source of information. The necessity for supplementation of multiple exogenous factors illustrates the dynamic array of extracellular processes that combine to create a suitable hESC niche *in vitro*. Recent work using a global proteomics approach has demonstrated the valuable data that can yield from analysis of this soluble environment [162]. In addition to the components supplemented or secreted into the microenvironment, in this study it was observed that hESCs generate fibroblast cells supportive of self-renewal [162]. From proteomic analysis comparing the secretome of MEF feeders and hESCs, a novel mechanism was proposed wherein the supportive fibroblast cells responded to FGF supplementation to secrete factors that aided in the prevention of cellular differentiation [163, 164]. Although this was not the first global analysis of the hESC secretome, it generated the greatest depth of coverage leading to the identification of numerous stem cell regulatory proteins in the extracellular space.

In order to obtain a complete understanding of the hESC *in vitro* microenvironment, analysis of components other than soluble media components is required. Although numerous studies have focused on analysis of the soluble portion of the microenvironment, the interactions between hESCs and ECM in the niche is poorly understood. The ECM is known to provide structural support for processes such as cell attachment and migration. Moreover, it is widely postulated that the ECM interacts with an array of growth factors, acting to provide sustained release or co-factors required for activation (reviewed in [165]). The complex matrix requirements for the efficient culture of hESCs *in vitro* emphasize the importance of the ECM and the necessity for analysis of this contributor to the niche. Moreover, it was recently observed that metastatic cells

Figure 1.5. Maintenance of human embryonic stem cells in a dynamic microenvironment. Cultures maintained on Matrigel™ have been observed to contain hESC-derived cells that support stem cell maintenance through paracrine signaling pathways. On mouse or human fibroblast layers, maintenance of pluripotency is maintained through paracrine signaling with the feeder cells. Alternatively, on Matrigel™ or other matrices, hESCs can be maintained in medium that contains supportive factors secreted from feeder cells during conditioning. Many studies have focused on analysis of factors secreted during conditioning to elucidate hESC supportive pathways. Recent work has demonstrated the ability of hESC conditioned matrices to reprogram metastatic cells. This observation highlights the potential importance of the interactions between hESCs and the growth matrix used *in vitro*. However, few studies have focused on the elucidation of these interactions or the identification of hESC-derived factors in conditioned matrix.

could be 'reprogrammed' to a state that resembled their non-metastatic counterparts following exposure to an hESC conditioned matrix [166]. This observation was dependent on contact with the matrix portion of the microenvironment, and was not observed after exposure to hESC conditioned medium [167]. Studies such as these illustrate the potentially complex interactions between hESCs and the ECM *in vitro*. However, this area of the hESC microenvironment remains poorly understood as a result of the difficulty analysis of the ECM and its interactions presents.

1.6 Thesis Objective

With the potential wealth of information that can be extracted from the analysis of the hESC microenvironment, studies directed at the large-scale analysis of this dynamic environment needs to be undertaken. Critical to these studies will be the development of efficient methods for the analysis of the in-solution and matrix portions of the microenvironment. Moreover, integration of data obtained through the analysis of secreted factors with that of other supportive components of the microenvironment will be paramount for a more comprehensive understanding hESC regulation *in vitro*. With the recent observation that matrix deposited factors have the potential to reprogram metastatic melanoma cells, the ECM component of the hESC microenvironment necessitates further analysis [168]. To this end, one of the goals of this thesis will be directed at creating proteomic methods to facilitate the analysis of hESC and hiPSC conditioned matrices, as well as functional validation of identified candidates of interest.

In working towards these objectives we first develop methods for the efficient growth of hESCs in conditions amenable to SILAC experimentation *in vitro* (Chapter 2). We demonstrate that mouse and human ESCs can be maintained in an undifferentiated and pluripotent state in medium containing isotopically labeled arginine and lysine. We also extend this protocol to the feeder-free growth of hESCs and hiPSCs in SILAC medium that is completely defined. For both of these media formulations, we are able to overcome conversion of isotopically labeled arginine into proline, a typical occurrence in SILAC experiments. Application of these culture methods facilitated the expansion of labeled hESCs for further proteomic experimentation.

In order to extract information on the composition of hESC-derived matrices, proteomic methods directed at the fractionation and analysis of complex ECM-like mixtures were required. To this end, we developed methods aimed at the analysis of the complex ECM Matrigel™ (Chapter 3). By employing a range of fractionation and digestion protocols we demonstrate the complex proteomic profile of Matrigel™. Following this, we applied these methods to other cell-derived and recombinant matrix mixtures commonly used in hESC culture. These analyses revealed commonalities between matrices used in hESC culture. Based on the proteomics data, fibronectin was found to be enriched in all of the cell-derived hESC supportive matrices. To validate the ability of our proteomics approach to identify components critical for the maintenance of hESCs *in vitro*, we exhibit the maintenance of an undifferentiated and pluripotent state for cells grown on fibronectin as a sole matrix support.

After validation of our culture (Chapter 2) and matrix analysis methods (Chapter 3), we applied these conditions to the characterization of hESC and hiPSC conditioned matrices (Chapter 4). From our proteomics screen, we identify over 80 extracellular proteins in matrix conditioned by hESCs and hiPSCs. Comparative analyses with published stem cell secretome datasets aided in the identification of hESC regulatory proteins from our dataset. Based on the ability of the hESC-derived CMTX to enhance the maintenance of an undifferentiated state, we carry out functional validation of candidates identified in the CMTX to determine their roles in hESC pluripotency (Chapter 5). Focusing on the candidate soluble frizzled-related protein 1 & 2 (sFRP) proteins, we utilize a combination of approaches to elucidate their effects on hESC behavior. Taken together, our improved culture methods, matrix analysis protocols, and detailed composition of hESC derived matrices provide an effective toolbox for obtaining a more comprehensive understanding of how this dynamic cell type is regulated *in vitro*.

Chapter 2

Development and Optimization of Growth Conditions for SILAC Experiments in Pluripotent Stem Cells

2.1 Introduction

Large scale identification of proteins using mass spectrometry (MS)-based proteomics has been made possible by recent advances in instrumentation, separation sciences, and bioinformatics [1]. However, the generation of increasingly long lists of proteins now confronts researchers with the more challenging problem of determining the biological significance of particular proteins. For this reason, quantitative proteomic strategies can now be used in order to extract more meaningful information from their datasets. By comparing multiple samples and different conditions vs controls, it is often possible to discern proteins that are altered in a given set of experimental or biological conditions from the thousands that are identified [2].

This chapter contains excerpts with permission from the following paper:

*Denotes equal author contribution

In MS-based proteomics, quantitative strategies typically involve the use of stable isotopic reagents to generate 'heavy' and 'light' samples, which retain their chemical identity and can then be differentiated and directly compared by MS analysis. While chemical labeling methods such as ICAT have demonstrated widespread applicability [1], metabolic incorporation strategies such as stable isotope labeling with amino acids in cell culture (SILAC) are becoming more common for cell types that can be grown for extensive periods of time *in vitro*. Though there are numerous advantages for using SILAC based methods, compared to chemical labeling, a major drawback is the unintended metabolic inter-conversion of isotopic amino acids in the labeling process, generating artifacts affecting the quantification. This is a particular problem with arginine which is a metabolic precursor for proline biosynthesis (Figure 2.1). In general, large scale SILAC experiments use both arginine and lysine to obtain labeling of all possible tryptic peptides thereby maximizing quantitative coverage of all potential peptides in a given experiment.

Several studies using SILAC have described the problematic conversion of isotopically labeled arginine to labeled proline in cells [3-7] (Figure 2.1) which results in an underestimation of the abundance of 'heavy' tryptic peptides containing proline in a relative quantification experiment. This is of particular concern since ~50% of all tryptic peptides between 700 and 6000 Da in the international protein index (IPI) human database contains at least one proline. Moreover, in a recent study it was reported that ~30-40% of all observable proline containing peptides exhibited some level of conversion from heavy arginine [7]. Besides acting to skew the relative abundance observed, conversion of 'heavy' arginine to 'heavy' proline also further complicates the

Figure 2.1. Metabolic conversion of isotope-coded arginine to proline in SILAC experiments. The unpredictable conversion of isotopic arginine to proline creates inaccuracy in SILAC based quantitative proteomic experiments. (A) A conceptual mass spectra of a non-proline containing peptide ion from a 1:1 mixture of 'light' and 'heavy' labeled samples. Here the expected 'light' and 'heavy' peptide ions have an equivalent signal. (B) A spectra from a proline containing peptide where arginine to proline conversion has occurred in the same 1:1 mixture. The resulting heavy proline peptide signal (red) has been subtracted from the expected 'heavy' peptide ion signal. (C) Metabolic pathway outlining the inter-conversion of arginine and proline. Isotope-coded arginine with carbon 13 (red) and nitrogen 15 (green) that when used as a synthetic precursor increases the expected mass of proline.

mass spectrometry data by increasing the number of peptide ion peaks. One proposed strategy to minimize this problem is the reduction of the arginine concentration in the SILAC media rendering it metabolically unfavorable as a precursor for proline synthesis [8]. While this does reduce the conversion, it does not prevent it completely [3]. The other is to avoid the use of arginine altogether or by removing the ability to perform arginine catabolism [3, 9, 10]. Finally, alternative corrections can be done mathematically, post-analysis, but these are inaccurate and do not solve the problem of increased peptide ion complexity [4, 11-14].

While reducing the concentration of available arginine in SILAC labeling media was a simple method for preventing its conversion to proline, this approach would be problematic for particular cells types like those with rapid cellular metabolism [15]. Moreover, certain sensitive cell types, such as human embryonic stem cells (hESCs) die or differentiate under restrictive metabolic conditions [7, 16]. To this end, Vanhoof et al. [7] sought to compensate for arginine to proline conversion in SILAC experiments by advocating the use of isotopically labeled arginine ($^{15}\text{N}_4$ Arg) in 'light' SILAC media as well as ($^{15}\text{N}_4$ $^{13}\text{C}_6$ Arg) in the 'heavy' media. With the assumption that arginine to proline conversion would be the same under both conditions, the monoisotopic peak of 'light' and 'heavy' proline containing peptide ions could be compared to correctly determine relative abundance, as both would be reduced proportionately. This method does provide a solution but it further complicates the procedure by generating additional converted proline peptide ions in the MS spectra and by adding the cost of expensive isotopic reagents. Also, there is no guarantee that the rate of arginine to proline conversion will be the same when comparing different cell types or treatments. Adding

to these difficulties is the fact that SILAC labeling of both hESCs [7] and ESCs from the mouse (mESC) [17] required the use of mouse embryonic fibroblast (MEF) feeder cells which precludes the attainment of high cell numbers necessary for large scale, SILAC-based proteomic applications [8, 18-21]. Faced with these challenges, we sought a simple solution, for arginine to proline conversion in SILAC experiments that would be compatible with a robust hESC culture protocol free of feeder cells.

In this chapter, we demonstrate that by supplementing SILAC media with standard L-proline, the conversion of isotope coded arginine to labeled proline can be prevented. In addition, when providing sufficient amounts of arginine, no back conversion from the increased proline supplement was observed. When proline supplementation of SILAC media was adapted to both mouse and human ESC culture reagents complete labeling with isotope-coded lysine and arginine can be routinely achieved using standard procedures in the absence of feeder cells without compromising the ESC phenotype. We then extend our approach to demonstrate the growth of hESC and hiPSC lines in SILAC conditions using fully-defined, serum-free growth medium.

2.2 Results

In mammalian cells, the metabolism of arginine and proline are related and each can serve as precursors for one another through slightly different, but related pathways (Figure 2.1 C, reviewed in [22]). In a related pathway, both glutamate and glutamine can be precursors for arginine biosynthesis and products of arginine metabolism (Figure 2.1 C). However, only artifacts of proline synthesis from isotopic arginine have been reported in SILAC experiments. This observation raised the question of availability of amino acids *in vitro* cell culture media, particularly in SILAC formulations, since previous *in vivo* mammalian studies have demonstrated that the inter-conversion of amino acids in this pathway (Figure 2.1 C) is primarily dependent on their bioavailability [23]. Since L-proline is a non-essential amino acid, its concentration in the two main basal media used in standard SILAC experiments, RPMI and DMEM, is only 20 and 0 mg/L, respectively. At the same time, the typical concentration of arginine, a metabolic precursor of proline (Figure 1B), is 200 and 84 mg/L, respectively. Based on this we surmised that the arginine to proline conversion artifacts in SILAC experiments were a direct result of the low or absent concentration of proline in standard SILAC labeling formulations.

2.2.1 - Proline availability effects on isotopic arginine conversion to proline. In standard DMEM based SILAC media, in the absence of proline supplement, cells readily convert isotopic arginine to proline, which is then incorporated into newly synthesized proteins. This conversion divides the MS signal of the 'heavy' proline containing peptide in a complex fashion, resulting in false relative abundance values when compared to an

equal amount of 'light' sample (Figure 2.1 A-B). To eliminate this artifact in arginine-based SILAC procedures, we investigated whether increased L-proline supplementation could prevent the conversion in a concentration dependent manner.

Equal amounts of cell lysates extracted from HeLa cells cultured in SILAC media ($^{13}\text{C}_6$ Arg) containing 0 – 800 mg/L proline were digested with trypsin and subjected to LC-MS/MS analysis. Detected proline conversion peptides were used to build a list of peptide candidates for quantification. By using +2 or +3 charge states, the selection of the peptide candidates was based on whether they were observed in all samples, the number of proline residues, the extent of conversion observed, and whether the sequence contained arginine. Based on the triplicate analysis of all lysates, a list of thirteen peptide candidates was chosen and quantified across the 0 – 800 mg/L proline concentrations.

Throughout the titration of L-proline in SILAC media signals of the converted proline containing peptides were monitored (Figure 2.2 A-B). In addition, the ratio of 'heavy' labeled Arg peptide to light peptide was measured in order to detect whether a decrease in the converted proline peptide signal resulted in a subsequent increase in the expected 'heavy' peptide (Figure 2.2 A-B). Within the set of peptide candidates proline conversion consumed an average of 28% of the monoisotopic signal of the 'heavy' arginine peptide in the 0 mg/L proline sample (standard SILAC media) [5]. As the proline concentration was increased to 50, 100, and 200mg/L the monoisotopic 'heavy' proline peak occupied 9%, 3%, and 2%, respectively. However, within this list of proline containing peptides no peaks corresponding to a converted proline could be

Figure 2.2. Titration of proline during SILAC labeling with isotope coded arginine.

Candidate proline containing tryptic peptides were monitored in whole cell extracts in ¹³C6 arginine samples with 0-800 mg/L L-proline. (A) A conceptual mass spectra indicating the possible peptide ion peaks observed in the arginine labeling experiment. Both the ratio of labeled to unlabeled peptide as well as relative intensity of converted proline peptide ion were monitored in the experiment across 0 – 800 mg/L proline (B) where * indicates no converted proline peptide ions were detectable from background. (C) A mass spectrum from 0 mg/L proline sample representing the peptide VAPEEHPVLLTEAPLNPK at m/z 652 demonstrating a prevalent converted proline peak at +1.7 m/z from the expected peptide ion. (D) Mass spectrum from the 200 mg/L proline sample depicting the same peptide ion as in (C) and the converted proline ion is notably absent.

detected in the MS spectrum beyond 100 mg/L of proline. As such, the 2% of total signal seen at 200 mg/L of proline was a result of un-subtracted background in the MS spectrum where there was low signal-to-noise. Moreover, maximum relative signal of 'heavy' arginine labeled peptide (~20% increase vs 0 mg/L Pro) was seen at 200 mg/L and beyond (Figure 2.2 B). Consequently, even in some of the worst cases of proline conversion (Figure 2.2 C) no proline conversion could be observed in cells supplemented with 200 mg/L of proline or greater (Figure 2.2 D). Taken together, these data not only demonstrate that supplementation of standard SILAC media can eliminate the proline conversion, but also return the "lost signal" to the expected peak within the 'heavy' SILAC sample. Most surprisingly, this critical improvement in arginine-based SILAC methods can be achieved by supplementing cell culture media with as little as 200 mg/L of L-proline.

2.2.2 - Proline availability effects on isotopic arginine labeling. One concern with supplementing an arginine-based SILAC experiment with proline is that, by a similar biosynthetic mechanism (Figure 2.1 C), the excess proline might be a precursor for arginine synthesis thereby decreasing the efficiency of labeling by the isotope-coded arginine provided. While proline is known to be one of the main substrates in the formation of citrulline, a direct precursor for arginine biosynthesis, it has been demonstrated that this process is only favorable when there is a lack of available arginine [23, 24]. Moreover, to date, the presence of other citrulline precursors, such as glutamine in standard SILAC media, has had no reported detrimental effect on SILAC procedures.

To prevent back conversion of proline into arginine and to increase the media's compatibility with nutritionally sensitive cell types like ESCs [7], we re-supplemented the DMEM-based SILAC media with its standard complement of isotope-coded arginine (0.398 mM). This was in direct contrast to the reported reduction of the concentration of isotope-coded arginine in order to prevent its availability for conversion to proline [5, 8]. At the endpoint in the same proline titration experiments we monitored the 'heavy' arginine labeling efficiency by tracking the ratio of 'heavy' to 'light' peptides which contained arginine (Figure 2.3 A). To minimize proline conversion artifacts that would interfere with these calculations, we avoided peptides with proline in their sequence.

In comparison to 0 mg/L proline (standard SILAC media), the average relative peak area for the 50 – 800 mg/L proline samples exhibited only slight deviations, but overall remained unchanged (Figure 2.3 B). Larger deviations were only observed for peptides with lower signal-to-noise ratios and did not have a noticeable trend as a function of proline concentration. None of the arginine peptides examined in the 0 mg/L proline sample (Figure 2.3 C) or even in samples that were supplemented with 800 mg/L of proline (Figure 2.3 D) exhibited an increase in unlabeled 'light' peptide signal. These data provide evidence that our SILAC media formulation (standard arginine in combination with proline supplementation) is effective in minimizing arginine to proline conversion artifacts without compromising the efficiency of isotope-coded arginine labeling. Thus, in the cell types examined here, an arginine concentration of 0.398 mM, even in the presence of high exogenous proline (up to 800 mg/L), is sufficient to prevent observable proline to arginine back conversion that would interfere with SILAC labeling efficiency.

Figure 2.3. Isotope coded arginine labeling efficiency across the titration of proline. Candidate arginine containing tryptic peptides lacking proline were monitored in whole cell extracts in ¹³C6 arginine samples with 0-800 mg/L L-proline. (A) A conceptual mass spectra indicating the possible peptide ion peaks observed in the arginine labeling experiment. The peak area ratio between the 'heavy' and 'light' arginine monoisotopic peaks was monitored across the 0 - 800 mg/L proline samples and plotted relative to 0 mg/L proline (B). (C) A mass spectrum representing the peptide AAVEEGIVLGGGCALLR at m/z 845 from the 0mg/L proline sample. (D) Mass spectra of the same peptide ion in the 800 mg/L proline sample demonstrating no compromise in the isotope-coded arginine labeling efficiency or proline to arginine back-conversion. Isotopic amino acids are underlined.

2.2.3 - Adaptation of SILAC labeling to feeder-free hESC culture. In order to perform a wide variety of large-scale SILAC-based proteomic experiments with hESCs the ability to generate large numbers of labeled cells has to be achieved. It became clear that SILAC methods compatible with feeder-cell free culture systems would be necessary to attain these high cell numbers (reviewed in [16]). In an attempt to extend standard SILAC labeling procedures to feeder-free hESC culture we confirmed incompatibilities previously highlighted using a feeder-cell based culture system [7]. Using standard SILAC media with $^{13}\text{C}_6$ arginine and supplemented with 36 ng/mL basic fibroblast growth factor (bFGF) [25], hESC cultures achieved maximum levels of isotope-coded arginine incorporation after only 2 passages or after more than 12 days under SILAC culture conditions (Figure 2.4 A). By day 15 in SILAC media, hESCs had reached 96.5% average efficiency in isotope coded amino acid labeling. However, in the same period of time the hESCs rapidly differentiated as demonstrated by the loss of SSEA3 expression (Figure 2.4 A), a marker of pluripotent stem cells. We also observed the loss of defined hESC undifferentiated colony structure and tight cell morphology indicating the presence of differentiated cell types (Figure 2.4 B). Moreover, manual inspection of the MS data showed that the conversion of arginine to proline was exacerbated in these cells. While it was clear that arginine incorporation was complete in day 14 samples the proline converted peptide ions were prevalent (Figure 2.4 C). In some extreme cases, converted proline peptide ions consumed greater than 50% of the expected peptide ion signal (Figure 2.4 D). The instability of the hESC phenotype combined with the pronounced arginine to proline conversion artifacts indicated that the

Figure 2.4. Labeling feeder cell free hESCs in standard SILAC media. hESCs culture on Matrigel™ were grown in standard SILAC media ($^{13}\text{C}_6$ Arg, dialyzed FBS, 0 mg/L proline) for two weeks. Arginine incorporation, conversion to proline, and hESC phenotype were monitored. (A) The relative SSEA3 frequency and percent heavy arginine incorporation over the SILAC labeling time-course. (B) Differentiated phenotype of hESC after 14 days in standard SILAC media as observed by light microscopy. Scale bars equal 250 μm . (C) A mass spectrum of heavy arginine peptide ion MSVQPTVSLGGFEITPPVLR at 745 m/z. Indicated are the prominent converted proline peptide ion shifted +1.7 m/z, and the absence of the unlabeled ‘light’ arginine peptide ion corresponding to the high level of isotopic amino acid incorporation. (D) A mass spectrum of the peptide ion VAPEEHPVLLTEAPLNPK at 652 m/z. Indicated are the peptide ions shifted +1.7 m/z and +3.4 m/z corresponding to the incorporation of 1 and 2 converted ‘heavy’ proline and consuming more than half of the expected peptide ion intensity. Isotopic amino acids are underlined.

standard SILAC media formulation was not a suitable protocol to adapt to feeder-cell free hESC culture.

There are two main factors responsible for the incompatibility of standard SILAC media with hESC culture, the first being the dialyzed fetal bovine serum (FBS) and the second, the limited growth factor microenvironment (problems reviewed in [16]). To address these issues we revisited the original development of feeder-cell free hESC culture protocols [26]. Xu and co-workers formulated a DMEM based hESC media using a serum replacement reagent [27] that is now commercially available as knockout serum replacement (KOSR – Invitrogen). The hESC media was then pre-conditioned on MEF cell feeder layers to supply the appropriate complement of signaling molecules and growth factors to maintain hESC homeostasis. This method has since become the most widely adopted form of feeder-cell free hESC culture. Coincidentally, the KOSR formulation contains no free lysine or arginine, making it compatible with most popular SILAC applications. Moreover, as we demonstrate to be important here, KOSR contributes 800 mg/L of proline when used at 20% (v/v) in hESC media [27].

A hESC SILAC media with 20% KOSR and ^{13}C ^{15}N arginine and lysine was formulated taking into account the SILAC compatibility of the media (see experimental methods). The hESC SILAC media was then pre-conditioned on irradiated MEFs according to previously established protocols [26]. The resulting media, when supplemented with 8 ng/mL of bFGF, allowed hESCs to incorporate the isotope coded amino acids at the same rate as observed with standard SILAC media where after 2 passages and more than 12 days in SILAC culture hESC had reached their maximum levels of incorporation

(Figure 2.5 A). Consistent with the preliminary proline titration data, there was no difficulty encountered in isotopic amino acid labeling since the cells were on average 96.1% labeled by day 14. Moreover, in the new media formulation the cells were now able to maintain SSEA3 expression (Figure 2.5 A) and continue to form tight, undifferentiated colony structures (Figure 2.5 B). Inspection of the MS spectra (Figure 2.5 C) of the hESC lysates labeled using the new formulation demonstrated the same level of isotopic amino acid incorporation as standard SILAC media when examining the same peptides (Figure 2.4 C). Additionally, for the same peptide there was no longer any arginine to proline conversion artifacts observed (Figure 2.5 C), even when examining peptides with the highest proportion of converted proline peptide ions (Figure 2.5 D vs 2.4 D). Consequently, when a 14 day SILAC labeled (^{13}C ^{15}N Arg and Lys) hESC extract was mixed 1:1 with a 'light' hESC lysate, equivalent levels of the expected 'light' and 'heavy' peptides are observed even in sequences most susceptible to proline conversion artifacts (Figure 2.5 D). These observations clearly demonstrate that combining KOSR as an alternative serum supplement with both a SILAC compatible hESC media formulation and pre-conditioning on feeder cells offers a reliable solution for large-scale hESC applications in quantitative proteomic without compromising data quality.

2.2.4 - SILAC procedures with feeder-free mESC cultures. Recently, a landmark analysis of mESCs using a SILAC approach was reported by Graumann *et al.* in which a total of 5111 proteins were identified [17]. However, this study was also routed in a feeder-cell based culture system which, by the authors own admission, contributed to contamination in the analysis. To circumvent this issue these authors performed a

Figure 2.5. Labeling feeder cell free hESCs in conditioned SILAC media with KOSR. hESCs cultured on Matrigel™ were grown in MEF conditioned ESC optimized SILAC media ($^{13}\text{C}^{15}\text{N}$ Arg and Lys, 20% KOSR providing 800 mg/L L-proline) for two weeks. Amino acid incorporation, conversion of arginine to proline, and hESC phenotype were monitored. (A) The relative SSEA3 frequency and percent heavy amino acid incorporation over the SILAC labeling time-course. (B) Undifferentiated phenotype maintained by hESCs after more than 15 days in optimized SILAC media as observed by light microscopy. Scale bars equal 250 μm . (C) A mass spectrum of heavy arginine peptide ion MSVQPTVSLGGFEITPPVLR at ~ 747 m/z. Indicated are the absence of both a converted proline peptide ion and the unlabeled 'light' arginine peptide ion. The absent 'light' peptide ion at 743 m/z also indicates no back-conversion of proline to unlabeled arginine. (D) A mass spectrum of the 1:1 mixed labeled and unlabeled hESC lysates showing 'light' and 'heavy' peptide ion VAPEEHPVLLTEAPLNPK at ~ 652 m/z and 655 m/z. The prominent converted proline peptide ions are now almost undetectable and do not effect the observed 1:1 ratio. Isotopic amino acids are underlined.

cumbersome transition from feeder cell to feeder cell free culture during the labeling process. As these authors noted, the use of dialyzed FBS, prescribed in standard SILAC media [28], made feeder cell independent culture of mESCs difficult. Moreover, having to culture mESCs on feeder layers and/or transition those to feeder cell independent conditions could negatively impact both the scalability of this procedure and the integrity of the mESC phenotype. Because KOSR was originally designed and used as an alternative to FBS for the culture of mESCs [27] we hypothesize that the formulation that we successfully applied to hESCs could also be used in creating a protocol to perform SILAC on completely feeder-cell independent mESC cultures.

Therefore a mESC SILAC media containing 15% KOSR was formulated [27] and the media supplemented with 1000 U/mL of leukemia inhibitory factor (LIF) prior to addition to feeder cell free mESC cultures. After 4 passages in our mESC SILAC media the pluripotent culture morphology was indiscernible from those mESCs cultured under standard conditions (Figure 2.6 A-B). After the same period of time mESCs also achieved maximum incorporation of isotopic amino acids (^{13}C ^{15}N Arg and Lys) (Figure 2.6 C) with an average labeling of 96.3%. Moreover, visual inspection of SILAC labeled mESC MS spectra demonstrates similar results as observed with hESCs samples where there is no compromise with levels of isotopic arginine incorporation and no detectable incidence of proline conversion artifacts even in peptide ions with multiple proline residues in the sequence (Figure 2.6 D). In accordance with the observations in the hESC system, the application of a KOSR based SILAC media to a feeder-cell free mouse ESC culture, now provides a robust protocol for routine, large-scale quantitative proteomic experiments using SILAC in mESCs as well.

Figure 2.6. Labeling feeder cell free mESCs in conditioned SILAC media with KOSR. mESCs cultured on gelatin were grown in ESC optimized SILAC media (^{13}C ^{15}N Arg and Lys, 15% KOSR providing 600 mg/L L-proline) for 4 passages (8 days). Amino acid incorporation, conversion of arginine to proline, and mESC phenotype were monitored. The undifferentiated phenotype of mESCs grown under standard feeder cell free conditions (A) compared to those grown in optimized SILAC media for 8 days (B) as observed by light microscopy. Scale bars equal 250 μm . (C) The average heavy Lys and Arg incorporation over the SILAC labeling time-course. (D) A mass spectrum of peptide ERPPNPIEFLASYLLK at 635.6 m/z from mESCs in ESC optimized SILAC media. The 'heavy' Lys and Arg peptide ion is prominent while the unlabeled 'light' peptide or converted 'heavy' proline peptide ions are absent. The absent 'light' peptide ion at m/z 633 also indicates no back-conversion of proline to unlabeled arginine. Isotopic amino acids are underlined.

2.2.5 - SILAC of hESCs and hiPSCs in Defined Conditions. With the recent demonstration that somatic cells can be reprogrammed to generate pluripotent cells, a significant increase in the number of studies employing these induced pluripotent stem cells (iPSC) have been carried out [29]. The clinical potential of human iPSCs (hiPSC) necessitates the need for their culture in defined, xeno-free conditions. As such, a variety of formulations have recently become commercially available [30], many of which can be paired with xeno-free growth matrices. However, very few of these alternatives offer the tested stability and universality of MEF-CM combined with the basement matrix MatrigelTM.

Our previously discussed methods for performing SILAC in human and mouse ESCs utilizes an undefined KOSR-based medium. Since this medium requires pre-conditioning on MEF feeder layers, it is xenogenic and undefined in nature. Coupled with this is the potential for contamination with unlabeled amino acids as a result of conditioning. Although proteomic analyses have attempted to profile the MEF derived contribution to MEF-CM, the composition can vary significantly from batch to batch [31-33]. In order to perform SILAC in any cell system, the ability to control culture medium components is essential. Development of a defined culture medium amenable to SILAC experimentation in hESCs and hiPSCs would be a significant development for proteomics researchers.

Based on this, we have adapted a commercially available, fully-defined, serum-free medium formulation for performing SILAC in hESCs and hiPSCs [34]. After 10 passages in SILAC medium (>60 days), H9, CA1, and BJ-1D stem cell lines maintained

expression for Oct3/4 and Nanog as indicated by RT-PCR (Figure 2.7 A). All of the tested stem cell lines also retained Oct3/4 and SSEA4 marker expression as visualized using immunofluorescence (Figure 2.7 B). Marker expression was further validated using flow cytometry for SSEA4 and SSEA1 in all cell lines (Figure 2.7 C). After the induction of differentiation *in vitro* using embryoid body assays, all cell lines exhibited increased expression of markers characteristic of each of the three primary germ layers (Figure 2.7 D). Additionally, H9 and CA1 hESCs also retained the ability to differentiate *in vivo* as observed using a teratoma assay. Taken together, these data indicate that extended culture in StemPro-based SILAC medium is capable of maintaining hESC and hiPSC lines in an undifferentiated and pluripotent state.

To test the compatibility of the defined medium for SILAC experimentation, we monitored incorporation of isotopically labeled versions of arginine and lysine. Examining multiple peptides revealed that >96% incorporation can be achieved after just 7 days in defined medium supplemented with isotopically labeled arginine and lysine (Figure 2.8 A). By examining the amino acid composition of the defined culture medium we determined that there was no significant source of L-proline. When cells were grown in defined medium containing no exogenous L-proline, significant conversion from arginine can be observed (Figure 2.8 B). After the addition of 800mg/L of L-proline, there is no longer any signal observable for the isotopically labeled proline containing peptide (Figure 2.8 C). Analysis of 1:1 mixed light and heavy lysates reveals that the addition of L-proline in defined medium restores the previously skewed expected peptide abundance ratio (Figure 2.8 B-C). These observations validate our previous data for SILAC experiments performed in KOSR-based medium.

Figure 2.7. Labeling feeder cell free hESCs and hiPSCs in defined serum-free SILAC media. H9, CA1, and BJ-1D were maintained in StemPro SILAC medium with ^{13}C , ^{15}N Arg and Lys, as well as 800mg/L of L-Proline. Following 10 passages, each cell line was assayed for conventional markers of an undifferentiated state. (A) Each cell line maintained strong expression for the markers Oct3/4 and Nanog as determined by RT-PCR. Data is relative to specific matched cell line controls on Matrigel™ in MEF-CM. Error bars represent SD, n=3 (B) Immunocytochemistry data demonstrate expression of Oct3/4 and SSEA4 in all cultures. Scale bars indicate 250um. (C) Flow cytometry data for all cell lines assaying SSEA4 and SSEA1 expression, n=3. All lines maintained strong signal for SSEA4 with minimal SSEA1. Viability was determined using 7-AAD staining. Populations were gated based on 7-AAD exclusion. (D) Embryoid bodies were generated using cells grown in SILAC medium. Phase contrast images showing representative embryoid bodies for each cell line. Scale bars represent 250um. Graphs below show RT-PCR analysis for the markers of pluripotency (Oct3/4, Nanog), trophoblast (CDX2), ectoderm (NeuroD1, PAX6), endoderm (GATA6, GATA4, alpha-fetoprotein), mesoderm (T). Values are fold change relative to cell line specific undifferentiated controls. Error bars represent SD, n=2. RT-PCR assays in both (A) and (D) use RPLPO as a positive control. (E) In vivo analysis of pluripotency. Representative tissues from the three primary germ layers are displayed. Endoderm : gut epithelium (i), columnar epithelium (iv), Mesoderm: muscle tissue (ii, v), cartilage (iv), Ectoderm: neural epithelium (iii), neural-like tissue (vi). Arrows denote structures of interest. Scale bars represent 100um.

Figure 2.8. Efficient isotopic label incorporation achieved through the use of defined SILAC medium. hESCs and hiPSCs were grown for a period of 7 days in StemPro SILAC medium containing ^{13}C , ^{15}N arginine and lysine. (A) H9, CA1, and BJ-1D stem cells were harvested at 0,1,3, and 7 days following application of StemPro SILAC medium. Label incorporation was obtained by comparing peak areas for combined scans of light and heavy peptides. A total of 5 peptides were compared in each cell line. (B-C) H9 stem cells grown in the presence and absence of L-proline were tryptically digested and analyzed by MS. Analysis of the proline containing peptide MSVQPTVSLGGFEITPPVLR revealed a significant heavy proline amino acid signal in the absence of exogenous L-proline. The resulting skew in expected peptide ratio from a 1:1 mixture of light and heavy cell lysate can be seen in (C). Following the addition of L-proline, negligible signal for the heavy proline containing peptide remains and the expected peptide ratio is restored in (C). Isotopically labeled amino acids are underlined.

2.3 Discussion

Most SILAC procedures take a reductionist approach in controlling amino acid content in cell culture to achieve the desired labeling outcome. These include the use of dialyzed FBS, reduced concentration or total removal of many amino acids (i.e. Arg and Pro), and overall culture conditions optimized using immortalized tissue culture. We believed these methodological aspects preclude the extension of SILAC procedures to ESCs and were at the heart of amino acid conversion artifacts seen using the general labeling procedure. In this chapter, we demonstrate that through supplementation of isotope-coded arginine based SILAC experiments with as little as 200 mg/L of L-proline, isotopic arginine to proline conversion artifacts can be virtually eliminated in a variety of cell types. In addition, using KOSR which provides 800 mg/L of L-proline at 20% as a serum supplement in lysine and arginine based SILAC experiments instead of dialyzed FBS creates a robust media formulation for completely feeder-cell free SILAC experiments using ESCs from both the mouse and the human. We also tested the compatibility of a fully-defined, serum-free medium for use in SILAC experiments with hESCs and hiPSCs. With this medium we were able to maintain all hESC and hiPSC lines tested for an extended period in an undifferentiated and pluripotent state. Moreover, with the addition of L-proline at a concentration of 800mg/L to the medium, we could successfully eliminate conversion from isotopically labeled arginine.

Based on the cellular pathways of proline and arginine metabolism, the addition of proline is an obvious solution to the conversion issue, however the concern has always been the potential back conversion to arginine which would interfere with isotope-coded

arginine labeling [8]. Some studies, such as the recent one using SILAC in mESCs stress that all reagents were prepared without proline for this very reason [17]. To our knowledge, no study to date has demonstrated that the presence of proline actually induces significant back conversion to arginine in a concentration dependent manner during a SILAC procedure. In fact, we demonstrate here that between 0 and 800 mg/L proline that there is no significant change detectable in the labeling of cells with isotope-coded arginine.

Proline is a preferred precursor for arginine biosynthesis in neonates *in vivo* just as arginine is for proline. However it has been clearly demonstrated in a number of studies that the *de novo* biosynthesis of either arginine or proline using the other as a precursor is most strongly influenced by their bioavailability [23, 24, 35]. In other words, if there is sufficient free proline present to maintain cellular homeostasis the endogenous production of proline will not be favored, regardless of the concentration of its available precursors. The same statement can be made in the opposite direction for arginine. With respect to energy and metabolism this observation makes sense as it would be the most efficient. Even though a diminished arginine concentration may be sufficient in certain cell types, it has been reported that this is not completely efficient at preventing proline conversion artifacts [3, 8]. Our study suggests that this was due to the absence of proline in the standard SILAC media formulation. While the inter-conversion of proline and arginine may still exist in cells labeled with isotope-coded arginine using our media formulation, we were unable to detect it with any level of significance. More importantly, our strategy of supplying additional or high concentrations of amino acids

appears to be more effective at eliminating the problem and makes our strategy the most applicable to biologically important *in vitro* cell types like embryonic stem cells.

This work however, is limited in the number of cell lines and peptides tested. Recent research from two groups has expanded this analysis to include a variety of cell lines and thousands of peptides [36, 37]. Comparing the log₂ ratios of peptides and proteins from 293T cells harvested under conventional SILAC conditions or those where proline is supplemented, Lossner *et al.* observed a shift in the expected peptide ratio only in the absence of exogenous proline supplementation. Marcilla *et al.* were able to virtually abolish arginine conversion by supplementing with as little as 300 mg/L of proline [37]. They also observed that there was no back conversion to arginine after proline supplementation as has been suggested previously [38], further validating our results. Both of these studies indicated no negative effects on cell viability as a result of proline addition.

We have illustrated the ability to eliminate conversion of isotopically labeled arginine to proline when performing SILAC experiments in ESCs. Through the supplementation of as little as 200mg/L of L-proline, conversion can be eliminated to undetectable levels. We also demonstrated the growth and maintenance of hESC and hiPSC lines in fully defined SILAC medium. Since our publication other groups have demonstrated large-scale characterization of hESCs using our methods [39]. Although the ability to perform SILAC in defined conditions is a significant step for hESCs and hiPSCs, extension of this work to a xeno-free medium is desirable.

2.4 Experimental Methods

2.4.1 SILAC media formulations - All SILAC media formulations and labeling procedures were modified from previously described protocols [5, 28]. With the exception of the defined SILAC medium, all SILAC labeling experiments used embryonic stem cell qualified Dulbecco's Modified Eagle's Medium (DMEM – 4500mg/L glucose, with Na pyruvate, and no L-glutamine) that was custom ordered without lysine or arginine (Specialty Media – Millipore). Before use, media was re-supplemented with 2.5 mM L-glutamine (Invitrogen), 0.798 mM isotope-coded L-lysine ($^{13}\text{C}_6$ $^{15}\text{N}_2$), and 0.398 mM isotope-coded L-arginine (either $^{13}\text{C}_6$ or $^{13}\text{C}_6$ $^{15}\text{N}_4$). In the case of 'light' media, standard L-lysine and L-arginine were used. The DMEM for ESC cell culture was supplemented with 0.1 mM 2-mercaptoethanol, 1% non-essential amino acids (NEAA - Invitrogen), and 20% or 15% Knockout Serum Replacement (KOSR - Invitrogen) reagent for hESC or mESC culture, respectively. Note that ESC media with 1% NEAA will have 11.5 mg/L proline while KOSR at 20% and 15% (v/v) will contribute an additional 800 and 600 mg/L of L-proline, respectively [27]. For HeLa cell culture the DMEM was supplemented with 10% (v/v) dialyzed fetal bovine serum (FBS), 1% (v/v) penicillin-streptomycin (both Invitrogen), and 0 to 800 mg/L of L-proline (Sigma). All media were filter sterilized at 0.2 μM .

2.4.2 SILAC labeling of human and mouse ESCs and iPSCs - For SILAC labeling of both hESC, hiPSC, and mESC cultures measures were taken to remove all non-isotopic Arg and Lys from the system. All cells were washed with either PBS or DMEM lacking Arg and Lys prior to exposure to SILAC media. Any reagents requiring dilution with

DMEM were prepared in DMEM lacking Arg and Lys as well. hESC lines H1 and H9 [40] were maintained in feeder-free culture on 1:15 MatrigelTM (BD Biosciences) coated plates. hESC SILAC media was supplemented with 4 ng/mL basic fibroblast growth factor (bFGF – Invitrogen) and pre-conditioned on irradiated mouse embryonic fibroblasts (MEFs) according to previously established protocols [26]. The MEF conditioned hESC SILAC media was further supplemented with 8 ng/ml bFGF prior to addition to hESC cultures and changed daily. Cells were passaged every 5-7 days through dissociation with 200 U/mL collagenase IV (Invitrogen). hESCs were cultured for two passages (> 12 days) in SILAC media to achieve maximum isotopic amino acid incorporation. Analysis of hESC culture integrity and expression of pluripotent cell surface markers was performed as previously described [41]. E14K mESC cultures from 129Ola mice were also maintained in the absence of feeder cells on 0.1%(v/v) gelatin (Sigma) coated plates as previously described [42]. mESC SILAC media was supplemented with 1000 units/ml leukemia inhibitory factor (LIF – ESGROW, Millipore) prior to addition to cultures. Cells were passaged 1:3 every 2 days through dissociation in 0.25% trypsin, 2.21 mM EDTA (Wisent). mESCs were cultured for 4 passages (> 8 days) in SILAC media to achieve maximum isotopic amino acid incorporation.

For SILAC experiments in defined medium, hESC (H9, CA1) and hiPSC (BJ-1D) cell lines were grown in feeder-free conditions on 1:30 MatrigelTM (BD Biosciences). The CA1 hESC line used in all experiments was obtained from Dr. Cheryle Séguin of The University of Western Ontario [43, 44]. The hiPSC line BJ-1D was derived by reprogramming using retroviral transduction of BJ fibroblasts with the Yamanaka factors

essentially as we have previously described [45] and validated as pluripotent using in vitro and in vivo differentiation assays and expression profiling (unpublished results). Custom DMEM/F12-glutamax that contained no L-arginine or L-lysine was ordered from Invitrogen. SILAC medium was prepared using the StemPro hESC Media system with our custom DMEM/F12 (Invitrogen) according to manufacturer instructions. [$^{13}\text{C}_6$, $^{15}\text{N}_4$] – L-arginine and [$^{13}\text{C}_6$, $^{15}\text{N}_2$] – L-lysine (Cambridge Isotope Laboratories, Andover, MA) were supplemented into the SILAC medium at 71.42mg/L and 80mg/L respectively. Unlabeled L-proline was added to the SILAC medium at a final concentration of 800mg/L. Culture medium was changed daily and cells were passaged every 4-5 days by manual dissection and harvesting of colonies.

Embryoid bodies (EB) were generated using Aggrewell 400Ex plates (StemCell Technologies, Vancouver, Canada). Briefly, 2×10^6 hESCs were harvested enzymatically using Accutase (Invitrogen) from MatrigelTM coated plates. Cells were reconstituted in Aggrewell medium supplemented with Rock inhibitor (Y-27632, Sigma-Aldrich, St. Louis, MO) at a final concentration of 10 μM . After plating in Aggrewell dishes, EBs were grown for 48 hours at 37°C prior to transfer to ultra-low adherence tissue culture dishes (Corning, Lowell, MA). After 15 days of culture, EB RNA was harvested using Trizol extraction according to the manufacturer's instructions (Invitrogen). EBs were assayed for expression of CDX2, alpha-feto protein (AFP), GATA-6, GATA-4, Oct3/4, PAX-6, T-brachyury, Nanog, and Neurogenic differentiation 1 (NeuroD1) using TaqMan primer probe sets (Invitrogen). Assay information can be found in Appendix Table 1.15. All EB assays were performed in biological and technical duplicate for each cell line and condition.

2.4.3 Preparation and digestion of cell samples - To monitor isotopic amino acid incorporation and conversion trypsin digests were prepared from whole cell lysates for LC-MS analysis. Cell culture media was removed and cells were washed with PBS. Cells were then mechanically removed from the plate, lysed by dissociation in 8M urea and 50 mM ammonium bicarbonate, and frozen at -80°C. The protein content was determined by Bradford assay and, where indicated, 'light' and 'heavy' isotopic samples were mixed 1:1 based on total protein concentration prior to digestion. For trypsin digestion, samples were reduced with 10 mM DTT, alkylated with 30 mM iodoacetamide, diluted 1:4 with 50 mM NH₄CO₃ and treated with modified trypsin (1:25 enzyme/substrate ratio - Promega) at 37°C overnight. The resulting tryptic peptides were extracted using a 1-mL C₁₈ solid phase extraction cartridge (Waters), eluted with 50% (v/v) ACN, 0.1% (v/v) formic acid (FA) to remove urea and salts and were re-concentrated in a vacuum centrifuge. Dried fractions were reconstituted in 10% FA for LC-MS/MS analysis.

2.4.4 Liquid chromatography tandem mass spectrometry (LC-MS/MS) analysis - Between 1.0 and 0.5 µg of each original sample was injected on a NanoAcquity UPLC (Waters) equipped with a 15cm x 75µm C18 reverse phase column employing a 90-minute LC gradient (5-40% ACN, 0.1% FA) and detected in a data-dependent acquisition (DDA) mode by tandem MS (Q-ToF Ultima - Waters). The MS was directed to use the following DDA parameters: survey scan range 400-1800 m/z, 1 s scan, 1-4 precursors selected based on charge state (+2, +3 and +4 ions). MS/MS fragmentation was then performed on the ions using the charge state collision energy profile function.

2.4.5 Analysis of isotopic amino acid labeling and conversion - Data analysis for all samples was performed in PEAKS 5.3 software (Bioinformatic Solutions Inc., Waterloo, Canada) [46, 47]. After import into PEAKS, MS/MS spectra from raw data files were refined using the following settings: merge spectra – true (100ppm mass tolerance, 60 second retention time tolerance), correct precursor mass – true, determine precursor charge state – true (minimum charge +2, maximum charge +5), spectral quality filter – true (0.65 threshold), centroid, deisotope, and deconvolute – true. Resulting MS/MS spectra were then *de novo* sequenced using the following parameters: parent monoisotopic mass tolerance – 100ppm, fragment monoisotopic mass tolerance – 0.15 daltons, enzyme specificity –Trypsin, fixed modifications – carbamidomethylation and +10 daltons on Arginine and +8 daltons on Lysine for SILAC, variable modifications – oxidized methionine. After *de novo* analysis, data were searched against the UniProt sequence database (Human taxonomy specified, 20236 total entries) using the following parameters: parent monoisotopic mass tolerance – 100ppm, fragment monoisotopic mass tolerance – 0.15 daltons, , enzyme specificity –Trypsin, fixed modifications – carbamidomethylation and +10 daltons on Arginine and +8 daltons on Lysine for SILAC, variable modifications – oxidized methionine, estimate false-discovery rate – true. Identified peptides were chosen randomly to be investigated manually using MassLynx 4.1. The peak area was determined by integration using the built-in algorithm in MassLynx 4.1 to output peak area values. Peak area of the monoisotopic ions were used for comparison and determination of quantitative ratios of peptide candidates.

2.4.6 Titration of proline - HeLa cells were passaged twice at a ratio of 1:8 in SILAC media containing the indicated amount of L-proline to ensure maximum incorporation of the isotopic arginine label (either $^{13}\text{C}_6$ or $^{13}\text{C}_6$ $^{15}\text{N}_4$ Arg). SILAC media was changed every 3 days, or as needed based on phenol red indicator. Whole cell lysates were digested and subject to LC-MS/MS in the initial sample analysis. Both potential and confirmed (by MS/MS) proline containing peptides resulting from the conversion of isotopic arginine were noted. All samples were then re-run in triplicate using the “include only” function to target previously detected/suspected proline containing peptides across all samples. The candidate list of proline containing peptides was then used to follow the conversion of arginine to proline over varying proline supplement concentrations. Peptides containing labeled proline derived from isotope-coded arginine were confirmed by MS/MS in the 0 and 50 mg/L proline samples. Thirteen proline converted peptides observed in the replicate analysis and confirmed by MS/MS were used to monitor isotopic arginine to proline conversion in these experiments. These were: VAPEEHPVLLTEAPINPK, LILPGELAK, PMFIVNTNVPR, NTGIICTIGPASR, MSVQPTVSLGGFEITPPVLR, PPYTVVYFPVRGR, YSSLVPIEK, AVFPSLVGRPR, VAPEEHPVLLTEAPINPK, SSGPYGGGGQYFAKPR, QYPKVPR, LAVNMVPFPR, and SSRAGLQFPVGR.

To investigate the possible back conversion of proline to arginine, a similar process was repeated except the arginine containing peptide candidates did not have a proline in their sequence, so that proline conversion could not interfere with arginine incorporation calculations. Based on replicate analysis, those peptides used for arginine incorporation that were consistently observed and confirmed MS/MS were: STELLIR,

AGTGVDNVDLEAATR, VIGSGCNLDSAR, TIAQDYGVKKADEGISFR,
GKVKVGVDGFGR, and GITINAAHVEYSTAAR.

2.4.7 SILAC Label Incorporation - In order to monitor isotope-coded amino acid incorporation and determine the optimum times for SILAC adaptation a list of both Lys and Arg containing candidate peptides for both human and mouse ESCs was generated. Incorporation was obtained by comparing peak areas from combined scans of light and heavy peptides. Those candidate peptides that were consistently identified by MS/MS across all samples during the labeling time course were: NLPQYVSNELLEEAHSVFGQVER, IHFPLATYAPVISA EK,
SLQDIIAILGMDELSEEDKLTVSR, LISWYDNEFGYSNR, GVDEVTIVNILTNR,
SSGPTSLFAVTVAPPGAR, ALMLQGVDLLADAVAVTMGPK,
EVAFAQFGSDLDAATQQLSR, LLEDGEDFN LGDALDSSNSMQTIQK,
EKPYFFIPEEYTFIQNVPLEDR, VGKDELFALEQSCAQVVLQAANER,
GFGFVTYATVEEVDAAMNARPHK, VVLAYEPVWAIGTGK, and YPIEHGIITNWDDMEK
for hESCs; and KATGPPVSELITK, ALLFVPR, GLFIIDDK, YQAVTATLEEK,
ALMLQGVDLLADAVAVTMGPK, SGETEDTFIADLVVGLCTGQIK, MVNHFIAEFK,
IGYPAPNFK, IAIYELLFK, ALYETELADARR, SLMDEVVKATSR,
ERPPNPIEFLASYLLK, TKVHAELADVLTEAVVDSILAIR for mESCs.

For hESCs and hiPSCs grown in defined SILAC medium, label incorporation was monitored for 7 days after exposure to heavy medium. Incorporation was determined through examination of the following peptides: HQGVMVGMGQKDSYVGDEA QSKR,
HLEINPDHPIVETLR, HVFGESDELIGQK, IHEGCEEPATHNALAK,

GVVDESDIPLNLSR, FQSSHPTDITSLDQYVER, SNYNFEKPFLLWLAR,
ISEQFTAMFR, VIHDNFGIVEGLMTTVHAITATQK, HSQFIGYPITLYLEKER,
VILHLKEDQTEYLEERR, MTDQEAIQDLWQWRK.

2.4.8 Real-time PCR – RNA was purified using Trizol reagent according to the manufacturer's instructions (Invitrogen) or with the 5 Prime PerfectPure RNA Extraction Kit (5 Prime, Gaithersburg, MD). After NanoDrop quantification, 1µg of cDNA was synthesized using the High Capacity cDNA Reverse Transcription Kit with RNase inhibitor (Invitrogen). Real-time PCR was performed using the TaqMan® Universal PCR Master Mix (Invitrogen). Samples were incubated at 50°C for 2 minutes followed by 10 minutes at 95°C. Samples were then amplified at 95°C for 15 seconds followed by 1 minute at 58°C for 46 cycles. All samples were normalized to RPLPO as a positive control. All primers were obtained from Invitrogen and assay information can be found in Appendix Table 1.15. Each biological replicate was run in triplicate for every marker assayed. All reagents were used according to the manufacturer's instructions.

2.4.9 Immunofluorescence – After 10 passages in SILAC medium, H9, CA1, and BJ-1D cells were plated in 6-well dishes coated with Matrigel™™. After 4 days of culture, cells were rinsed and fixed with 4% para-formaldehyde containing 20 mM sucrose. Prior to staining, cells were blocked using the Dako Serum Free Protein Block solution (Dako, Cambridgeshire, UK). Oct-4 (clone 10H11.2), SSEA-4 (clone MC-813-70), and SSEA-1 (clone MC-480) primary antibodies were obtained from Millipore (Billerica, MA). Cells for Oct-4 labeling were permeabilized using a 0.1% Triton X-100 solution prior to blocking. Cells were labeled with primary antibodies for Oct-4 or SSEA-4 as

undifferentiated markers and SSEA-1 for differentiated cells all at concentrations concentrations of 2 µg/mL for 60 minutes at room temperature. Secondary Alexa-fluor 488 goat anti-mouse IgG and Alexa-fluor 568 goat anti-mouse IgM were obtained from Invitrogen (Carlsbad, CA). Secondary antibodies were probed at concentrations of 1 µg/mL for 60 minutes at room temperature. All products were used according to manufacturer's instructions.

2.4.10 Flow Cytometry – All reagents and probes for flow cytometry were obtained from eBiosciences (San Diego, CA) unless noted otherwise. Cells were enzymatically harvested using Accutase (Invitrogen) to obtain a single cell suspension. After centrifugation, cell pellets were resuspended in 5% FBS in PBS. Alexa-488 conjugated SSEA-4 and Alexa-647 conjugated SSEA1 were diluted into the cell mixture according to the manufacturer's instructions. Negative control samples contained respective isotype controls for the primary antibodies used. Solutions were incubated for 2 hours and analyzed using an Accuri C6 (BD Biosciences) flow cytometer after rinsing to remove unbound antibody. Populations were gated according to forward and side scatter patterns with filtering for viable cells using 7-aminoactinomycin D staining. Data were analyzed using FlowJo software (Tree Star, Ashland, OR).

2.4.11 Teratoma Formation and Histological Analysis – All animal protocols used here have been approved by the University of Western Ontario Council on Animal Care. Nude (Crl:NU-Foxn1^{nu}; Charles River) mice were injected in the flank subcutaneously with H9 or CA1 hESCs grown for >10 passages in StemPro SILAC medium. Prior to injection, hESCs were rinsed with PBS, trypsinized, and counted

using trypan blue exclusion. Approximately 1×10^6 cells based on live cell counts were resuspended in a 50:50 DMEM:Matrigel™™ mixture totaling 100µL in volume. Injections were performed on each side of three separate mice for each treatment (n=3). Teratomas were allowed to form for 6 – 8 weeks. Teratomas were removed, fixed and embedded in paraffin. Sections were taken from three areas spaced evenly through the tissue and tissue types were defined with hematoxylin and eosin staining.

2.4.12 Statistical Analysis – Statistical analyses were performed using GraphPad Prism software. Results are expressed as SD or SEM as indicated in figure legends. Statistical significance was determined using unpaired Students T-tests. Differences were reported as follows: * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$.

Chapter 3

Proteomic Analysis of Complex Matrices used in Human Embryonic Stem Cell Culture

3.1 Introduction

The *in vivo* and *in vitro* extracellular matrix (ECM) is known to play an important role in numerous decisions that direct cell fate and behavior [1-4]. Typical ECM mixtures include combinations of laminins, collagens, glycoproteins, and proteoglycans [5, 6]. However, the constituents of the ECM differ greatly between tissue types. *In vitro*, the main function of the extracellular matrix is to support cell growth and maintenance. For example, the ECM provides physical support for cells whilst maintaining cellular polarization and tissue morphology. Moreover, the ECM is a reservoir for cell signals as it contains specific carbohydrates, proteins, nutrients and growth factors that can direct cellular processes and behavior. An example ECM component being laminin, which cells sense via integrin receptors. Such interactions between cells and laminin have been shown to affect a variety of biological functions, such as cell growth, morphology, differentiation, and migration in a cell-specific manner [7].

This chapter contains excerpts with permission from the following papers:

Hughes, C.S., Postovit, L.M., Lajoie, G.A.. (2010) "Matrigel: A Complex Protein Mixture Required for Optimal Growth of Cell Culture". *Proteomics*. 10;9:1886 – 1890

Hughes, C.S., Radan, L., Betts, D., Postovit, L.M., Lajoie, G.A.. (2011) "Proteomic Analysis of Extracellular Matrices used in Stem Cell Culture". *Proteomics*. 11;20:3983 – 3991

In vitro, protein matrices are commonly used when cell proliferation is not favorable on chemically treated tissue culture plastic. Depending on the cellular system of interest, these matrices can consist of a range of components. The most widely utilized example of this is the basement-membrane matrix commercialized as Matrigel™ [8, 9]. Matrigel™ is an assortment of extracellular matrix proteins that have been extracted from Englebreth-Holm-Swarm tumors in mice [8-10]. Matrigel™, which primarily consists of laminin, collagen IV, and enactin, is considered to be a reconstituted basement membrane preparation. Previous research studies have emphasized the need for caution when drawing conclusions based on changes in cellular activity when using Matrigel™ [11]. This recommendation was based on the detection of several growth factors in standard Matrigel™ through the use of immunoassays; these included bFGF, EGF, IGF-1, TGF-β, PDGF, and NGF [11]. Growth factor reduced (GFR) is a version of Matrigel™ that has been modified to reduce the abundance levels of these growth factors [11].

One important application of Matrigel™ is its use for the growth of human embryonic stem cells (hESC). In contrast to mouse ESC culture, hESCs cannot be maintained in an undifferentiated and pluripotent state on gelatin. Thus, Matrigel™ is conventionally used as a substitute for gelatin in feeder-free hESC culture. Unfortunately, the derivation of Matrigel™ from mouse tissue makes it undesirable for the growth of hESCs that can be potentially applied in therapeutic treatments [12, 13]. A variety of alternative ECM proteins or culture systems have been evaluated for their ability to support hESC proliferation [14-28]. In combination or individually, some of these promote the pluripotent growth of undifferentiated hESCs in 2D, 3D, and suspension

culture [16, 29]. Cell-derived matrices generated from human fibroblasts have also been shown to promote pluripotent hESC growth, but the supportive constituents of such preparations are largely unknown or proprietary [30-35]. While most of the previously noted matrices have been shown to support the maintenance of self-renewal and pluripotency in hESCs, none have proven as effective as Matrigel™ [36].

The lack of a defined xeno-free growth matrix remains a significant limitation for the potential extension of hESCs to therapeutic applications [17, 37, 38]. It would be of tremendous value if support proteins that enhance the *in vitro* culture of hESCs could be identified. The development of a defined matrix for hESC growth is currently limited by our understanding of the ECM proteins that regulate hESC attachment and proliferation. Although it has been the subject of a number of studies, there is still a lack of understanding of how ESCs interact with the surrounding ECM *in vitro* and *in vivo* [39-45]. Proteomic analysis of supportive matrices could help elucidate components that promote hESC growth, analogous to the characterization of conditioned medium from supportive fibroblast feeder layers for the identification of soluble regulatory cytokines [46-50].

A major obstacle that examination of these matrices presents is the significant challenge in proteomic analysis due to the complex nature of the samples. ECM mixtures typically consist of large amounts of high molecular weight protein and a variety of low abundance species. Identification of these low abundance proteins can only be obtained by extensive fractionation prior to liquid chromatography (LC) mass spectrometry (MS) analysis [51, 52]. The two most common methods used in

proteomics are fractionation with one dimensional SDS-PAGE at the protein level or, after digestion with trypsin, by ion exchange chromatography at the peptide level. These fractionation steps are typically followed by further separation on a reversed-phase column prior to MS analysis [53]. It has recently been shown that some fractionation protocols prior to LC-MS are in fact complementary [46, 54].

In this chapter we utilize a combination of fractionation and digestion protocols for the analysis of complex ECM samples to attempt to identify hESC supportive proteins. We show that Matrigel™ contains an array of proteins in addition to those known to be directly involved in the structural basis of the basement matrix. This is accomplished by utilizing an in-depth proteomic approach that employs ammonium sulfate precipitation and a dynamic iterative exclusion MS (IE-MS) strategy to detect low abundance components [46]. Using a combination of strong anion and cation exchange as well as SDS-PAGE methods [46, 55], we analyze CellStart, StemXVivo, BridgeECM, and HumanBME, four previously uncharacterized ECM matrices. We also analyze a matrix deposited by irradiated mouse embryonic feeder layers (MEF-CMTX) after maintenance on gelatin for 7 days. After MEF lysis, the remaining matrix has been shown to promote the undifferentiated growth of pluripotent hESCs [56]. By comparing the proteins identified from these samples, we identify fibronectin as a primary component of nearly all the matrix samples, suggesting its importance in the promotion of hESC maintenance and pluripotency. To validate this observation, H9 and CA1 hESCs were cultured in mTeSR1 medium on fibronectin as the sole matrix component.

3.2 Results

3.2.1 Fractionation of Matrigel. Matrigel™ is known to be highly enriched in laminin, collagen, and enactin. Previously published research that revealed the presence of multiple active growth factors in Matrigel™ was based upon detection using immunoassays that are not amenable to a more global analysis of protein composition [11]. Comprehensive analysis of Matrigel™ using MS-based proteomics could potentially reveal the presence of other growth factors and cytokines. The main protein components of Matrigel™, laminin (800,000 Da), collagen IV (540,000 Da), and enactin (158,000 Da) are all significantly larger than the average size of most protein growth factors (<~45,000Da). To facilitate identification of these low abundance factors, fractionation that depletes the abundant high molecular weight (MW) components of Matrigel™ is critical.

Using size exclusion chromatography (SEC) to fractionate Matrigel™ samples, we were unable to obtain effective separation. We observed a large peak early due to the more rapid elution of large proteins from both the standard (N-GFR) and GFR Matrigel™. SEC runs were repeated for 3 technical replicates and typically resulted in ~15 fractions dependent on the elution profile of the sample. Analysis of each SEC fraction with one dimensional SDS-PAGE (1D-SDS-Gel) resulted in gels with very poor resolution, and showed minute amounts of low molecular weight proteins, as determined by Coomassie blue staining. Nevertheless fractions resulting from SEC runs were digested in-solution with trypsin prior to analysis by LC-MS.

Due to the limited separation and loading capacity provided by 1D-SDS-Gels, and the poor resolution of SEC, we adapted a two step ammonium sulfate (AS) precipitation protocol to fractionate both N-GFR and GFR Matrigel™ (Figure 3.1). AS precipitation is not commonly used in proteomics, but has been used for the depletion of N-GFR Matrigel™ to generate the GFR variety [11]. The two step procedure utilized here precipitates protein from Matrigel™ at 15% and 90% AS (w/v). Treatment of Matrigel™ with 15% AS gave a precipitate that was further fractionated by SEC prior to in-solution trypsin digestion. The supernatants from the 15% AS step were further adjusted to 90% AS. The resulting pellets were reconstituted in 8M urea and separated on a 1D-SDS-Gel. These gels contained visible amounts of low molecular weight proteins after staining that were then digested with trypsin and subjected to IE-MS analysis.

3.2.2 LC-MS Analysis of Fractionated Matrigel. LC-MS analysis of the SEC fractions from N-GFR Matrigel™ resulted in identification of 1117 unique peptides. The same analysis on GFR Matrigel™ SEC fractions resulted in the identification of 1521 unique peptides (Figure 3.2 C). The overlap between the two datasets indicates (~20% common) significant differences between the two types of Matrigel™ based on unique peptide identifications. LC-MS analysis of the pellets from 90% AS precipitation after 1D-SDS-Gel fractionation resulted in the identification of 5465 unique peptides for N-GFR and 5080 from GFR (Figure 3.2 C). Combination of SEC and AS precipitation datasets resulted in an increase in the total number of unique peptide identifications to 5910 for N-GFR and 5604 for GFR Matrigel™. Of these peptides, only 457 were matched to laminin/enactin from N-GFR Matrigel™, and 681 from GFR.

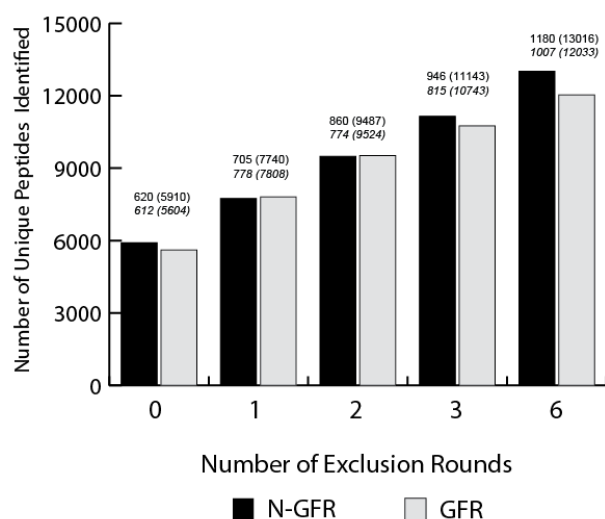

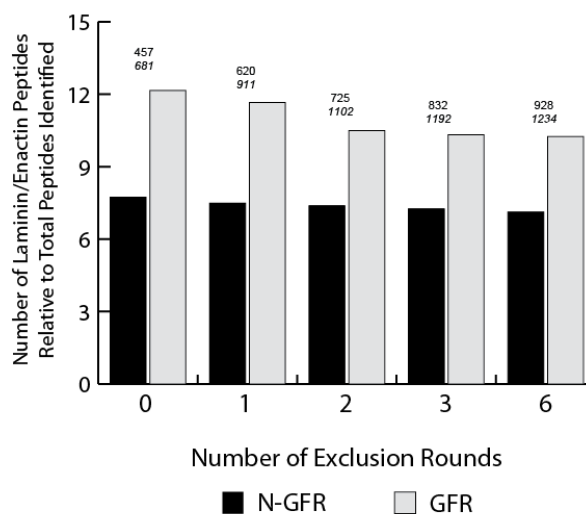

Figure 3.1. Schematic of experimental preparation of N-GFR and GFR Matrigel samples for proteomic analysis. Aliquots of Matrigel were subject to fractionation with SEC without prior precipitation using AS methods. The pellets of Matrigel aliquots that were precipitated with 15% AS were also subjected to SEC fractionation prior to in-solution digestion with trypsin and LC-MS analysis. The retained supernatant from 15% AS precipitation was further adjusted to 90% AS. Following centrifugation, the resolubilized pellet was subject to in-solution digestion with trypsin or further fractionation using a 1D-SDS-Gel. All samples were analyzed using a combination of LC-MS and IE-MS approaches to maximize the depth of sample coverage.

Even with utilization of SEC and AS precipitation coupled with 1D-SDS-Gels, there was still a considerable dynamic range in each fraction to address. To address this, we employed IE analysis to facilitate identification of low-abundance peptide species in the MS as demonstrated previously [11]. IE-MS analysis of the SEC fractions resulted in an increase in the number of unique peptides identified in N-GFR and GFR Matrigel™ to 2588 and 3781 respectively after 4 exclusion rounds (Figure 3.2 B). Six rounds of IE-MS analysis of the fractions resulting from 1D-SDS-Gel separation of the reconstituted pellets from 90% AS precipitation resulted in an increase in unique peptides identified to 11955 and 10368 for N-GFR and GFR Matrigel™ respectively (Figure 3.2 B). Combination of the IE-MS datasets from the SEC and AS methods resulted in an increase in the total number of unique peptides identified to 13016 in N-GFR Matrigel™, corresponding to 1180 proteins (Appendix Table 1.1 – 1.2). Combination of the data for GFR Matrigel™ increased the total number of identifications to 12033 for peptides and 1007 for proteins. These values represent an approximate 2-fold increase in the number of proteins identified through the use of IE-MS with samples from all fractionation types (Figure 3.2 A).

Through the combination of the data from N-GFR and GFR Matrigel™, we can generate a comprehensive dataset. Combination of the SEC datasets from N-GFR and GFR Matrigel™ resulted in the identification 5288 peptides and 452 unique proteins (Figure 3.2 C). Combination of the AS precipitation data resulted in 16995 peptide and 1343 protein identifications (Figure 3.2 C). Of the peptide hits, 748 were assigned to laminin/enactin for samples from SEC fractionation and 1046 for the samples from AS precipitation. These results illustrate the utility of the AS precipitation protocol for the

Figure 3.2. Iterative exclusion analysis of Matrigel samples. Samples of N-GFR and GFR Matrigel were fractionated using either SEC or AS precipitation coupled with 1D-SDS-Gel methods prior to IE-MS analysis. All LC-MS data files were searched using PEAKS 5.3 software as described in the Methods. (A) Total numbers of unique peptides identified in each round of IE-MS analysis. The number of peptide hits is given above each set of exclusion bars in the format protein# (peptide#) with N-GFR values in normal font and GFR in italics. Values represent total identifications following the combination of SEC and AS datasets. (B) Relative number of laminin/enactin peptides to the total number of identifications as assigned by PEAKS 5.3 across 6 exclusion rounds. As before, total numbers are found above with GFR in italics. (C) Lists the total numbers of peptide identifications found using conventional LC-MS analysis compared with IE-MS for SEC or AS fractionation of N-GFR and GFR Matrigel. LC-MS represents a single injection for each sample, whereas IE-MS represents multiple injections with exclusion lists applied during data acquisition.

depletion of high-MW components in comparison with SEC in order to facilitate the identification of other proteins in Matrigel™. Combining the data from all Matrigel™ batches and fractionation protocols, we identified a total of 19063 unique peptides and 1466 unique proteins from 280 LC-MS datafiles (Figure 3.3). Gene ontology analysis of the N-GFR and GFR Matrigel™ datasets revealed the presence of numerous intracellular proteins in both formulations (Figure 3.3). Taken together, these data indicate the significant complexity at the protein level for both N-GFR and GFR Matrigel™.

3.2.3 Comparative Analysis of N-GFR and GFR Matrigel. GFR is a variant of N-GFR Matrigel™ that has decreased levels of the growth factors and other low molecular weight proteins [11]. This is achieved using an AS precipitation protocol which we have adapted to facilitate analysis of all Matrigel™ samples tested in this study (Figure 3.4 A). Comparison of N-GFR and GFR Matrigel™ revealed that there are at least 721 proteins in common between the two preparations (Figure 3.4 B). N-GFR and GFR Matrigel™ yielded an additional 459 and 286 protein identifications specific to each dataset. Primary structural proteins common between the two types of Matrigel™ such as laminin, nidogen, and fibronectin were more abundant in GFR based on unique peptide number. In N-GFR proteins secondary to the main structural components of Matrigel™, such as SPARC and transferrin were more abundant. Interestingly, a variety of growth factors and their associated pathway members were identified in N-GFR that were not in GFR Matrigel™ (Figure 3.4 C).

Figure 3.3. Comprehensive proteomics dataset from the analysis of N-GFR and GFR Matrigel. The number in the green circle on the left represents the total number of protein identifications obtained following the analysis of the combined N-GFR and GFR Matrigel datasets. Identifications were made using PEAKS 5.3 software. Protein identifiers from the list of N-GFR and GFR proteins were mapped to Gene Ontology terms using STRAP software. The three graphs represent Biological Process, Cellular Component, and Molecular Function ontology groupings. The number of mapped annotations for each term for N-GFR can be found in red and for GFR in blue. The wide range of terms that the identifiers mapped to indicates the complexity and range of cellular localizations present for the proteins found in either variety of Matrigel.

Figure 3.4. Comparative analysis of N-GFR and GFR Matrigel. (A) Representative lanes from N-GFR and GFR Matrigel samples that were subject to electrophoresis on 1D-SDS gels. Lane A is neat Matrigel directly as it comes from the manufacturer. Lane B is the pellet that remains after precipitation using a solution of 15% ammonium sulfate precipitation. Lane C is the supernatant after precipitation with 90% ammonium sulfate. Following AS precipitation, a significant increase in protein staining can be seen in the low-MW range in 1D-SDS-Gels of N-GFR and GFR Matrigel samples. (B) Venn diagram illustrating the number of protein and peptide identifications for N-GFR (blue) and GFR (red) Matrigel. Numbers represent total numbers of identifications from data generated by employing IE-MS analysis of Matrigel samples prepared using SEC and AS precipitation fractionation protocols. Data files were analyzed using PEAKS 5.3 software as discussed in the Methods. (C) Table of growth factor and associated binding proteins found in N-GFR or GFR Matrigel. Values in the N-GFR and GFR columns represent the number of unique peptide identifications in each matrix as determined by PEAKS 5.3 software. If the protein was not found, it is denoted by “N/A”.

3.2.4 Fractionation of Alternative hESC Supportive Matrices. Adaptation of the AS protocol to the analysis of the HumanBME proved straightforward due to the similar protein abundance profile it shares with Matrigel™. Fractionation of CellStart with the AS protocol proved difficult due to the increased abundance of high-MW protein in this matrix compared with Matrigel™. Due to the limited amount of material we could obtain for MEF-CMTX, BridgeECM, and StemXVivo matrices, we were unable to apply the AS protocol. The limited utility of the AS protocol for the analysis of these matrices highlights the primary shortcoming of this method: the requirement for a large amount of sample due to the high potential for protein loss during the procedure.

In order to overcome the dynamic range of abundance and detect low abundance proteins in these new matrices, we employed a combination of conventional proteomic fractionation and digestion techniques. By utilizing an in-solution digestion protocol coupled to fractionation on strong cation and anion exchange chromatography columns, we could overcome loading constraints caused by lane bleeding on 1D-SDS-Gels to facilitate detection of low-abundance proteins. However, 1D-SDS-Gel fractionation proved applicable to HumanBME, StemXVivo, BridgeECM, and MEF-CMTX, but could not be used for the CellStart matrix due to lane bleeding problems caused by the large abundance of high-MW proteins.

Optimization of the fractionation methods on a HeLa whole cell lysate revealed that numerous peptide identifications were isolated to a single method (Figure 3.5). We also observed that the number of unique peptides identified could be increased by employing IE-MS analysis as described previously [46]. Comparison of the peptides identified for

Figure 3.5. Comparison of methods used to fractionate a complex HeLa cell lysate. Following enzymatic digestion using trypsin with an in-solution protocol, samples were fractionated using SCX or SAX with a pH gradient elution. Alternatively, cell lysate was separated using a 1D-SDS-Gel and subsequently digested using trypsin with an in-gel protocol. Samples were analyzed by MS with (Single Exclusion Round) or without (No Exclusion) IE-MS. Numbers represent the number of unique peptides identified in the combined fractions for each sample following analysis in PEAKS 5.3 software. Score thresholds were set to ensure an FDR<1% in all datasets.

the three primary fractionation methods tested (SDS-PAGE, SCX, and SAX), revealed that there was only a 2.0% overlap prior to iterative exclusion, and 2.6% after IE-MS analysis (Figure 3.5). This indicates that the differences in identifications are a result of the fractionation methods, as IE analysis will limit changes due to under-sampling of ions in the MS. These results prompted us to employ a combination of in-solution digestion followed by SCX, SAX, or SDS-PAGE fractionation and analysis using IE-MS.

3.2.5 Analysis of Alternative hESC Supportive Matrices. Using SAX and SCX fractionation with pH elution, a total of 70 proteins were identified in the CellStart matrix (Figure 3.6, Appendix Table 1.3). From these LC-MS analyses, the two most abundant proteins were fibronectin and serum albumin, representing >60% of all unique peptide identifications. These two high abundance proteins were likely the cause of the difficulties in the 1D-SDS-Gel method, where increasing the gel load resulted in their overloading. The other proteins identified represented a mix of intra and extracellular proteins, the majority of which were identified in Matrigel™.

Fractionation of HumanBME with SAX, SCX, and SDS-PAGE methods yielded 208 protein identifications (Figure 3.6, Appendix Table 1.4). From the analysis we observed that HumanBME is primarily composed of fibronectin, nidogen-1, and alpha-2, gamma-1, and beta-2 laminin isoforms based on the number of unique peptides identified. Other proteins identified included vitronectin, biglycan, insulin-like growth factor – 2, transforming growth factor beta 2, and growth receptor bound protein 2 (Grb2). Comparing the composition of HumanBME with that of Matrigel™ based on protein identifiers indicates a significant similarity between the two matrices. Although the

Figure 3.6. Comparison of the most abundant components of the ECM samples tested. Each sample was fractionated using either SCX or SAX chromatography, or 1D-SDS-Gel separation. Fractions were analyzed using IE-MS for a single exclusion round. Numbers in each circle represent the total number of protein identifications for the labeled matrix following the combination of data from all fractionation methods. Protein lists for CellStart, Human BME, StemXVivo, BridgeECM, and MEF-CMTX were generated and compared using PEAKS 5.3 software. Identification numbers include proteins that were matched with 2 unique peptides and had scores above the 1% FDR threshold. Six proteins commonly found at high abundances across the ECM samples are listed in the lower table. Of the proteins identified, fibronectin was an abundant component of 5 of the 6 matrices.

HumanBME dataset appears less complex based the total number of proteins identified when compared with Matrigel™, only a single exclusion round of IE-MS for was performed for the analysis.

Fractionation of StemXVivo with SCX, SAX, and SDS-PAGE methods resulted in a total of 67 unique proteins (Figure 3.6, Appendix Table 1.5). StemXVivo is primarily composed of nidogen-1 and vitronectin. These two proteins comprised >50% of the total unique peptides identified from analysis of StemXVivo. In addition to the primary components identified, a variety of other intra and extracellular proteins were also found, such as syndecan-2, multiple isoforms of actin, and pigment epithelium derived factor (PEDF). A search of unidentified spectra from the StemXVivo dataset against the entire UniProt database (not species restricted, Appendix Table 1.6) yielded numerous non-human peptides, such as 24 for bovine albumin. StemXVivo is marketed as a mixture of recombinant proteins, so the presence of non-human proteins is somewhat surprising.

After fractionation of the MEF-CMTX layer with SAX, SCX, and SDS-PAGE, a total of 460 proteins were identified (Figure 3.6, Appendix Table 1.7). As this matrix is generated through the lysis of mouse feeder cells, the increase in complexity as indicated by the number of proteins identified is not surprising. However, the primary constituents, fibronectin and perlecan, are both classified as extracellular based on gene ontology. The data for MEF-CMTX correlates well with a previous LC-MS analysis of a matrix generated through the lysis of human foreskin fibroblasts [30]. Although the analysis of matrix composition completed by Meng *et al.* was only to a minimal depth,

the majority of proteins identified in their matrices are present in MEF-CMTX based on comparison with our data.

Fractionation of the BridgeECM matrix with SAX, SCX, and SDS-PAGE resulted in 25 protein identifications (Figure 3.6, Appendix Table 1.8). BridgeECM matrix is primarily composed of albumin, comprising 45 of the total 142 identified unique peptides. The matrix also contained the fibronectin, retinol-binding protein 4, plasminogen activator inhibitor 1, and SPARC. Gene ontology analysis of the proteins found in BridgeECM and the other cell-derived ECMs indicates the presence of a range of cellular localization assignments, and a variety of non-ECM proteins (Figure 3.7).

3.2.6 hESC Growth on a Defined Fibronectin Surface. Of the ECM samples analyzed, CellStart, BridgeECM, and StemXVivo are marketed as products for the maintenance of hESCs [35, 56]. CellStart and BridgeECM are sold as humanized growth matrices, and StemXVivo as a defined recombinant protein mixture for hESC growth. We were able to maintain H9 hESCs that retained expression of Oct4 and Nanog on CellStart, StemXVivo, and MEF-CMTX matrices using mTeSR1 medium for a maximum of 5 passages (Figure 3.8 A). We were, however, unable to maintain H9 hESCs on BridgeECM or HumanBME matrices for >1 passage using mTeSR1. Despite the limited ability of these matrices to promote hESC growth with mTeSR1, we decided to investigate the viability of a defined matrix based upon the abundant components identified in the matrices analyzed.

Upon comparative examination of the matrix datasets, we observed that fibronectin is a primary component of the all of the cell-derived matrices (Figure 3.6). Based on

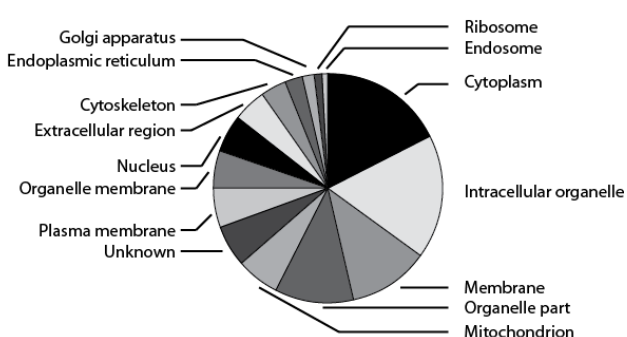

Figure 3.7. Gene ontology analysis of the cell-derived matrices tested. Analysis was done using Scaffold 3.0 software to search protein identifiers against the NCBI Entrez Gene knowledgebase. Protein identifiers were generated using IE-MS analysis of fractionated matrices. With the exception of BridgeECM, all of the matrices tested share similar cellular component profiles with Matrigel (Figure 3.3) and are composed of numerous intracellular proteins. Complete protein identification datasets can be found in the Appendix.

previous evidence that hESCs can be maintained on a combination of collagen IV, laminin, fibronectin, and vitronectin with TeSR1 [17] or on fibronectin alone with defined medium [18, 37], we evaluated a defined system that utilized a combination of fibronectin and mTeSR1. After 10 and 5 passages on fibronectin coated plates, H9 and CA1 hESCs retained typical colony morphology and strong staining for both Oct4 and SSEA-4 markers (Figure 3.8 C-D). For CA1 hESCs, cell growth was not as robust on fibronectin as with H9's, making it difficult to retain a stable culture free of differentiation and amenable to expansion. On other matrices, as well as fibronectin, H9 hESCs retained high levels of Oct4 and Nanog transcript as evidenced by RT-PCR data when compared with hESCs grown on Matrigel™ (Figure 3.8 A). Embryoid bodies generated from H9 cells displayed strong signal for markers of endoderm, ectoderm, and mesoderm lineages in comparison to undifferentiated hESCs grown on fibronectin (Figure 3.8 B). Taken together, these results indicate the ability of fibronectin to sustain H9 hESC self-renewal and pluripotency *in vitro*.

Figure 3.8. hESC growth characteristics on fibronectin. H9 and CA1 hESCs were grown on fibronectin for a period of 10 or 5 passages and analyzed for markers of an undifferentiated phenotype. (A) Shows fold change values for Oct4 and Nanog expression in H9 hESCs relative to those grown on Matrigel™ based on RT-PCR analysis. (B) RT-PCR data for embryoid body markers and the pluripotency marker Oct3/4. Values are shown as fold change for embryoid bodies relative to undifferentiated hESCs grown on fibronectin using GAPDH as a control. In both (A) and (B), error bars represent SD, n=3. (C) Phase contrast image illustrating colony morphology during growth on fibronectin coated plates for H9 hESCs. White arrows indicate areas for point of reference to observe undifferentiated cells. (D) Shows immunofluorescence pictures from H9 and CA1 hESCs grown on fibronectin coated plates for 10 or 5 passages respectively. Immunofluorescence was done directly in 24-well fibronectin coated dishes for the markers Oct3/4 and SSEA-4. Scale bars represent 0.2mm on all images.

3.3 Discussion

An often overlooked aspect in stem cell culture systems is the composition of the ECM. The primary matrix currently in use continues to be Matrigel™ in the absence of an acceptable alternative that is supportive of a wide range of hESC lines and media formulations. Exactly how Matrigel™ helps stem cells remain in an undifferentiated state remains poorly understood. With the rising demand for xeno-free hESC products, the development of a suitable defined growth matrix is of paramount importance. A contributing factor to the recent developments of defined culture media for hESC growth were data yielded from the analyses of conditioned medium from supportive feeder-cell layers [46-48, 50, 57]. Analogous to the analysis of conditioned medium, characterization of the components of cell-derived matrices could potentially aid in the development of defined surfaces for hESC culture. However, proteomic analysis of complex ECM mixtures is difficult due to the abundance profiles of the common constituents. Here, we demonstrate the development and optimization of methods for the fractionation and analysis of complex ECM mixtures to aid in the identification of hESC supportive matrix components.

In the analysis of Matrigel™, SEC fractionation proved to be of limited utility, even when used in combination with IE-MS. A significant number of the unique peptides identified were assigned to laminin/enactin, the primary components of Matrigel™. AS precipitation in combination with 1D-SDS-Gel fractionation facilitated the identification of a large number of peptides outside of those belonging to laminin and enactin. Gene ontology analysis of the Matrigel™ dataset indicates the presence of numerous cellular

proteins that were either cytoplasmic or nuclear in origin. This implies that although structurally important proteins such as laminin constitute the bulk of what is being extracted from the EHS sarcoma cells, there are also numerous intracellular proteins present. Depletion of low molecular weight components using AS precipitation to create GFR Matrigel™ results in the enrichment of laminin/enactin peptides in comparison to N-GFR. However, the lack of specificity for this method means that numerous other matrix components are lost, as shown through analysis of the supernatant obtained after 15% AS precipitation. This lack of reproducibility combined with limitations in the MS approach due to dynamic range constraints likely contributed to the identification of proteins apparently unique to GFR Matrigel™. As GFR is derived from N-GFR Matrigel™, the identification of proteins unique to GFR Matrigel™ is unexpected. Further proteomic analysis of Matrigel™ using the SAX and SCX methods utilized on the other matrices tested would potentially reconcile these differences by obtaining greater depth of coverage. However, differences between N-GFR and GFR are potentially derived from batch-to-batch variability of Matrigel™ that cannot be addressed in the proteomics approach.

As noted above, Matrigel™ was previously reported to contain specific growth factors [11]. With the optimized proteomics protocol used here we identified several growth and transcription factors such as Grb2 and connective tissue growth factor (CTGF). However, the growth and transcription factors represent only a small fraction of the proteins identified in the analysis of the matrix. We identified numerous proteins directly related to binding and signaling of growth factors. Other ECM proteins identified in this study, fibronectin [58], collagen type IV [59], follistatin [60], and thrombospondin [61],

have been proposed to interact with members TGF- β superfamily. The presumed functions of these interactions are to enhance activity and stability of these cytokines in culture. Examples of these ECM interactions have been found to be involved in a variety of pathways, such as fibronectin and vitronectin binding to hepatocyte growth factor receptors leading to enhanced cell migration [62]. Fibronectin type-III domains have also been shown to be involved with vascular endothelial growth factor (VEGF) signaling [63]. Similar interactions have also been demonstrated for a variety of other growth factors [64-67].

The in-depth proteomic analysis of Matrigel™ presented in this study reveals a complex and intricate mixture consisting of numerous structural, growth factors and their binding partners, as well as several other proteins of roles that are not clear in cell culture. We speculate that many of these of proteins play a role in the self-renewal of stem cells when cultured in the presence of Matrigel™. Our analysis of Matrigel™ revealed that it was primarily composed of laminin, collagen, enactin, and fibronectin. Of these, laminin, nidogen-1, and different collagen isoforms have all been shown to be beneficial for hESC maintenance [17, 23, 24, 68-71]. It is perhaps not surprising then that Matrigel™ is the gold standard for the maintenance of a wide array of hESC lines, as it contains most of the proteins shown to promote hESC growth when used individually. However, as a result of the significant depth of coverage we were able to obtain with the use of AS-IE-MS methods, this study also suggests that it will be challenging to replace Matrigel™ in a variety of cell culture and experimental assays due to its complexity.

To complement the Matrigel™ data and facilitate the identification of hESC supportive proteins, we sought to compare matrix components from a variety of cell-culture matrices. Employing a combination of SCX, SAX, and 1D-SDS-Gel approaches, we analyzed other cell-derived and commercial matrices used in hESC culture. Upon inspection of CellStart, StemXVivo, BridgeECM, HumanBME, MEF-CMTX, and Matrigel™ proteomic data, the complexity of these protein mixtures becomes apparent. Based on the number of proteins identified StemXVivo, BridgeECM, and CellStart are more defined matrices in comparison with HumanBME, MEF-CMTX, and Matrigel™. However, based on the proteomics data presented here, none of these matrices are fully defined. Although CellStart and StemXVivo are marketed as such, the number of proteins found indicates they are not as well defined as suggested by the manufacturers.

With the exception of StemXVivo, fibronectin was found to be highly abundant in all of the matrices analyzed. StemXVivo is manufactured as a recombinant protein mixture, and based on our analysis is primarily composed of vitronectin. Vitronectin has previously been shown to sustain hESC pluripotency and survival [15, 19]. This is highlighted in our study by the ability of StemXVivo to promote the growth of H9 hESCs that retain expression of markers indicative of an undifferentiated state (Figure 3.7 A). It has previously been shown that fibronectin and vitronectin both bind integrins that support hESC adhesion [15, 72]. Recent research into synthetic growth surfaces has revealed that integrin RGD and heparin binding peptides promote attachment and proliferation of hESCs [25-28, 73]. These studies suggest that integrin binding by the primary proteins present in ECM mixtures regulate attachment and proliferation.

Undifferentiated hESCs are known to express the fibronectin-specific integrin receptor $\alpha_5\beta_1$ [18], thus supporting the observation of fibronectin as an effective growth matrix. However, it is likely that other proteins detected in these matrices are also of importance for the growth of a wide range of hESC lines, such as is the case with culture on Matrigel™ or MEFs. This is highlighted by the identification of other proteins like serum albumin and PEDF in several of the matrices analyzed. FBS, of which serum albumin is a primary component, has previously been used as a growth matrix for hESCs [74]. Moreover, PEDF has recently been shown to be beneficial for the feeder-free maintenance of hESCs [75].

Here, we have illustrated the utility of employing different and complementary fractionation methods for the analysis of complex ECM samples in order to elucidate factors essential for hESC survival. Our proteomics analysis reveals the ubiquity of fibronectin in the majority of commonly available matrices. It is noteworthy that none of the matrices tested, including fibronectin, were able to promote and maintain the growth of hESCs with the same efficiency and stability of Matrigel™ when using mTeSR1 medium. H9 and CA1 hESCs differentiated and proliferated poorly after 15 and 5 passages on fibronectin respectively. This indicates that while a defined matrix consisting of a sole component, such as fibronectin is suitable for hESC growth, long-term maintenance and expansion requires a mixture of supportive components in the matrix, medium, or both. Revealing these components through characterization of hESC supportive matrices is a valuable tool for elucidating factors that can have a positive effect on the maintenance of pluripotency.

3.4 Methods

3.4.1 Cell culture and harvest – H9 (passage 26) and CA1 (passage 27) hESCs were maintained on hESC Qualified Geltrex (Invitrogen, Carlsbad, CA) before passage on to fibronectin coated plates (Millipore, Billerica, MA or BD Biosciences, Franklin Lake, NJ). H9 cells were obtained from WiCell (Wisconsin). The CA1 hESC line used in all experiments was obtained from Dr. Cheryle Séguin of The University of Western Ontario [76, 77]. For all fibronectin experiments conventional 6 well dishes were used. Geltrex, StemXVivo, and BridgeECM were used according to the manufacturer's instructions. CellStart was used as a 25X solution instead of the manufacturer recommended 50X. Cells were maintained in mTeSR1 medium (StemCell Technologies, Vancouver, Canada) on all matrices. Cells were passaged mechanically to minimize variability from enzymatic methods.

Embryoid bodies were generated using the RCCS-2SC 3D bioreactor (Synthecon, Houston, TX) with 2 x10 mL high aspect ratio vessels (HARV). Briefly, $\sim 2 \times 10^6$ hESCs were harvested from fibronectin coated plates. The equivalent of $\sim 1 \times 10^6$ hESCs were re-suspended in 8 mL of EB medium containing Knockout DMEM/F12, 20% KOSR (Invitrogen), 2 mM L-glutamine, 0.1 mM β -mercaptoethanol, and 1% non-essential amino acids. The remaining 2 mL was added using syringes to ensure the removal of air bubbles from the vessels. Vessels were left in a 37°C incubator with a rotation rate of 8 rpm. Once EBs had formed (typically after 3-4 days), they were transferred to ultra-low adherence cell culture dishes and grown for a period of 21 days. Cells were then harvested and assayed by RT-PCR for the differentiation markers CDX2, alpha-feto

protein (AFP), GATA-6, GATA-4, Sox-1, PAX-6, T-brachyury, Vimentin, and Neurogenic differentiation 1 (NeuroD1) using TaqMan primer probe sets (Appendix Table 1.15).

3.4.2 Extracellular matrix analysis – Human Cultrex basement membrane extract from Trevigen (Gaithersburg, MD), BridgeECM (GlobalStem, Rockville, MD), and CellStart matrix from Invitrogen (Carlsbad, CA) were assayed for protein content using a Bradford assay (data not shown). StemXVivo (R&D Systems, Minneapolis, MN) and BridgeECM were concentrated from their stock solutions using 3 kDa centrifugal filters and reconstituted in 8M Urea and 100mM ammonium bicarbonate (ABC). Lysed MEF matrix was generated by plating of 250,000 irradiated CF-1 cells in each well of a 6-well plate coated with 0.1% gelatin. After 7 days the cells were lysed using a 20 mM NH₄OH solution. MEF-matrix layers were harvested using a solution of 8 M urea and 100 mM ABC. All matrix samples were analyzed using in-solution digestion followed by fractionation on SCX and SAX columns with pH elution. All samples were also fractionated with 1D-SDS-PAGE and prepared with an in-gel digestion as described earlier. Each fractionation method was run using iterative exclusion as a single technical replicate for each matrix analyzed, for a total of 2 injections per sample.

3.4.3 Matrigel Preparation - Two separate lots of growth factor reduced Matrigel™ (A1105 & A3105, CAT# 356234, BD Biosciences, Mississauga, Canada), and one lot of standard Matrigel™ (A3873, CAT# 356230) were aliquoted into 100 µl fractions and stored at -80°C until use. The stock solution of Matrigel™ is at a concentration of ~10 mg/mL based on manufacturer specifications. Protein concentration was assessed with the Bradford assay.

3.4.4 Reduced Matrigel by Precipitation - Individual aliquots of standard and GFR Matrigel™ were precipitated using a 15% AS solution as described previously [11]. While the previous study employed a 20% AS solution, we found the 15% AS solution provided a precipitation that resulted in a greater removal of low molecular weight components as deduced from SDS gels analysis. Aliquots were diluted 1:1 using a 30% saturated AS solution to give a final concentration of 15%. Mixtures were left at 4°C for 60 minutes before centrifuging at 12000 g for 15 minutes. The supernatant was drawn into a new tube and brought to 90% AS saturation to precipitate any remaining protein. Solutions were centrifuged for 15 minutes at 12000g and the pellet was reconstituted in 100 mM NH₄CO₃. The reconstituted pellet was then subjected to an in-solution digestion with trypsin, or in-gel following 1D-SDS PAGE [46, 78].

3.4.5 Size Exclusion Chromatography – 500 µg equivalents of Matrigel™ (as determined by the Bradford assay), as well as pellets from the 15% AS precipitation were run through an off-line size exclusion system. A BioSep-SEC-S2000 column (Phenomenex) fitted with a Security Guard pre-column (Phenomenex) with a phosphate buffer (BioShop Canada Inc.)(0.5 M, pH 7.0) mobile phase was used for separation. The sample was injected manually to an Agilent 1100 HPLC system (Agilent Technologies Inc.) system that provided flow (1 ml/min) as well as detection at 210 nm and 280 nm using a diode array detector.

3.4.6 In-solution trypsin digestion – Matrix samples were reduced with 10 mM dithiothreitol (DTT) for 60 minutes. Samples were then alkylated with 40 mM iodoacetamide (IAA) for 60 minutes. The reactions were quenched through the addition

of DTT and left to incubate for another 60 minutes. Samples were then diluted 1/6 in 50 mM ABC. Trypsin (Promega, Madison, WI) at a concentration of 1 μ g enzyme to 25 μ g of total protein was added to the mixtures and left to incubate for 24 hours at 37°C. The next day, digests were acidified using neat trifluoroacetic acid and desalted on C18 cartridges (CAT# 2001, Applied Separations, Lehigh Valley, PA). After elution with 50% acetonitrile, samples were evaporated using a SpeedVac. Prior to loading on an SCX column, dried samples were reconstituted in 0.5% formic acid at a pH of ~2. Samples for SAX analysis were reconstituted in 0.5% NaOH at a pH of ~12.

3.4.7 In-gel trypsin digestion – 40 μ g of each matrix was diluted in Laemmli buffer. After heating, matrix samples were loaded in each of two lanes on a 12% SDS-Gel. The gel was stained with Coomassie blue and the gel lanes were divided into 12 fractions based on visual assessment of protein concentration. Gel cubes in each fraction were destained using 20% acetonitrile (ACN) in 1M ABC. Proteins were reduced using 10 mM DTT for 60 minutes, followed by alkylation with 100 mM IAA for 60 minutes. Digestion was carried out using trypsin at a 1/25 ratio overnight in a 37°C water bath. Fractions were extracted the next day using 10% formic acid, sonication, and a final ACN step. Each fraction was dried using a SpeedVac and reconstituted in 10% formic acid prior to injection on to the MS.

3.4.8 Column preparation – Columns were packed in 360 O.D. x 200 I.D. capillaries (PolyMicro Technologies, Phoenix, AZ) using a conventional pressure bomb (Next Advance, Averill Park, NY). Frits were prepared by mixing 75 μ L of potassium silicate with 25 μ L of formamide, vortexing for 1 minute and rapidly inserting and removing the

capillary end from the resulting mixture. Capillary frits were dried and hardened in a 100°C oven for 2 hours. Capillaries were then rinsed with forward and reverse flow of methanol using the pressure bomb at 200 psi. Prior to packing, capillaries were rinsed for 30 minutes with 0.5% formic acid for SCX and 0.5% NaOH for SAX columns. PolySULFOETHYL A SCX beads (5 μm , 300Å, CAT# PLBMSE0503) were purchased from PolyLC (Columbia, MD) and reconstituted in 10 mM citric acid. SAX beads were purchased from Varian Inc. (10 μm , 1000Å, CAT# PL1451-2102, Palo Alto, CA) and reconstituted in 10 mM NH_4OH . SCX and SAX columns were packed to a length of ~3 cm for all experiments. All packing was done at a pressure of 200 psi until the desired column length was obtained, then pressurized to 1000 psi to complete packing. Packed columns were rinsed with solvents for conditioning as recommended by the manufacturer.

3.4.9 Peptide Fractionation – Peptides were fractionated with SCX and SAX columns using a CapLC system (Waters, Milford, MA) with a flow rate of 2 $\mu\text{L}/\text{min}$. Mobile phase A was composed of 10mM citric acid at a pH of ~2.3, mobile phase B was pH 11.4 10 mM NH_4OH , and mobile phase C was 500 mM ammonium acetate. Mobile phases were all prepared fresh prior to fractionation to ensure the stability of pH from run to run. Fractionation with pH was carried out using a 120 minute gradient from pH 2 to 12 for SCX, and 12 to 2 for SAX. Salt fractionation was carried using the following steps: 0 mM, 7.5 mM, 15 mM, 30 mM, 45 mM, 60 mM, 75 mM, 90 mM, 105 mM, 120 mM, 150 mM, 300 mM, 500 mM ammonium acetate over 120 minutes. Each fraction was collected offline in a volume of 20 μL . Fractions were dried using a SpeedVac, and reconstituted in 10% formic acid prior to injection on the MS.

3.4.10 MS Data Acquisition – Fractions were injected and separated using a nanoAcquity system (Waters, Milford, MA) equipped with a 25 cm x 75 μ m I.D. C18 column. Fractions were separated using a 1 to 40% ACN gradient over 90 minutes at a flow rate of 300 nL/min. MS analysis was done on a Q-ToF Ultima (Micromass/Waters) using data-dependent acquisition with selection of the four top precursor masses per survey scan. Survey scans were set at 1s, and MS/MS acquisition set at 1s or 6000 cps TIC cut-off. Exclusion lists were generated using in-house software that automatically adds 0.7amu to the precursor masses selected in previous runs and outputs a file also containing retention time information. Each fraction was analyzed for a single exclusion round (2 injections total), adjusting the injection volume dependent on signal intensity in the previous run. In analyses of Matrigel™, each fraction was injected a total of 7 times (6 exclusion rounds).

3.4.11 MS Data analysis – Data analysis for all matrices tested was performed in PEAKS 5.3 software (Bioinformatic Solutions Inc., Waterloo, Canada) [79, 80]. After import into PEAKS, MS/MS spectra from raw data files were refined using the following settings: merge spectra – true (100 ppm mass tolerance, 60 second retention time tolerance), correct precursor mass – true, determine precursor charge state – true (minimum charge +2, maximum charge +5), spectral quality filter – true (0.65 threshold), centroid, deisotope, and deconvolute – true. Resulting MS/MS spectra were then *de novo* sequenced using the following parameters: parent monoisotopic mass tolerance – 100ppm, fragment monoisotopic mass tolerance – 0.15 daltons, enzyme specificity – semi-Trypsin, fixed modifications – carbamidomethylation, variable modifications – N-terminal acetylation and oxidized methionine. After *de novo* analysis, data were

searched against the UniProt sequence database (Human taxonomy specified, 20236 total entries or Mouse taxonomy specified, 16376 total entries) using the following parameters: parent monoisotopic mass tolerance – 100 ppm, fragment monoisotopic mass tolerance – 0.15 daltons, enzyme specificity – semi-Trypsin, fixed modifications – carbamidomethylation, variable modifications – N-terminal acetylation and oxidized methionine, estimate false-discovery rate – true.

3.4.12 Protein identification – Resultant protein identification data from the database search were processed using PEAKS 5.3 software [81]. Identifications were filtered by assigned score to give a <1.0% false-discovery rate for peptide-spectral matches based on estimation from a decoy-fusion method of database search. Identified proteins were also required to be matched by >2 unique peptides. Proteins that contained similar peptides and could not be differentiated based on MS/MS analysis alone were grouped to satisfy the principles of parsimony. For all matrices analyzed, keratin hits were manually removed from the final datasets.

3.4.13 Real-time PCR – RNA was purified using Trizol reagent according to the manufacturer's instructions (Invitrogen) or with the 5 Prime PerfectPure RNA Extraction Kit (5 Prime, Gaithersburg, MD). After NanoDrop quantification, 1 µg of cDNA was synthesized using the High Capacity cDNA Reverse Transcription Kit with RNase inhibitor (Invitrogen). Real-time PCR was performed using the TaqMan® Universal PCR Master Mix (Invitrogen). Samples were incubated at 50°C for 2 minutes followed by 10 minutes at 95°C. Samples were then amplified at 95°C for 15 seconds followed by 1 minute at 58°C for 46 cycles. All samples were normalized to large ribosomal

protein RPLPO as a positive control. All primers were obtained from Invitrogen and assay information can be found in Appendix Table 1.15. Each biological replicate was run in triplicate for every marker assayed. All reagents were used according to the manufacturer's instructions.

3.4.14 Immunofluorescence – Passage 10 H9 and 5 CA1 hESCs grown on fibronectin were plated in wells of a 24-well dish coated with the same matrix. After 4 days of culture in mTeSR1 medium cells were rinsed and fixed with 4% para-formaldehyde containing 20 mM sucrose. Prior to staining, cells were blocked using the Dako Serum Free Protein Block solution (Dako, Cambridgeshire, UK). Oct-4 (clone 10H11.2), SSEA-4 (clone MC-813-70), and SSEA-1 (clone MC-480) primary antibodies were obtained from Millipore (Billerica, MA). Cells for Oct-4 labeling were permeabilized using a 0.1% Triton X-100 solution prior to blocking. Cells were labeled with primary antibodies for Oct-4 or SSEA-4 as undifferentiated markers and SSEA-1 for differentiated cells all at concentrations of 2 µg/mL for 60 minutes at room temperature. Secondary Alexa-fluor 488 goat anti-mouse IgG and Alexa-fluor 568 goat anti-mouse IgM were obtained from Invitrogen (Carlsbad, CA). Secondary antibodies were probed at concentrations of 1 µg/mL for 60 minutes at room temperature. All products were used according to manufacturer's instructions.

Chapter 4

Proteomic Analysis of the Human Embryonic Stem Cell Depositome

4.1 Introduction

The ECM is a complex network of structural proteins and glycosaminoglycans that function to support cells through the regulation of processes such as adhesion and growth factor signaling [1]. It is not surprising that the generation of a well-defined matrix supportive of these processes in the complex hESC microenvironment has been difficult. Although gelatin is sufficient for the maintenance of mESCs in the presence of specific growth factors, hESCs cannot be propagated in the same conditions. Currently, in the absence of a suitable alternative, Matrigel™ remains the matrix of choice for hESC culture *in vitro*. However, the complex nature of Matrigel™ has been demonstrated previously in this thesis (Chapter 3), and has been described by others who have revealed that it contains numerous growth factors and signaling proteins [2]. Although recent studies have revealed that a variety of defined matrices support the growth of hESCs, few of these can maintain a wide array of stem cell lines and as such are typically not used in place of Matrigel™ [3]. The universality of Matrigel™ indicates that current defined matrices are lacking in critical components required to generate a supportive hESC microenvironment.

This chapter contains excerpts from the following paper:

Hughes, C.S., Radan, L., Stanford, W., Postovit, L.M., Lajoie, G.A.. (2012) "Proteomics Analysis of the Human Embryonic Stem Cell Depositome". (In Preparation)

Because of the challenge proteomic examination of the ECM presents, the majority of studies that have analyzed the hESC microenvironment have focused on support cells and paracrine signaling pathways. The desire to generate well-defined conditions for hESC culture *in vitro* has prompted these investigations into the factors critical for the maintenance of stem cells. Proteomic studies have focused on the analysis of media conditioned by hESC supportive feeder cell layers to elucidate pathways important for maintaining the balance between self-renewal and differentiation [4-9]. These analyses were important contributors to our current knowledge of how hESCs are regulated in the extracellular space by pathways in the soluble portion of the microenvironment. However, there is still a lack of information of how the ECM modulates hESC behavior *in vitro* through interactions with both the cells themselves and the soluble cytokines present in the extracellular milieu.

Given the common underlying plasticity of stem and cancer cells, recent studies have established the ability of embryonic microenvironments to alter the tumorigenic properties of cancer cells (reviewed in [10]). Building on these findings, it was later observed that metastatic melanoma cells could be 'reprogrammed' to a more benign melanocyte phenotype following exposure to a matrix microenvironment generated from hESCs [11]. Importantly, this effect was found to be dependent on the exposure of metastatic cells to the conditioned matrix, and was not observed after treatment with hESC conditioned medium. It was later found that the left-right determination (Lefty) proteins that were deposited in the matrix by hESCs were effectors of the cellular change observed in metastatic cells [12]. The Lefty proteins are antagonists of TGF- β signaling that act directly on Nodal protein. Differences in the methylation status and

microRNA profiles for genes and pathways directly related to Lefty/Nodal signaling in metastatic cells on conditioned matrix have recently been observed [13]. Subsequent work with conditioned matrix utilizing mESCs implicated the bone morphogenic protein (BMP) 4 antagonist Gremlin as a primary regulator of the observed changes in metastatic cells [14]. Collectively, these studies were all biased by a targeted analysis of potential effectors of metastatic cells. A comprehensive proteomic analysis of the matrix microenvironment could potentially reveal other factors involved in metastatic cell reprogramming. Furthermore, proteomic analysis of the conditioned matrix could reveal factors important in the regulation of hESC and human induced pluripotent stem cell (hiPSC) pluripotency by the microenvironment *in vitro*.

To this end, we have employed a mass spectrometry (MS)-based proteomics screen to identify proteins deposited by hESCs and hiPSCs grown on Matrigel™ *in vitro*. To investigate the hESC-derived matrix, we utilize a metabolic labeling technique known as stable isotope labeling with amino acids in cell culture (SILAC) [15]. SILAC facilitates the identification of hESC-derived proteins in the presence of significant background protein complexity from Matrigel™. Additionally, in order to minimize intracellular protein contamination in our analysis, we have developed methods that remove the requirement for cell lysis to generate CMTX. From proteomic analysis of H9, CA1, and BJ-1D pluripotent stem cell lines, we identify a total of 621, 1355, and 1350 unique proteins respectively. This work represents the first analysis of a stem cell conditioned matrix and resulted in the identification of at least one new microenvironmental contributor responsible for the regulation of hESCs and hiPSCs.

4.2 Results

4.2.1 Proteomic Analysis of Pluripotent Stem Cell Derived CMTX. To determine factors being deposited by hESCs during growth on Matrigel™, we employed a global MS-based proteomics approach to screen CMTX. Previous studies that have illustrated the effects of CMTX on metastatic cells have employed an NH₄OH cellular lysis protocol to remove hESCs from Matrigel™. Lysis of cells on the matrix could potentially confound our analysis by releasing high abundance intracellular proteins. To limit the potential for intracellular protein contamination in the CMTX resulting from lysis, we developed a protocol based on Matrigel™ de-polymerization to remove intact cells from the matrix. With this method, the vast majority of the hESCs that were removed remained intact and viable as indicated by 7-AAD staining in flow cytometry (Figure 4.1 B). Moreover, the removal of cell-lysis from the protocol permitted analysis of the undifferentiated state and differentiation capacity of the cells that deposited the matrix (Figure 4.1 A, C).

After cell removal and concentration of the CMTX solution, a combination of strong cation and anion exchange (SCX, SAX), and 1D-Gel methods was employed for fractionation of the complex ECM-like mixture with iterative exclusion MS analysis as discussed previously (Chapter 3). MS analysis of these samples illustrated the limited ability of our assay to determine hESC-derived proteins in our list of identifications (Figure 4.2 A – B). This limitation is directly the result of performing the CMTX experiments on Matrigel™. Since the mixture that gets analyzed by MS represents a mixture of hESC-derived and Matrigel™ proteins, identification specificity is reliant on non-homology between human and mouse proteins. However, by searching the

Figure 4.1. Cell viability and pluripotency during generation and harvest of CMTX.

H9 and CA1 hESCs as well as BJ-1D iPSCs were used to generate CMTX. Following harvesting using our cell recovery method that eliminates cell lysis, remaining cells were assayed for viability and markers of pluripotency. (A) RT-PCR analysis of harvested cells for the markers Oct3/4 and Nanog. Values are relative to undifferentiated cells grown in feeder-free conditions not exposed to the CMTX harvesting methods. Error bars represent SD, $n=3$. (B) Flow cytometry analysis of cells harvested from CMTX. Cells were assayed for SSEA4 and SSEA1. Viability was determined using 7-AAD staining. (C) Cells harvested from CMTX were used to generate embryoid bodies. Following 14 days in culture, embryoid bodies were harvested and assayed for markers of pluripotency (Oct3/4, Nanog), trophoblast (CDX2), ectoderm (NeuroD1, PAX6), endoderm (GATA6, GATA4, alpha-fetoprotein), and mesoderm (T). Error bars represent SD, $n=2$. Values are fold change relative to undifferentiated cells. Phase contrast images of embryoid bodies are provided above. Scale bars represent 250 μ m. In both (A) and (C), RPLPO is used as a positive control.

data set against a concatenated human and mouse sequence database, we observe that few proteins are identified as belonging to a single species (Figure 4.2 A - B). Many of the identified proteins have also been found in Matrigel™ in our previous proteomic analysis (Figure 4.2 A - B). Taken together, these complications severely limit the specificity and sensitivity of the proteomic analysis. To overcome these challenges, we employed a metabolic labeling approach known as SILAC that we have previously optimized for application in hESCs and hiPSCs (Chapter 2). Using this approach, hESCs and hiPSCs would be fully labeled with 'heavy' arginine and lysine prior to being plated for CMTX generation (Figure 4.3). In this approach, proteins that were deposited during CMTX generation will carry a heavy label and can be distinguished on the MS from Matrigel™ contaminants.

With this protocol, we analyzed CMTX from H9 and CA1 hESCs, as well as BJ-1D hiPSCs. MS analysis yielded a total of 621, 1355, and 1350 labeled proteins identified for H9, CA1, and BJ-1D cell lines respectively (Figure 4.4 A, Appendix Tables 1.9 - 1.11). Comparison of protein identifiers between the cell lines indicates a ~30% overlap between the three datasets (Figure 4.4 A). The gain in the number of proteins in the CA1 and BJ-1D stem cell lines is due to their decreased stability in the StemPro SILAC medium. We observed an increase in cell death and subsequent lysis during general growth of the CA1 and BJ-1D cell lines compared with H9 in StemPro SILAC medium resulting in the identification of additional intracellular proteins. Gene ontology analysis revealed that in the dataset corresponding to each cell line there are proteins representative of several cellular components present. This suggests that a variable

Figure 4.2. Proteomic analysis of unlabeled hESC derived CMTX. H9 (A) and CA1 (B) hESC CMTX generated using unlabeled cells was analyzed using an MS-based proteomics approach. Data were searched simultaneously against a concatenated database containing all Mouse and Human protein sequences available in UniProt. Human vs. Matrigel represents the overlap between proteins identified as Human derived in CMTX by PEAKS 5.3 compared with those found in Matrigel (Chapter 3). Mouse vs. Matrigel represents the overlap between proteins identified as Mouse derived in CMTX by PEAKS 5.3 compared with those found in Matrigel. Human vs. Mouse represents the overlap within the CMTX dataset between proteins specified as Human or Mouse derived by PEAKS 5.3. To facilitate inter-species comparisons, protein descriptions were used in all cases. Comparisons were done manually. Overlapping identifications are denoted by a solid black box, and those that are unique by a grey box. For both H9 and CA1 derived CMTX, n=1.

Figure 4.3. Proteomic analysis of CMTX from hESCs cultured in SILAC medium. H9 and CA1 hESCs, and BJ-1D iPSCs are grown in defined SILAC medium containing [$^{13}\text{C}_6$, $^{15}\text{N}_4$] - arginine and [$^{13}\text{C}_6$, $^{15}\text{N}_2$] - lysine optimized previously (Chapter 2). After culture for a sufficient amount of time to obtain complete labeling, cells are passaged to culture dishes pre-coated with Matrigel. After 4-5 days of culture on Matrigel in medium containing the heavy isotopic labels, cells are removed using a protocol that does not induce lysis of the cells (see Methods). The remaining conditioned matrix layer is rinsed and harvested. The conditioned matrix solution is then enzymatically digested and fractionated using protocols optimized previously (Chapter 3). Mass spectrometry analysis of the conditioned matrix generated using labeled hESCs permits identification of human proteins. Peptides derived from hESCs will carry an isotopic label and will display a resultant mass shift in the MS, whereas those previously present in Matrigel will not have this difference.

amount of cell lysis is occurring during growth or harvest of the CMTX for all the cell lines.

To limit the contaminants from cell lysis, the dataset was filtered using the “extracellular” and “cell surface” cellular component gene ontology terms. Filtering reduced the number of proteins identified in each dataset to 71, 100, and 95 labeled proteins for H9, CA1, and BJ-1D respectively (Figure 4.4 A, Appendix Tables 1.12 – 1.14). However, the data still contained numerous intracellular proteins (histones, mitochondrial, and cytoskeleton associated). This is primarily the result of the limited specificity of the gene ontology assignments. The overlap between the three individual CMTX datasets is ~35% based on protein identifiers after gene ontology filtering. However, coverage between biological replicates of the same cell line using the identical fractionation methods overlap a minimum of 71% across the samples in the experiment. The reproducibility between biological replicates from single stem cell lines illustrates the consistency of not only the proteomics method, but of the CMTX assay itself.

The hESC and hiPSC CMTX proteomics data indicate that numerous cell line specific factors were deposited based on comparisons between the protein lists. When comparing core ECM proteins, isoforms of fibronectin and laminins, and heparan sulfate proteoglycan linked proteins were present at similar abundance levels based on the number of unique peptides in CMTX from H9 and BJ-1D cell lines. However, BJ-1D CMTX was enriched in matrix remodeling factors, such as matrix metalloproteinase-14 and -15. On the other hand, CMTX derived from CA1 hESCs was found to contain multiple collagen and laminin isoforms not identified in the matrices from the other stem

cell lines. Low abundance factors such as soluble frizzled related protein (sFRP) 1 and 2, and Lefty A and B were identified in CMTX from all cell lines. Interestingly, connective tissue growth factor (CTGF) was identified in CMTX from both hESC lines, but not in that from BJ-1D hiPSCs. In addition, other low abundance factors such as Cerberus and fibroblast growth factor-15 were only identified in CA1 CMTX.

4.2.2 Secretome Analysis of the hESC Microenvironment. To further validate and enrich for candidates in the CMTX data, a comparison was performed with a previously published proteomics screen of the H9 hESC secretome obtained from the analysis of hESC conditioned medium [6]. We performed a re-analysis of the H9 hESC secretome raw dataset in the same software (PEAKS 5.3) used to process the CMTX data, to facilitate comparison and minimize variability from protein assignments or identifiers. Comparison with the H9 hESC secretome protein identifiers revealed a 73%, 55%, and 54% overlap between the unfiltered and 77%, 72%, and 68% for the filtered H9, CA1, and BJ-1D CMTX datasets (Figure 4.4 B). These data indicate that although there was a significant variability in the cellular localization of proteins in the unfiltered dataset, this distribution is not unexpected since proteins in the secretome and CMTX datasets share similar profiles. Comparison with the Matrigel™ dataset previously acquired (Chapter 3) revealed that 53%, 40%, and 40% of proteins for H9, CA1, and BJ-1D cell lines are identified in both matrices prior to filtering (Figure 4.4 C). Gene ontology filtered datasets share 62%, 55%, and 50% of proteins with Matrigel™ for H9, CA1, and BJ-1D cell lines. These data illustrate the necessity for SILAC when performing this analysis because many of the proteins found in the CMTX are also found in Matrigel™.

Furthermore, it highlights the ability of this methodology to enhance the sensitivity of our analysis by increasing the confidence in the identification of hESC-derived proteins.

4.2.3 Factors Identified in Stem Cell Derived CMTX. As mentioned previously, investigation of the CMTX dataset revealed the presence of numerous hESC and hiPSC regulatory proteins. In order to enrich for hESC and hiPSC derived proteins that are facilitating the maintenance of an undifferentiated state on CMTX, we opted to focus on only those classified as extracellular or cell surface by gene ontology. Not surprisingly, within this filtered dataset we find many core ECM proteins that are also present in Matrigel™ (Figure 4.5 A). The presence of hESC and hiPSC-derived labeled versions of these proteins indicates that the stem cells are generating a self-supporting matrix microenvironment *in vitro*. Further investigation of the filtered CMTX dataset revealed the presence of numerous factors with potential roles in hESC and hiPSC pluripotency (Figure 4.5 B). Other identified factors, such as hepatoma derived (HDGF) and connective tissue growth factor (CTGF) are of particular interest due to their relevance in cancer cell systems, as well as the known interactions of CTGF with the ECM [16-18]. Interestingly, after pathway analysis of the filtered datasets we observe a significant enrichment for molecules involved in cell motility as well as apoptosis or invasion of cancer cells (Figure 4.5 C).

Also of interest in the list of hESC proteins identified are the potential extracellular regulators of hESCs (Figure 4.5 B). The soluble frizzled related proteins (sFRP) 1 and 2 are inhibitors of canonical Wnt signaling [19]. Wnt signaling has been observed to

Figure 4.4. Proteomic analysis of SILAC hESC and hiPSC derived CMTX. (A) CMTX from H9 and CA1 hESCs, as well as BJ-1D hiPSCs was analyzed in biological triplicate using an MS-based proteomics protocol. Data files were analyzed using PEAKS 5.3 software. Numbers within the Venn diagrams represent the total number of protein identifications found in each matrix for the specific overlap. Data sets were also filtered using gene ontology classification for cellular component based on the terms “extracellular” and “cell surface”. These values are represented in the lower diagram. (B) CMTX identifications were further compared with a secretome data set acquired through proteomic analysis of hESC conditioned medium. (C) Each data set was individually compared with that previously acquired for Matrigel (Chapter 3). Overlapping identifications are denoted by a black box, and unique identifications are found in grey. The total number of overlapping identifications can be found at the top of the bar in text. All comparisons were done manually based upon protein identifiers. In the case of Matrigel data, protein descriptions were used for comparison as identifiers are species specific. Gene ontology filtered data were compared against entire Matrigel or Secretome data sets. The rightmost bar in the top graphs of (B) and (C) represent total identifications found in Matrigel respectively and the Secretome. * - datasets can be found in reference 6 and Chapter 3.

Figure 4.5. Proteins and pathways identified in CMTX from hESCs and hiPSCs. CMTX was analyzed using an IE-MS proteomics based approach. Proteins were identified using PEAKS 5.3 software. (A) Represents a subset of the core ECM proteins found in CMTX that were also identified in the previous proteomics analysis of Matrigel (Chapter 3). In the case of collagen, the top isoform was chosen. (B) Represents growth factors and proteins known to regulate core hESC pluripotency pathways found in CMTX. * - indicates when a protein was identified as a single peptide hit. Only proteins with 2 unique peptides are retained, such that these single peptide hits are lost in the final dataset. (C) Pathway analysis performed using Ingenuity Systems Software. The top biological functions identified in all three cell lines were related to cellular movement, growth, and death or invasion of tumor cell lines. Number of molecules denotes the number of candidate proteins identified as being involved with that function found in our dataset. Black boxes represent the $-\log(p\text{-value})$ for the probability of identifying these pathways as being enriched in our dataset by chance.

contribute to the regulation of both mESCs and hESCs [20]. Extracellular antagonists of Activin/Nodal signaling, left-right determination factors (Lefty) A and B, are also found in the CMTX [21]. Since the Lefty proteins were previously implicated as being involved in the reprogramming of metastatic cells with CMTX, their identification provides additional validation of our proteomics approach [12]. We also identify Cerberus in the CMTX, a regulator of both TGF- β and bone morphogenic protein (BMP) signaling. Previous studies directed at the analysis of hESC-derived CMTX have focused on antagonism of the BMP pathway using Gremlin, a protein which shares significant overlap in functionality with Cerberus [14, 21]. The presence of these factors is not surprising since several have previously been identified in screens of MEF and hESC conditioned medium [6]. However, their identification in the CMTX indicates that the ECM is potentially playing a role in their activity.

4.3 Discussion

A thorough knowledge of the processes that control the maintenance of pluripotency or differentiation to lineage specific cell types will be critical as hESC research moves toward the clinic. Central to this goal is comprehensive characterization of the extracellular processes governing regulation of hESCs and hiPSCs in their niche. Proteomic analysis of conditioned medium has aided in the development of an understanding of signaling pathways present in the microenvironment. However, few studies have examined the direct interactions of hESCs with the matrix portion of the microenvironment. Utilizing cell culture and proteomics methods developed earlier, we report the characterization of matrices conditioned by hESCs as well as hiPSCs.

The presence of core ECM components in CMTX, such as isoforms of fibronectin, collagen, and laminin illustrates that hESCs and hiPSCs generate a self-supportive niche for attachment and proliferation. All three of these matrix proteins have been shown to promote the growth of hESCs when used as the sole growth support [3, 22-25]. These core proteins regulate critical cellular processes such as cell attachment through integrin binding. Integrin interactions are capable of mediating signal transduction responses similar to those triggered by soluble ligands [26, 27]. Therefore, hESCs potentially utilize these interactions to regulate a diverse array of cellular functions. The presence of these core ECM proteins in the matrix likely promotes these interactions, and explains why matrices that contain them in combination are better at facilitating hESC and hiPSC growth, such as is the case with Matrigel™ [3, 28].

The identification of multiple growth factors and their binding partners in CMTX highlights another potential function for these core fibrous ECM proteins in the matrix. The ECM has been proposed to contribute to the regulation of growth factor signaling in the microenvironment (reviewed in [1]). Central to this function is the presence of specialized domains designed to bind growth factors like VEGF, EGF, HGF, and PDGF on proteins such as fibronectin and laminin. Furthermore, fibronectin has been observed to contribute to TGF- β signaling through interaction with latent-TGF- β binding proteins [29, 30]. Binding between growth factors and these glycoproteins can also be mediated by interactions with heparan sulfate, a molecule that has been shown to regulate the self-renewal of hESCs [1, 31]. In addition to core ECM proteins, the CMTX also contains an array of binding proteins involved in pathways such as IGF, BMP, and EGF signaling. These binding partners can complement interactions with glycoproteins such as fibronectin. The result of these interactions potentially implicates the ECM in the direction of cellular processes through binding and sequestering of growth factors.

The importance of controlling the activity and concentration of growth factors present in the microenvironment is critical for maintenance of the hESC and hiPSC state. Three key pathways from which we identified regulatory proteins in the CMTX are Wnt, TGF- β through Activin/Nodal, and BMP signaling. The sFRP1 and sFRP2 proteins are thought to regulate canonical Wnt signaling through direct binding to the Wnt proteins, although their role in hESCs remains unclear (reviewed in [32]). Wnt signaling through the canonical pathway has been shown to be important in the maintenance of mESC and hESC self-renewal and pluripotency [20]. Lefty A and B are known to regulate TGF- β signaling through antagonism of the activating protein Nodal [33]. TGF- β activation

through Activin/Nodal signaling is one of the core pathways critical for the maintenance of self-renewal and pluripotency of hESCs [21]. The Lefty proteins were also identified in the original CMTX work involving metastatic cells as a potential regulator of the observed phenotype, acting through hESC-derived matrix deposition [12]. Inhibition of BMP mediated activation of TGF β signaling also promotes the maintenance of hESC pluripotency. BMP activates SMAD1/5/8 mediated TGF- β pathways that have been implicated in the differentiation of hESCs [21]. Cerberus is an inhibitor of BMP mediated activation that acts through antagonism of BMP-4 [34, 35]. Interestingly, Cerberus has also been shown to inhibit Nodal as well as Wnt signaling pathways [35, 36].

The identification of sFRP1 and sFRP2 as well as the Lefty A and Lefty B proteins further validates the ability of our CMTX proteomic analysis to identify potential regulators of hESC fate. Aside from their activity in the regulation of core hESC pluripotency pathways, both sFRP and Lefty proteins are known to be matrix deposited [37, 38]. Taken together, the findings of this study highlight the ability of MS-based proteomics screening of CMTX to determine *in vitro* effectors of hESC control involving the ECM microenvironment.

4.4 Methods

4.4.1 Cell culture and harvest – H9 (passage 26) and CA1 (passage 20) hESCs, and BJ-1D (passage 65) iPSCs were maintained on CF-1 irradiated mouse embryonic fibroblast (MEF) feeder layers (GlobalStem, Rockville, MD) using media composed of knockout DMEM/F12, 20% knockout serum replacement, 1% non-essential amino acids, 2mM glutamine (CellGro, Manassas, VA), 0.1 mM 2-mercaptoethanol (Fisher, Toronto, ON), and 4 ng/mL of basic fibroblast growth factor. All media reagents were obtained from Invitrogen unless noted otherwise. H9 cells were obtained from WiCell (WISC, Wisconsin). The CA1 hESC line used in all experiments was obtained from Dr. Cheryle Séguin of The University of Western Ontario [39, 40]. The hiPSC line BJ-1D was derived by reprogramming using retroviral transduction of BJ fibroblasts with the Yamanaka factors essentially as we have previously described [41] and validated as pluripotent using in vitro and in vivo differentiation assays and expression profiling (unpublished results). Cells were passaged mechanically in all experiments and for general maintenance.

For SILAC experiments, hESC and hiPSC cell lines were grown in feeder-free conditions on Matrigel™ (BD Biosciences, Franklin Lake, NJ). Custom DMEM/F12-glutamax that contained no L-arginine or L-lysine was ordered from Invitrogen. SILAC medium was prepared using the StemPro hESC Media system with our custom DMEM/F12 (Invitrogen) according to manufacturer instructions. [$^{13}\text{C}_6$, $^{15}\text{N}_4$] – L-arginine and [$^{13}\text{C}_6$, $^{15}\text{N}_2$] – L-lysine (Cambridge Isotope Laboratories, Andover, MA) were

supplemented into the SILAC medium at 90mg/L and 92mg/L respectively. Unlabeled L-proline was added to the SILAC medium at a final concentration of 800 mg/L [42].

Embryoid bodies (EB) were generated using Aggrewell 400Ex plates (StemCell Technologies, Vancouver, Canada). Briefly, 2×10^6 hESCs were harvested enzymatically using Accutase (Invitrogen) from Matrigel™ coated plates. Cells were reconstituted in Aggrewell medium supplemented with Rock inhibitor (Y-27632, Sigma-Aldrich, St. Louis, MO) at a final concentration of 10 μ M. After plating in Aggrewell dishes, EBs were grown for 48 hours at 37°C prior to transfer to ultra-low adherence tissue culture dishes (Corning, Lowell, MA). After 15 days of culture, EB RNA was harvested using Trizol extraction according to the manufacturer's instructions (Invitrogen). EBs were assayed for expression of CDX2, alpha-feto protein (AFP), GATA-6, GATA-4, Oct3/4, PAX-6, T-brachyury, Nanog, and Neurogenic differentiation 1 (NeuroD1) using TaqMan primer probe sets (Invitrogen). Details of this assay can be found in Appendix Table 1.15. All EB assays were performed in biological and technical duplicate for each cell line and each condition.

4.4.2 Generation and Harvest of Conditioned Matrix – H9, CA1, or BJ-1D stem cells were grown in feeder-free conditions on Matrigel™ in heavy-isotope containing SILAC medium for 7 days prior to passaging to plates for CMTX preparation. SILAC labeled stem cells were permitted to grow for a period of 5 days on Matrigel™ in SILAC medium for generation of CMTX. Wells were then rinsed thoroughly with PBS to ensure removal of medium components and cells removed from the Matrigel™ layer using Cell Recovery Solution according to the manufacturer's instructions (BD Biosciences). The

remaining CMTX layer was incubated in a solution containing 8 M urea, 100 mM ammonium bicarbonate (ABC), and 1 M NaCl for 24 hours at 4°C. After the removal of stem cells by spinning, the cell recovery solution was combined with the urea solution and concentrated using high-capacity C18 cartridges (Phenomenex, Torrance, CA). Eluted components were dried using a SpeedVac and reconstituted in 8 M urea with 100 mM ABC for analysis by 1D-SDS-PAGE, strong cation exchange (SCX), or strong anion exchange (SAX) fractionation. CMTX was analyzed in technical duplicate and biological triplicate for each cell line.

4.4.3 In-solution trypsin digestion – Matrix samples were reduced with 10 mM dithiothreitol (DTT) for 60 minutes. Samples were then alkylated with 40 mM iodoacetamide (IAA) for 60 minutes. The reactions were quenched through the addition of DTT and left to incubate for another 60 minutes. Samples were then diluted 1/6 in 50 mM ABC. Trypsin (Promega, Madison, WI) at a concentration of 1 µg enzyme to 25 µg of total protein was added to the mixtures and left to incubate for 24 hours at 37°C. The next day, digests were acidified using neat trifluoroacetic acid and desalted on C18 cartridges (Phenomenex, Torrance, CA). After elution with 50% acetonitrile, samples were evaporated using a SpeedVac. Dried samples were reconstituted in 0.5% formic acid at a pH of ~2 prior to loading on an SCX column. Samples for SAX analysis were reconstituted in 0.5% NaOH at a pH of ~12.

4.4.4 Column preparation – Columns were packed in 360 O.D. x 200 I.D. capillaries (PolyMicro Technologies, Phoenix, AZ) using a conventional pressure bomb (Next Advance, Averill Park, NY). Frits were prepared by mixing 75 µL of potassium silicate

with 25 μL of formamide, vortexing for 1 minute and rapidly inserting and removing the capillary end from the resulting mixture. Capillary frits were dried in a 100°C oven for 2 hours. Capillaries were then rinsed with forward and reverse flow of methanol using the pressure bomb at 200 psi. Prior to packing, capillaries were rinsed for 30 minutes with 0.5% formic acid or 0.5% NaOH for SCX and SAX respectively. PolySULFOETHYL A SCX beads (5 μM , 300 \AA , CAT# PLBMSE0503) were purchased from PolyLC (Columbia, MD) and reconstituted in 50% MeOH. SAX beads were purchased from Varian Inc. (10 μm , 1000 \AA , CAT# PL1451-2102, Palo Alto, CA) and used in the vendor supplied buffer. SCX and SAX columns were packed to a length of 3 cm for all experiments. All packing was done at a pressure of 200 psi until the desired column length was obtained, then pressurized to 1000 psi to complete packing. Packed columns were rinsed with solvents for conditioning as recommended by the manufacturer.

4.4.5 Peptide Fractionation – Peptides were fractionated off of SCX and SAX columns using a CapLC system (Waters, Milford, MA) with a flow rate of 2 $\mu\text{L}/\text{min}$. Mobile phase A was composed of 20 mM citric acid at a pH of ~ 2.3 , mobile phase B was pH 11.4 20 mM NH_4OH . Mobile phases were all prepared fresh prior to fractionation to ensure the stability of pH from run to run. Fractionation with pH was carried out using a 120 minute gradient from pH 2 to 12 for SCX, and 12 to 2 for SAX. Each fraction was collected offline at a volume of 20 μL . Fractions were dried using a SpeedVac, and reconstituted in 10% formic acid prior to injection on the MS.

4.4.6 In-gel trypsin digestion – 60 µg of conditioned matrix was diluted in Laemmli buffer. Matrix samples were loaded in each of two lanes on a 10% SDS-Gel. After staining of the gel with Coomassie blue, gel lanes were divided into fractions based on visual assessment of protein concentration. Gel cubes in each fraction were destained using 20% acetonitrile (ACN) in 1 M ABC. Proteins were reduced using 10 mM DTT for 60 minutes, followed by alkylation with 100mM IAA for 60 minutes. Digestions were carried out using trypsin at a 1/25 ratio overnight in a 37°C water bath. Fractions were extracted the next day using 10% formic acid and ACN with sonication. Each fraction was dried using a SpeedVac and reconstituted in 10% formic acid prior to injection on the MS.

4.4.7 MS analysis – Fractions were injected and separated using a nanoAcquity system (Waters, Milford, MA) equipped with a 25 cm x 75 µm I.D. C18 column. Fractions were separated using a 1 to 40% ACN gradient over 150 minutes at a flow rate of 300 nL/min. MS analysis was done on a Q-ToF Ultima (Micromass/Waters) using data-dependent acquisition with selection of the four top precursor masses per survey scan. Survey scans were set at 1 s, and MS/MS acquisition set at 1 s or 8000 cps TIC cut-off. Exclusion lists were generated using in-house software that automatically adds 0.7 amu to the precursor masses selected in previous runs and outputs a file also containing retention time information. Each fraction was analyzed for a four exclusion rounds (5 injections total), adjusting the injection volume dependent on signal intensity in the MS survey scan.

4.4.8 Proteomic Data analysis – Data analysis for all samples was performed in PEAKS 5.3 software (Bioinformatics Solutions Inc., Waterloo, Canada) [43, 44]. After import into PEAKS, MS/MS spectra from raw data files were refined using the following settings: merge spectra – true (100 ppm mass tolerance, 60 second retention time tolerance), correct precursor mass – true, determine precursor charge state – true (minimum charge +2, maximum charge +5), spectral quality filter – true (0.65 threshold), centroid, deisotope, and deconvolute – true. Resulting MS/MS spectra were then *de novo* sequenced using the following parameters: parent monoisotopic mass tolerance – 100ppm, fragment monoisotopic mass tolerance – 0.15 daltons, enzyme specificity – semi-Trypsin, fixed modifications – carbamidomethylation and +10 daltons on Arginine and +8 daltons on Lysine for SILAC, variable modifications – N-terminal acetylation and oxidized methionine. After *de novo* analysis, data were searched against the UniProt sequence database (Human taxonomy specified, 20236 total entries) using the following parameters: parent monoisotopic mass tolerance – 100 ppm, fragment monoisotopic mass tolerance – 0.15 daltons, enzyme specificity – semi-Trypsin, fixed modifications – carbamidomethylation and +10 daltons on Arginine and +8 daltons on Lysine for SILAC, variable modifications – N-terminal acetylation and oxidized methionine, estimate false-discovery rate – true.

Resultant protein identification data from the database search were further processed using PEAKS 5.3 software. Proteins were filtered by assigned score to give a <1.0% false-discovery rate for peptide-spectral matches based on estimation from a decoy-fusion method of database search. Identified proteins were also required to be derived by >2 unique peptides. Proteins that contained similar peptides and could not be

differentiated based on MS/MS analysis alone were grouped to satisfy the principles of parsimony. For all matrices analyzed, keratin hits were manually removed from the final datasets. Gene ontology analysis was performed using STRAP software (CPC Tools).

4.4.9 Real-time PCR – RNA was purified using Trizol reagent according to the manufacturer's instructions (Invitrogen) with the following modification: precipitated RNA pellets in isopropanol were centrifuged for 60 minutes at 12000 g at room temperature. After NanoDrop quantification, 1 µg of cDNA was synthesized using the High Capacity cDNA Reverse Transcription Kit with RNase inhibitor (Invitrogen). Real-time PCR was performed using the TaqMan® Universal PCR Master Mix (Invitrogen). Samples were incubated at 50°C for 2 minutes followed by 10 minutes at 95°C. DNA was then amplified at 95°C for 15 seconds followed by 1 minute at 58°C for 46 cycles. All samples were normalized to the large ribosomal protein RPLPO as a positive control. All primers were obtained from Invitrogen and details of the assay can be found in Appendix Table 1.15. Each biological replicate was run in triplicate for every marker assayed. All reagents were used according to the manufacturer's instructions.

4.4.10 Flow Cytometry – All reagents and probes for flow cytometry were obtained from eBiosciences (San Diego, CA) unless noted otherwise. Cells were enzymatically harvested using Accutase (Invitrogen) to obtain a single cell suspension. After centrifugation, cell pellets were resuspended in 5% FBS in PBS. Alexa-488 conjugated SSEA-4 and Alexa-647 conjugated SSEA1 were diluted into the cell mixture according to the manufacturer's instructions. Negative control samples contained respective isotype controls for the primary antibodies used. Solutions were incubated for 2 hours

and analyzed using an Accuri C6 (BD Biosciences) flow cytometer after rinsing to remove unbound antibody. Populations were gated according to forward and side scatter patterns with filtering for viable cells using 7-aminoactinomycin D staining. Data was analyzed using FlowJo software (Tree Star, Ashland, OR).

Chapter 5

Functional Characterization of hESC-Derived CMTX

5.1 Introduction

The two defining characteristics of human embryonic stem cells (hESC), self-renewal and pluripotency, are maintained by a delicate balance of intracellular and extracellular signaling processes. Extracellular regulation is primarily the result of changes in the microenvironment surrounding the cells during growth *in vitro* or *in vivo*. hESCs interact with this 'niche' through support cells, extracellular matrix (ECM) components, and autocrine/paracrine signaling (reviewed in [1-3]). Modulation of any of these supportive elements individually or in combination has been used extensively to alter hESC behavior [1-3]. For example, exogenous growth factor supplementation is used to facilitate the maintenance of hESCs as well as to induce their differentiation. Moreover, recent studies have illustrated that hESC self-renewal and differentiation can be altered through modulation of the properties of the ECM using synthetic mimics, highlighting its importance in the microenvironment (reviewed in [4]).

This chapter contains excerpts from the following paper:

Hughes, C.S., Radan, L., Stanford, W., Betts, D., Postovit, L.M., Lajoie, G.A.. (2012) "Proteomics Analysis of the Human Embryonic Stem Cell Depositome". (In Preparation)

A number of proteomics studies have been conducted to determine factors secreted by feeder layers in an attempt to elucidate proteins and pathways essential for hESC survival [5-8]. Currently only one of these studies has identified members of the soluble frizzled related protein (sFRP) family [9]. As part of our proteomics investigation into the components of CMTX, we identified sFRP1 and 2 across multiple cell lines. The sFRP family of proteins has been shown to regulate canonical Wnt signaling through direct binding to the secreted Wnt cytokines [10]. Central to this role is the direct interaction of sFRP1 and sFRP2 with Wnt3a [11]. The Wnt family is a group of secreted glycoproteins consisting of 19 members that contain 22 - 24 conserved cysteine residues (reviewed in [12]). Wnt signaling plays a prominent role during development and its aberrant regulation plays a role in multiple disease phenotypes (reviewed in [13]).

In humans, the sFRP family is made up of 5 members, sFRP1 – 5 [14]. The sFRPs were originally discovered due to their shared sequence similarity with the frizzled receptors that are directly involved with Wnt signaling [15, 16]. This family now constitutes the largest group of Wnt antagonists [17]. Structurally, the sFRP proteins contain two distinctive domains, an N-terminal cysteine rich domain (CRD) and a C-terminal netrin-like domain [18]. The CRD contains ten conserved cysteine residues and shares a significant similarity with the extracellular domain of the frizzled receptors [19]. The C-terminal netrin domain is postulated to confer heparin binding properties [18, 20, 21]. The primary interest in the sFRPs however, stems from the properties of the N-terminal CRD, that because of the sequence homology with the frizzled receptors,

has been proposed to bind Wnt proteins. This ability to bind Wnt proteins has subsequently been verified and intensely studied since that time (reviewed in [17]).

The sFRP family of proteins have been shown to encompass a diverse profile of expression patterns and context dependent interactions in a variety of tissues and cellular systems (reviewed in [22]). However, although sFRPs family members are known to be important during embryonic development, very little is known about their role in the regulation of ESCs [22]. This is surprising when it is considered that Wnt signaling has been shown to be involved in the direct regulation of the pluripotent state of ESCs (reviewed in [23]). Furthermore, in a recent study comparing 59 different hESC lines a positive correlation between Nanog and sFRP2 gene expression was observed [24]. In addition, sFRP2 was identified as a potential target for Nanog in CHIP on CHIP analyses of hESCs [25]. Taken together, these findings indicate that sFRP family members are potentially playing a vital role in hESC pluripotency.

Here we investigate the ability of hESC conditioned matrix (CMTX) to enhance the maintenance of undifferentiated stem cells. To identify and characterize factors potentially responsible for this effect, we utilize the data generated in our proteomics screen of CMTX (Chapter 4) to validate the role of sFRP1 and sFRP2. A combination of techniques is used to characterize the role of the sFRP candidates in the regulation of hESC pluripotency *in vitro*. Additionally, utilizing a metastatic melanoma cell line we demonstrate the effects of exogenous supplementation of sFRP1 and sFRP2. This work represents the first investigation of the hESC and hiPSC matrix microenvironment.

5.2 Results

5.2.1 hESC Derived Matrix for the Maintenance of an Undifferentiated State. The ability of embryonic microenvironments to suppress the tumorigenic phenotype has been previously illustrated in a number of developmental and cellular systems (reviewed in [26]). However, a limited number of studies have focused on reprogramming stem cells with these same microenvironments. Analogous to metastatic cells, embryonic stem cells can direct cellular changes in response to cues from their microenvironment. With the recent observation that a hESC-derived matrix microenvironment could modulate the behavior of metastatic cells [27], we sought determine what effect exposure would have on the stem cell phenotype. To this end, we monitored changes in the gene and protein expression of hESCs grown on CMTX in the absence of exogenous growth factor supplementation. In this way, matrix dependent changes in hESC behavior could be monitored without interference from soluble factors present in MEF-CM.

After 4 days of culture in medium that contained no exogenous bFGF (embryoid body medium, EB medium), a decrease in Oct3/4 and Nanog gene and protein expression was observed for H9 hESCs grown on control Matrigel™ and CMTX. However, the reduction in expression was significantly smaller in H9 hESCs grown on CMTX when compared with control cells (Figure 5.1 A-B). A similar trend was observed when H9 hESCs were measured using flow cytometry for SSEA4 and SSEA1 fluorescence. H9 hESCs induced to differentiate on CMTX exhibited an increase in SSEA4 mean fluorescence intensity relative to SSEA1 when compared with control cells (Figure 5.1 C-D). When cultures were examined by immunofluorescence, pockets of SSEA1

Figure 5.1. hESC generated CMTX enhances the maintenance of an undifferentiated state in H9 cells when compared to those grown on Matrigel™. Matrigel™/CMTX was generated by growing H9 hESCs on Matrigel™ for 4 days. Following cell removal, fresh H9 hESCs were plated on the CMTX layers. Control Matrigel™ was generated by treating normal Matrigel™ with the cell removal procedure prior to the plating of fresh hESCs as discussed in the Methods. Cells in both conditions were fed with medium not containing bFGF for 4 days. Control samples are hESCs grown on normal Matrigel™ in MEF-CM. (A) RT-PCR data for H9 hESCs cultured on control Matrigel™ and Matrigel™/CMTX. Values represent fold change of Oct3/4 or Nanog expression relative to control hESCs cultured under standard conditions. RPLPO was used as an internal control for both samples. Error bars represent SEM, n=3. (B) Western blot for Oct3/4 and Nanog in H9 hESCs grown on CMTX. Actin is shown as a control. (C) Flow cytometry data for H9 hESCs grown on CMTX. For each sample, plot (i) shows SSEA4 fluorescence (blue) relative to a matched isotype control (solid red), (ii) shows SSEA1 fluorescence relative to isotype control, (iii) scatter plot with the gated cell population shown, (iv) scatter plot with the viable cell population gated. Percentages denote fraction of cells within the gates shown. (D) Results from flow cytometry analysis of H9 hESCs grown on CMTX for the markers SSEA4 and SSEA1. Values represent mean fluorescence intensity of SSEA4 relative to SSEA1 for Matrigel™ Control or Matrigel™/CMTX samples. Values are derived from the data in (C). Error bars represent SEM, n=3. (D) Immunocytochemistry for H9 hESCs grown on Control Matrigel™ or Matrigel™/CMTX. Cells were stained with Oct3/4, SSEA4, DAPI, and SSEA1. Scale bars represent 250um.

Figure 5.2. hESC generated CMTX enhances the maintenance of an undifferentiated state in CA1 cells when compared to those grown on Matrigel™. Matrigel™/CMTX was generated by growing CA1 hESCs on Matrigel™ for 4 days. Following cell removal, fresh CA1 hESCs were plated on the CMTX layers. Control Matrigel™ was generated by treating normal Matrigel™ with the cell removal procedure prior to the plating of fresh hESCs as discussed in the Methods. Cells in both conditions were fed with medium not containing bFGF for 4 days. Control samples are hESCs grown on normal Matrigel™ in MEF-CM. (A) RT-PCR data for CA1 hESCs cultured on control Matrigel™ and Matrigel™/CMTX. Values represent fold change of Oct3/4 or Nanog expression relative to control hESCs cultured under standard conditions. RPLPO was used as an internal control for both samples. Error bars represent SEM, n=3. (B) Western blot for Oct3/4 and Nanog in CA1 hESCs grown on CMTX. Actin is shown as a control. (C) Flow cytometry data for CA1 hESCs grown on CMTX. For each sample, plot (i) shows SSEA4 fluorescence (blue) relative to a matched isotype control (solid red), (ii) shows SSEA1 fluorescence relative to isotype control, (iii) scatter plot with the gated cell population shown, (iv) scatter plot with the viable cell population gated. Percentages denote fraction of cells within the gates shown. (D) Results from flow cytometry analysis of CA1 hESCs grown on CMTX for the markers SSEA4 and SSEA1. Values represent mean fluorescence intensity of SSEA4 relative to SSEA1 for Matrigel™ Control or Matrigel™/CMTX samples. Values are derived from the data in (C). Error bars represent SEM, n=3. (E) Immunocytochemistry for CA1 hESCs grown on Control Matrigel™ or Matrigel™/CMTX. Cells were stained with Oct3/4, SSEA4, DAPI, and SSEA1. Scale bars represent 250um.

positive cells could be observed in control cells, indicating differentiation (Figure 5.1 E). SSEA1 positive colonies were observed with a reduced frequency in cells cultured on CMTX. Subsequent analysis of a second hESC line, CA1, revealed similar trends (Figure 5.2 A-E). Taken together, these data indicate that CMTX promotes the preservation of an undifferentiated state and hESCs secrete factors into the matrix that are beneficial for their own maintenance.

5.2.2 Generation and Testing of an Artificial CMTX. To functionally validate the proteomics method for profiling the CMTX to identify hESC regulatory proteins, we investigated the roles of sFRP1, sFRP2, Lefty A, and Gremlin further. These proteins were selected on the basis of their suspected roles in hESC regulation as well as their previous implications in CMTX studies involving metastatic cells [27-29]. Moreover, these proteins were not identified in Matrigel™ itself, making their functional validation possible in a CMTX assay that utilizes this matrix without background interference. To determine the potential roles of these candidates in the CMTX, we repeated the hESC CMTX experiments utilizing two separate platforms for analysis.

We first sought to determine if supplementation of recombinant proteins to the matrix, in the absence of conditioning prior to hESC plating, could enhance the maintenance of an undifferentiated state. Recombinant versions of sFRP1 and sFRP2, Lefty A, and Gremlin were supplemented into Matrigel™ at a maximum concentration of 5µg/mL prior to gelation. To ensure maximal recombinant protein incorporation into the matrix, undiluted Matrigel™ was used in all assays to coat culture dishes. The Matrigel™™ layer was then treated with the lysis-free cell removal process (see Chapter 4) prior to

hESC plating to ensure reproducibility with the previous experiments. In H9 hESCs, supplementation with any of the selected proteins did not significantly enhance the expression of the markers of pluripotency Oct3/4 and Nanog (Figure 5.3 A). Alone or in combination, none of the proteins were able to fully replicate the effect observed on CMTX. Similar trends are seen in the CA1 hESC line, where individually or in combination, the matrix supplemented proteins are unable to promote maintenance of an undifferentiated state (Figure 5.3 C). In immunoblotting for Oct3/4 and Nanog we observe analogous changes in Oct3/4 and Nanog protein abundance in both H9 and CA1 hESCs (Figure 5.3 E). These data suggest that sFRP1, sFRP2, Gremlin, and Lefty A are unable to replicate the effects observed on hESC-derived CMTX. However, previous studies have shown that recombinant proteins are not as effective as their equivalent hESC-derived versions [27].

Antibody blocking experiments were performed to further investigate the potential role of the sFRP and Lefty proteins in the CMTX. CMTX was generated by growing H9 or CA1 hESCs on Matrigel™ as before. After cell removal, CMTX was treated with antibodies specific for sFRP1, sFRP2, or Lefty A candidates, individually or in combination, to generate a 'knockdown' CMTX. Unbound antibody was removed by washing and fresh hESCs were plated and grown in EB medium. In this way, sFRP or Lefty proteins that had been deposited in the CMTX during hESC growth would no longer be available for interaction with the newly plated cells. Monitoring changes in gene expression and protein abundance of Oct3/4 and Nanog revealed that none of the antibody treatments promoted a reduction in the maintenance of an undifferentiated state of H9 hESCs when compared with a secondary antibody control (Figure 5.3 B, F). Assay of the CA1

Figure 5.3. Characteristics of hESCs on recombinant and knockdown CMTX. Recombinant CMTX was generated by supplementing Matrigel™ with recombinant versions of sFRP1, sFRP2, Lefty, or Gremlin alone or in combination. Knockdown CMTX was made by incubating hESC-derived CMTX with antibodies specific for sFRP1, sFRP2, or Lefty A and Lefty B prior to plating of fresh hESCs. (A) Oct3/4 and Nanog expression in H9 hESCs grown on Recombinant CMTX as determined by RT-PCR. Values represent fold change relative to hESCs grown on Control Matrigel™ (treated with the cell removal process, but not supplemented with recombinant protein). Error bars indicate SD, n=3. (B) Oct3/4 and Nanog expression in H9 hESCs grown on Knockdown CMTX as determined by RT-PCR. Values represent fold change relative to hESCs grown on Matrigel™/CMTX (hESC-derived CMTX treated with the cell removal process, not treated with antibody). Error bars represent SD, n=3. Secondary denotes CMTX treated with a secondary antibody as a control (C) Oct3/4 and Nanog expression in CA1 hESCs on Recombinant CMTX. Error bars indicate SD, n=5. (D) CA1 hESCs on Knockdown CMTX. Error bars indicate SD, n=4. All RT-PCR experiments used RPLPO as an internal control for each sample. (E) Western blots for Oct3/4 and Nanog in H9 and CA1 hESCs grown on Recombinant CMTX. Actin is shown as a control. (F) Western blots for Oct3/4 and Nanog in H9 and CA1 hESCs grown on Knockdown CMTX. Actin is shown as a control.

hESC line revealed identical trends to the H9 cell line (Figure 5.3 D, F). Taken together, these experiments indicate that the sFRP and Lefty proteins do not solely modulate the state of hESCs on the CMTX. This suggests that there are other factors potentially acting to enhance undifferentiated hESC maintenance on CMTX. However, it is also possible that the antibodies utilized are potentially unable to block the function of the selected proteins, or are unable to bind if the target is localized in the matrix.

5.2.3 Roles of sFRP Proteins in hESC Pluripotency. Canonical Wnt signaling is a critical pathway with characterized roles during development as well as in ESCs themselves (reviewed in [12]). However, the regulation of hESC pluripotency through Wnt signaling is poorly understood, specifically how the pathway is controlled in the extracellular space. The sFRP family of proteins are known Wnt antagonists whose differential expression has been shown to have significant effects in a variety of cell types and pathological conditions (reviewed in [17]). Interactions between the sFRPs and hESCs and the resultant effects on self-renewal or differentiation are inadequately characterized. Given the importance of Wnt signaling in developmental processes, we chose to investigate the role of the sFRP1 and sFRP2 in the maintenance and regulation of hESC pluripotency.

To measure the effect of sFRP1 and sFRP2 on hESC behavior, we employed shRNA mediated knockdowns of each target gene. Initially we attempted to utilize the tetracycline inducible vector, pTRIPZ (Open Biosystems). An inducible system was chosen to permit generation of a homogenous population of undifferentiated cells should our shRNA promote differentiation. We successfully generated stable lines in

HEK293 cells and subsequently verified sFRP1 and sFRP2 knockdown. However, after production of stable H9 and CA1 hESC lines, we were unable to induce shRNA or reporter gene expression using doxycycline in any of the clones tested. Since the puromycin resistance and shRNA genes are on separate promoters, the effect we observe is potentially the result of promoter silencing, a common occurrence in hESCs [30]. To overcome this problem, we utilized a separate tetracycline inducible vector system known as pSUPERIOR. Along with the tetracycline repressor vector, pTetRnls, pSUPERIOR had previously been used to generate stable inducible Oct3/4 shRNA expressing cell lines [31]. However, although we were able to successfully generate stable H9 and CA1 lines, the cells grew poorly under dual-antibiotic selection and were prone to differentiation.

Because of these difficulties, we decided to employ a transient expression of our shRNAs in hESCs. Transient knockdown of gene expression in hESCs is challenging due to the poor efficiency of transfection of these cells. Using cationic lipid based transfection of H9 and CA1 hESCs we were able to achieve >60% efficiency based on GFP reporter expression (Figure 5.4 A-B). Expression of the shRNA constructs could be maintained by transfection on multiple days during experimentation as we did not observe a global reduction in viability as a result of the protocol (Figure 5.4 B). However, when examining colonies that contained small numbers of cells in conditions containing sFRP1 and sFRP2 shRNAs (<10 total cells), we observed a significant reduction in viability in both H9 and CA1 hESCs compared with controls (Figure 5.4 C). Using transient expression of our shRNA constructs, we were only able to obtain ~30% knockdown for both sFRP1 and sFRP2 based on gene expression in H9 and CA1

Figure 5.4. shRNA mediated knockdown of sFRP1 and sFRP2 expression. sFRP1 and sFRP2 expression were individually knocked down in H9 and CA1 hESCs using pSUPERIOR plasmid containing shRNA constructs against target transcripts. (A) Phase contrast and fluorescence images of H9 and CA1 hESC colonies transfected with pSUPERIOR plasmid expressing GFP and a scrambled shRNA control. Scale bars represent 250um. (B) Efficiency of transfection using flow cytometry detection of GFP positive cells after treatment. Smaller plots show viability using 7-AAD staining. N=2 for both cell lines. (C) Phase contrast images demonstrating the poor viability of small hESC colonies following transfection compared with scrambled control hESC lines. Scale bars represent 250um. (D) Knockdown of sFRP1 and sFRP2 expression in H9 and CA1 hESCs as measured by RT-PCR. Values are fold change relative to control samples transfected with a scrambled shRNA. Error bars depict SD, n=3. (E) Oct3/4 and Nanog expression in knockdown cells as determined by RT-PCR. Error bars show SD, n=3. For all RT-PCR experiments RPLPO is used as an internal sample control. (F) Immunoblot for Oct3/4, Nanog, sFRP1, and sFRP2 in knockdown and control H9 and CA1 hESCs. Actin is shown as a control for both cell lines.

hESCs (Figure 5.4 D). To test the effects of these knockdowns on hESC behavior, H9 and CA1 cells were grown in MEF-CM for 4 days post-transfection. In hESCs containing sFRP1 or sFRP2 shRNA expressing plasmids grown in MEF-CM, we observed no significant change in Oct3/4 and Nanog at both the transcript and protein level (Figure 5.4 E-F). Taken together, these data suggest that sFRP1 and sFRP2 are unable, on their own, to modulate pluripotency marker expression in MEF-CM. However, the effectiveness of the shRNA treatment is potentially confounded by the limited extent of knockdown achieved.

Although we obtained a knockdown of gene expression for sFRP1 and 2 in the hESC lines tested, we observed that the protein level remained relatively unchanged compared with control cells (Figure 5.4 F). To effect sFRP signaling at the protein level, we utilized two separate small molecule inhibitors specific for sFRP1 (herein referred to as sFRP1 Inhibitor A and sFRP1 Inhibitor B) [32]. When H9 or CA1 hESCs grown in MEF-CM were supplemented with either inhibitor, we observed only minor alterations in Oct3/4 and Nanog expression that were not significant at the transcript level (Figure 5.5 A-B). Additionally, we observed no differences based on immunoblot data, indicating that the changes observed at the transcript level were not biologically significant (Figure 5.5 C). Taken together, these results suggest that inhibition of sFRP1 cannot, on its own, promote the changes in the expression of genes directly involved in the maintenance of the stem cell phenotype in MEF-CM.

To test whether inhibition of sFRP1 by small molecule inhibitors has an effect on the differentiation of hESCs, we supplemented multiple concentrations of either inhibitor in

Figure 5.5. hESCs in MEF-CM supplemented with sFRP1 inhibitors. H9 and CA1 hESCs were grown in MEF-CM that was supplemented with small molecule inhibitors of sFRP1. Oct3/4 and Nanog expression were assayed by RT-PCR following 4 days of culture in the presence of supplementation. (A) Fold change of Oct3/4 and Nanog expression relative to control for H9 and CA1 hESCs grown in MEF-CM supplemented with sFRP1 inhibitor A. (B) Fold change of Oct3/4 and Nanog expression relative to control for H9 and CA1 hESCs grown in MEF-CM supplemented with sFRP1 inhibitor B. Error bars represent SD, n=3. All RT-PCR experiments used RPLPO as an internal control. (C) Western blots depicting Oct3/4 and Nanog protein expression for H9 and CA1 hESCs grown in MEF-CM supplemented with sFRP1 inhibitors. Actin is shown as a control.

EB medium. Similar to the observed effect in MEF-CM, neither sFRP1 inhibitor was able to alter the expression of Oct3/4 or Nanog in H9 or CA1 hESCs (Figure 5.6 A-B). Analogous to MEF-CM, no observable changes were seen in immunoblots for Oct3/4 and Nanog (Figure 5.6 C). However, due to the poor abundance of Nanog following differentiation based on immunoblots, correlation of gene expression and protein abundance data is challenging.

Since Wnt signaling is known to be involved in the induction of mesendoderm, we examined whether hESCs grown in EB medium supplemented with sFRP1 inhibitors would display an induction of this lineage type [33]. As indicators of mesendoderm, we monitored Goosecoid (GSC) [34] and Mix paired-like homeobox 1 (MIXL1) [35] expression. We observed a significant decrease in GSC expression and subsequent increase in MIXL1 in H9 hESCs grown in the presence of sFRP1 inhibitor A in EB medium (Figure 5.6 D). We observe a similar trend for H9 hESCs grown in the presence of sFRP1 inhibitor B; although significance is not reached in the case of MIXL1 (Figure 5.6 E). We observe no significant change in GSC or MIXL1 expression in CA1 hESCs grown in the presence of either sFRP1 inhibitor in EB medium (Figure 5.6 D).

In order to maximize the knockdown in sFRP1 and sFRP2 activity, we combined transient transfection of the hESCs with small molecule inhibition in both MEF-CM and EB medium. Similar to the previous results in MEF-CM and EB medium supplemented with either sFRP1 inhibitor, we observed no significant changes Oct3/4 in transcript or protein abundance in sFRP1 and sFRP2 shRNA expressing hESCs (Figure 5.7 A-D).

Figure 5.6. hESCs in embryoid body medium supplemented with sFRP1 inhibitors. H9 and CA1 hESCs were grown in EB medium that was supplemented with small molecule inhibitors of sFRP1. Oct3/4 and Nanog expression were assayed by RT-PCR following 4 days of culture in the presence of supplementation. (A) Fold change of Oct3/4 and Nanog expression relative to control for H9 and CA1 hESCs grown in EB medium supplemented with sFRP1 inhibitor A. (B) Fold change of Oct3/4 and Nanog expression relative to control for H9 and CA1 hESCs grown in EB medium supplemented with sFRP1 inhibitor B. Error bars represent SD, n=3. (C) Western blots depicting Oct3/4 and Nanog protein expression for H9 and CA1 hESCs grown in embryoid body medium supplemented with sFRP1 inhibitors. Actin is shown as a control. (D) Goosecoid and MIXL1 expression as indicators of mesendoderm induction for H9 and CA1 hESCs grown in the presence of sFRP1 inhibitor A. (E) Goosecoid and MIXL1 expression as indicators of mesendoderm induction for H9 and CA1 hESCs grown in the presence of sFRP1 inhibitor B. Significance was determined through comparison with embryoid body controls. Error bars represent SD, n=3. All RT-PCR experiments used RPLPO as an internal control.

Examination of hESCs grown in EB medium supplemented with sFRP1 inhibitor A or B revealed significant increases in GSC and MIXL1 expression in the sFRP2 knockdown CA1 lines (Figure 5.7 G-J). No significant changes were observed in the H9 hESC line in the presence of either inhibitor (Figure 5.7 G-J). Taken together, these results suggest that modulation of sFRP using sFRP1 inhibitors or shRNA knockdowns are unable to direct changes in hESCs in MEF-CM.

To further examine the potential effects of sFRP1 and sFRP2 on hESCs, we supplemented recombinant versions of these proteins in MEF-CM and EB medium. Since the sFRP family is known to regulate Wnt signaling, and sFRP1 and sFRP2 act directly on Wnt3a, we decided to investigate what role this pathway plays in hESCs [11]. Direct supplementation of Wnt3a in either MEF-CM or EB medium proved beneficial for the maintenance of Oct3/4 and Nanog expression (Figure 5.8 A - C). Supplementation with Wnt3a in EB medium also induced the expression of GSC in H9 and CA1 hESCs (Figure 5.8 D). MIXL1 expression was also significantly upregulated in CA1 hESCs grown in the presence of Wnt3a (Figure 5.8 E).

When H9 and CA1 hESCs were supplemented with recombinant sFRP1, sFRP2, and Wnt3a in MEF-CM, we observed that no significant changes were present at both the transcript and protein level (Figure 5.9 A, C, E). However, in EB medium, we observed a significant increase in Nanog expression when sFRP1 or sFRP2 were supplemented in combination with Wnt3a (Figure 5.9 D, F). In CA1 hESCs, we also observed an increase in Oct3/4 expression in the presence of Wnt3a and sFRP1 or sFRP2 (Figure 5.9 B, F). Unfortunately, the low-abundance of Nanog in differentiated hESCs

Figure 5.7. hESCs with combined exposure to sFRP1 inhibitors and shRNA mediated knockdowns. H9 and CA1 hESCs transfected with shRNA expressing vectors against sFRP1, sFRP2, or scrambled control were grown in MEF-CM or embryoid body medium that was supplemented with small molecule inhibitors of sFRP1. Oct3/4 and Nanog expression were assayed by RT-PCR following 4 days of culture in the presence of supplementation. (A) Fold change of Oct3/4 and Nanog expression relative to control for H9 and CA1 hESCs grown in MEF-CM supplemented with sFRP1 inhibitor A. Error bars represent SD, n=3. (B) Fold change of Oct3/4 and Nanog expression relative to control for H9 and CA1 hESCs grown in embryoid body medium supplemented with sFRP1 inhibitor A. Error bars represent SD, n=3. (C) Fold change of Oct3/4 and Nanog expression relative to control for H9 and CA1 hESCs grown in MEF-CM supplemented with sFRP1 inhibitor B. Error bars represent SD, n=3. (D) Fold change of Oct3/4 and Nanog expression relative to control for H9 and CA1 hESCs grown in embryoid body medium supplemented with sFRP1 inhibitor B. Error bars represent SD, n=3. (E) Western blots for Oct3/4 and Nanog in H9 and CA1 hESCs transfected with shRNA expressing vectors grown in MEF-CM supplemented with sFRP1 inhibitors. Actin is shown as an internal control. (F) Western blots for Oct3/4 and Nanog in H9 and CA1 hESCs transfected with shRNA expressing vectors grown in embryoid body medium supplemented with sFRP1 inhibitors. Actin is shown as an internal control. (G-J) Fold change of Goosecoid and MIXL1 expression relative to control for H9 and CA1 hESCs grown in embryoid body medium supplemented with sFRP1 inhibitor A (G-H) or sFRP1 inhibitor B (I-J). Error bars represent SD, n=3. All RT-PCR experiments used RPLPO as an internal control.

Figure 5.8. hESCs in MEF-CM and embryoid body medium with recombinant Wnt3a supplementation. H9 and CA1 hESCs were grown in MEF-CM or embryoid body medium that was supplemented with recombinant Wnt3a. Oct3/4 and Nanog expression were assayed by RT-PCR following 4 days of culture in the presence of supplementation. (A) Fold change of Oct3/4 expression relative to control for H9 and CA1 hESCs grown in MEF-CM or EB medium supplemented with recombinant Wnt3a at 100ng/mL. Error bars represent SD, n=3. (B) Fold change of Nanog expression relative to control for H9 and CA1 hESCs grown in MEF-CM or EB medium supplemented with recombinant Wnt3a at 100ng/mL. Error bars represent SD, n=3. (C) Western blots for Oct3/4 and Nanog in H9 and CA1 hESCs grown in the presence or absence of 100 ng/mL of Wnt3a. Actin is shown as a control. (D) Fold change of Goosecoid expression relative to control for H9 and CA1 hESCs grown in embryoid body medium supplemented with recombinant Wnt3a, at 100ng/mL. Significance was determined through comparison with the appropriate EB medium control. Error bars represent SD, n=3. (E) Fold change of Goosecoid expression relative to control for H9 and CA1 hESCs grown in embryoid body medium supplemented with recombinant Wnt3a, at 100ng/mL. Significance was determined through comparison with the appropriate EB medium control. Error bars represent SD, n=3. All RT-PCR experiments use RPLPO as an internal control.

confounded the validation of gene expression results at the protein level (Figure 5.9 E-F). Examination of GSC expression revealed significant increases in H9 hESCs in the presence of Wnt3a and sFRP1 or sFRP2 (Figure 5.9 G). GSC could be reduced through the addition of sFRP1 and sFRP2 in CA1 hESCs (Figure 5.9 G). However, this reduction could be reversed through the addition of Wnt3a (Figure 5.9 G). In CA1 hESCs we also observed a significant induction in MIXL1 expression in the presence of Wnt3a, sFRP1, and sFRP2 (Figure 5.8 H). These data indicate that sFRP1 and sFRP2 proteins are able to act on hESCs during differentiation on their own or through interaction with Wnt3a dependent on the growth factor composition of the microenvironment.

5.2.4 Effect of sFRP Expression in Metastatic Melanoma Cells. sFRP1 and sFRP2 have multiple convergent and divergent roles in metastatic cell types (reviewed in [10]). To examine the effects of sFRP1 and sFRP2 expression we utilized a metastatic melanoma cell line (C8161) that was previously employed to demonstrate the reprogramming ability of hESC-derived CMTX [27, 36]. Expression of sFRP2 was found to be minimal in C8161 cells when compared with hESCs and HEK293 lines (Figure 5.10 A). Interestingly, sFRP1 expression was similar to H9 hESCs based on RT-PCR data (Figure 5.10 A). Since sFRP2 expression was found to be low, we transfected the C8161 cells with a vector containing the sFRP2 open-reading frame (ORF) under the control of a constitutive promoter. After 48 hours post-transfection, C8161s transfected with the sFRP2 ORF had a significant decrease in total cell number compared to control cells transfected with the same vector without the sFRP2 ORF (Figure 5.10 B). After selection with puromycin, no cells were able to form stable cell

lines from those transfected with the sFRP2 ORF, whereas numerous clones were derived from the control plate (Figure 5.10 B). However, validation of sFRP2 expression in C8161 cells was difficult due to the inability to harvest cellular RNA and protein as a result of cell death.

To further assess the effects of sFRP1 and sFRP2 on the C8161s we carried out an anchorage independent growth assay. C8161 cells that had been supplemented with 200 ng/mL of sFRP1 and sFRP2 for 4 and 7 days were seeded into soft-agar and permitted to form colonies for 14 days. Cells exposed to sFRP1 and sFRP2 had a significant increase in colony formation relative to control, whereas those exposed to sFRP2 had a significant decrease (Figure 5.10 C). Although the sFRP2 supplemented wells displayed colonies, they tended to be smaller than those found in the sFRP1 or control wells (Figure 5.10 D). Taken together, these data indicate divergent roles for sFRP1 and sFRP2 in metastatic C8161 cells.

Figure 5.9. hESCs in MEF-CM and embryoid body medium with recombinant protein supplementation. H9 and CA1 hESCs were grown in MEF-CM or embryoid body medium that was supplemented with recombinant versions of sFRP1, sFRP2, and Wnt3a. Oct3/4 and Nanog expression were assayed by RT-PCR following 4 days of culture in the presence of supplementation. (A) Fold change of Oct3/4 expression relative to control for H9 and CA1 hESCs grown in MEF-CM medium supplemented with recombinant sFRP1, sFRP2, and Wnt3a, each at 100ng/mL. (B) Fold change of Oct3/4 expression relative to control for H9 and CA1 hESCs grown in embryoid body medium supplemented with recombinant sFRP1, sFRP2, and Wnt3a, each at 100ng/mL. (C) Fold change of Nanog expression relative to control for H9 and CA1 hESCs grown in MEF-CM medium supplemented with recombinant sFRP1, sFRP2, and Wnt3a, each at 100ng/mL. (D) Fold change of Nanog expression relative to control for H9 and CA1 hESCs grown in embryoid body medium supplemented with recombinant sFRP1, sFRP2, and Wnt3a, each at 100ng/mL. Significance was determined through comparison with the appropriate MEF-CM or EB medium control. Error bars represent SD, n=3. (E-F) Western blots depicting Oct3/4 and Nanog protein expression for all experiments. Actin is shown as a control. (G-H) Goosecoid and MIXL1 expression as indicators of mesendoderm induction for H9 and CA1 hESCs grown in embryoid body medium supplemented with recombinant sFRP1, sFRP2, and Wnt3a, each at 100ng/mL. Significance was determined by comparison with MEF-CM and EB medium controls. All RT-PCR experiments use RPLPO as an internal control.

Figure 5.10. Metastatic melanoma cell line characteristics following sFRP1 and sFRP2 modulation. C8161 metastatic melanoma cells were grown in the presence or absence of recombinant sFRP1 and sFRP2 or transfected with the sFRP2 open-reading frame under the control of a constitutive promoter. (A) Expression of sFRP1 and sFRP2 in H9 and CA1 hESCs, HEK293, and C8161 cells as determined by RT-PCR. RT-PCR values are fold change relative to H9 hESCs using RPLPO as an internal control. Error bars represent SEM, n=2. (B) C8161 cells were transfected with either a vector containing the sFRP2 open-reading frame or with the same vector containing no insert. Cells were counted 48 hours post transfection and 7-days following the addition of puromycin to assess survival. Error bars represent SD, n=3. (C) C8161 cells grown in the presence or absence of 200 ng/mL of sFRP1 and sFRP2 for 4 or 7 days were tested for anchorage independent growth using a soft-agar assay. Pictures were taken after 7 days, colonies were allowed to form for a total of 14 days prior to counting. Error bars represent SD, n=3. Significance was determined relative to control for all treatments.

5.3 Discussion

The interactions between hESCs and their soluble microenvironment are essential for control over pathways related to self-renewal and differentiation. Cytokines involved in the regulation of these core pathways are often associated with other factors in the microenvironment that aid in the management of their activity or stability. Many of these co-factors can be bound to, or present in the ECM. As such, the study of the interactions between hESCs and the ECM represents a potentially rich source of information regarding regulation of core pluripotency pathways. Highlighting this is the recent observation that hESC-derived matrix microenvironments can reprogram metastatic melanoma cells [27, 36]. Bioactive factors deposited by hESCs during growth are able to direct cell-fate through activity in extracellular pathways within the microenvironment [27]. However, currently there are few studies that aim to investigate the interactions of hESCs with the ECM mediated by protein deposition in the extracellular space.

Based on our work, growth on CMTX in the absence of bFGF promotes the maintenance of an undifferentiated state in hESCs. This indicates that hESCs are depositing factors in the CMTX that serve to regulate the stem cell state. To investigate this finding further and to validate the ability of our MS-based proteomics screen to identify hESC regulatory factors in the matrix, we targeted sFRP1 and sFRP2 for functional analysis. sFRP1 and sFRP2 are thought to regulate canonical Wnt signaling through direct binding to the soluble Wnt cytokines or their cognate membrane receptors (reviewed in [23]). However, the role of sFRP1 and sFRP2 in hESCs remains

unclear. By utilizing a combination of methods, we analyzed the roles of these Wnt regulators in hESCs.

Using shRNA mediated inhibition of sFRP1 and 2 we observed no significant change in Oct3/4 and Nanog in MEF-CM. Similar trends can be observed in the sFRP1 inhibitor data, where neither inhibitor is able to direct a significant change in pluripotency marker expression at both the transcript and protein level. When shRNA mediated knockdown of expression sFRP1 or sFRP2 is combined with the sFRP1 inhibitors, we observe no significant change in Oct3/4 and Nanog expression at the transcript and protein level. Taken together, these findings indicate that sFRP1 and sFRP2 are not able to direct a significant change in hESCs grown in the complex growth factor microenvironment provided by MEF-CM. However, these findings are limited by the lack of positive control for the small molecule inhibitor due to the poor transfectability coupled with the low activity of the canonical Wnt pathway in hESCs.

To determine whether sFRP1 or sFRP2 were acting through Wnt signaling activated by Wnt3a, we investigated their effects when supplemented exogenously. Previous studies have demonstrated that Wnt signaling in ESCs functions in an 'activation' type model [37, 38]. In this model, Wnt signaling induced by Wnt3a promotes hESC survival and proliferation, but also differentiation to mesendoderm, dependent on the culture conditions. However, there is discordance in the literature regarding the activity of Wnt signaling in hESCs, where activation of canonical signaling through Wnt3a is believed to prevent differentiation, referred to as the 'maintenance' model [39]. Based on our observations Wnt3a functions in the 'activation' model to promote stem cell fate

determination. Supplementation of exogenous Wnt3a promotes hESC survival and proliferation, as well as differentiation dependent on the growth factor conditions. Addition of recombinant sFRP1 and sFRP2 in combination with Wnt3a were able to induce pluripotency marker expression, but only in EB medium in the absence of other exogenous growth factors. When supplemented into Matrigel™ matrix to generate an artificial CMTX, both sFRP1 and sFRP2 could not induce maintenance of an undifferentiated state of hESCs. These data suggest that sFRP1 and sFRP2 are not required for the maintenance of hESC pluripotency in the presence of other growth factors, such as in MEF-CM. However, based on the observation that sFRP1 and sFRP2 can regulate the expression of GSC and MIXL1, they are potentially acting to regulate Wnt induced formation of mesendoderm in differentiating hESCs.

These findings are in agreement with the current 'activation' type model suggested for Wnt regulation in hESCs and recent data regarding the cooperative action of the Wnt, FGF, and Activin/Nodal pathways [37]. Wnt activation in hESCs grown in the presence of a supportive growth factor environment can help promote survival and proliferation [39]. However, in MEF-CM Wnt signaling is not required for the maintenance of self-renewal or pluripotency, and cannot direct a cellular change in the presence of strong activation of the core stem cell Activin/Nodal and FGF signaling pathways [40]. In the absence of growth factor supplementation, activation of Wnt signaling promotes differentiation to mesendoderm, a process that can potentially be regulated by sFRP1 and sFRP2.

Due to the biphasic mode of activity for sFRPs as well as Wnt signaling, the ability of sFRP1 or sFRP2 to regulate hESC behavior is potentially dependent on the dynamic balance between the interacting partners [20, 41]. The recombinant protein concentrations tested in our assay may not have been optimal for sFRP activity in the presence of other Wnt regulatory proteins. Previous studies that have attempted to study the effects of sFRP supplementation on hESCs have required the use of non-physiological amounts of recombinant protein to observe a minor effect [42, 43]. The interactions between sFRP proteins and Wnt ligands may also require facilitation through binding with the ECM, as indicated by the identification of sFRP1 and sFRP2 in the CMTX. sFRP action is known to be regulated by heparin mediated binding to Wnt as well as to the ECM [20, 44]. These interacting factors may cooperate to promote hESC fate determination through regulation of Wnt ligand availability. In other cell types, the sFRP proteins have been reported to antagonize, but also augment canonical Wnt signaling [11, 45]. In the metastatic C8161 cell line we observed that sFRP1 promoted and sFRP2 inhibited their malignant potential based on colony formation in a soft-agar assay. In addition, overexpression of sFRP2 prompted a significant decrease in viable cell number. These findings are not surprising given the divergent roles for sFRP1 and sFRP2 in a variety of pathological conditions (reviewed in [17, 22]). However, based on the limited effects of sFRP1 and sFRP2 on hESC state, it is likely that other factors are combining to contribute to the dynamic regulation of the core pluripotency pathways *in vitro*.

5.4 Methods

5.4.1 Cell culture and harvest – H9 (passage 26) and CA1 (passage 20) hESCs were maintained on CF-1 irradiated mouse embryonic fibroblast (MEF) feeder layers (GlobalStem, Rockville, MD) using media composed of knockout DMEM/F12, 20% knockout serum replacement, 1% non-essential amino acids, 2 mM glutamine (CellGro, Manassas, VA), 0.1 mM 2-mercaptoethanol (Fisher, Toronto, ON), and 4 ng/mL of basic fibroblast growth factor. For feeder-free growth, conventional hESC medium that was conditioned on a layer of mouse embryonic fibroblast feeders (MEF-CM) was used with Matrigel™ (BD Biosciences, Franklin Lake, NJ) coated plates. Medium used for the induction of differentiation in CMTX experiments uses the same recipe as conventional hESC media for growth on MEF feeders as outlined above, minus basic FGF. All media reagents were obtained from Invitrogen unless noted otherwise. H9 cells were obtained from WiCell (WISC, Wisconsin). The CA1 hESC line used in all experiments was obtained from Dr. Cheryle Séguin of The University of Western Ontario [46, 47]. The hiPSC line BJ-1D was derived by reprogramming using retroviral transduction of BJ fibroblasts with the Yamanaka factors essentially as we have previously described [48] and validated as pluripotent using in vitro and in vivo differentiation assays and expression profiling (unpublished results). Cells were passaged mechanically in all experiments and for general maintenance.

Embryoid bodies (EB) were generated using Aggrewell 400Ex plates (StemCell Technologies, Vancouver, Canada). Briefly, 2×10^6 hESCs were harvested

enzymatically using Accutase (Invitrogen) from Matrigel™ coated plates. Cells were reconstituted in Aggrewell medium supplemented with Rock inhibitor (Y-27632, Sigma-Aldrich, St. Louis, MO) at a final concentration of 10 μ M. After plating in Aggrewell dishes, EBs were grown for 48 hours at 37°C prior to transfer to ultra-low adherence tissue culture dishes (Corning, Lowell, MA). After 15 days of culture, EB RNA was harvested using Trizol extraction according to the manufacturer's instructions (Invitrogen). EBs were assayed for expression of CDX2, alpha-feto protein (AFP), GATA-6, GATA-4, Oct3/4, PAX-6, T-brachyury, Nanog, and Neurogenic differentiation 1 (NeuroD1) using TaqMan primer probe sets (Invitrogen). Assay information can be found in Appendix Table 1.15. All EB assays were performed in biological and technical duplicate for each cell line and condition.

5.4.2 sFRP Knockdown and Inhibition - sFRP2 and sFRP1 shRNA knockdown cell lines were generated using the pSUPERIOR.neo + GFP vector (Oligoengine, Seattle, USA). shRNA sequences were obtained using the shRNA design tool from Ambion. Oligos were designed to contain 5' XhoI and 3' HindIII restriction enzyme sites. All oligos were synthesized by Invitrogen unless otherwise noted. Oligos were ligated into pSUPERIOR.neo + GFP vector that was previously digested with XhoI and HindIII (New England Biolabs, Ontario, Canada) and transformed into TOP10 chemically competent *E. coli* (Invitrogen). Transformed clones were selected based on ampicillin resistance and plasmid purified using a PureLink HiPure Midi-prep kit (Invitrogen). shRNA effectiveness was tested in HEK293 cells stably transfected with the pCAGTetRnls vector (Addgene.org). After transfection with pSUPERIOR, HEK293 cells were maintained in RPMI + 10% FBS containing 700 ng/mL puromycin and 700 μ g/mL G418.

shRNA efficiency was determined after 4 days of induction using 1 µg/mL of doxycycline. Sequences for the shRNA constructs found to give the greatest decrease in specific gene expression were selected for use in hESCs. Selected shRNA sequences can be found in Appendix Table 1.16.

hESC lines were transiently transfected with GeneIn reagent (GlobalStem, Rockville, MD). H9 (p30) and CA1 (p22) hESCs were plated at ~80% confluence 24 hours prior to transfection. GeneIn reagents (1:1 mixing ratio) were combined with 4 µg of vector and supplemented into MEF-CM. hESCs were incubated in the media-transfection reagent mixture for 24 hours, followed by a second treatment for a further 24 hours. In cases where differentiation was induced, the second transfection was performed in hESC media –bFGF. Transfection efficiency was determined using flow cytometry based on detection of the GFP reported on the pSUPERIOR vector.

Inhibition of sFRP-1 was carried out using two separate small molecules obtained from Calbiochem (EMD Biosciences, Darmstadt, Germany) [32]. Inhibitors were supplemented at concentrations of 5, 10, 20, 40, and 80 µM in MEF-CM or medium that contained no bFGF. Controls were supplemented with the maximum amount of DMSO used in the experiments with inhibitors present. hESCs were grown in the presence of inhibitor for a period of 4 days during which medium was changed daily.

5.4.3 Generation of Conditioned Matrix – H9 or CA1 stem cells were grown in feeder-free conditions on Matrigel™ in MEF-CM. Stem cells were permitted to grow for a period of 5 days on Matrigel™ for generation of CMTX. Wells were then rinsed thoroughly with PBS to ensure removal of medium components and cells removed from

the Matrigel™ layer using Cell Recovery Solution according to the manufacturer's instructions (BD Biosciences). Fresh hESCs were plated on the after rinsing of the matrix layer. After 24h of culture, hESCs were induced to differentiate through feeding with conventional hESC media –bFGF. Control experiments were prepared using regular Matrigel™ that had not been conditioned but had been treated with the cell removal process.

In antibody blocking CMTX experiments, antibodies were obtained as follows: sFRP2 (Origene, Rockville, MD), sFRP1, Lefty 1, 2 (Epitomics, Burlingame, CA). Anti-rabbit IgG secondary antibody was used as a control. After cell removal from the conditioned Matrigel™, layers were rinsed with 1:1000 dilutions of manufacturer antibody stocks in 1% bovine albumin in PBS. Matrices were incubated for 2 hours at 37°C. After incubation, layers were rinsed multiple times with PBS prior to plating of fresh hESCs. In supplementation CMTX experiments, recombinant sFRP1, sFRP2, Lefty A or B, or Gremlin were added to Matrigel™ prior to polymerization at a concentration of 5 µg/mL. After incubation at 37°C for 1 hour, matrices were treated with the cell removal process and rinsed prior to playing of fresh hESCs. Recombinant sFRP1 & 2, Lefty A, and Gremlin proteins were obtained from R&D Systems (Minneapolis, MN). Recombinant Lefty B was obtained from Sigma (St. Louis, MO). In all cases, cells were fed daily with hESC media –bFGF for 3 days prior to harvest.

5.4.4 Metastatic Melanoma Cell Experimentation – C8161 cells (described in [49]) were cultured in RPMI containing 10% FBS (Invitrogen). In anchorage independent growth assays, C8161 cells were maintained in the presence or absence of 200ng/mL of

sFRP1 and sFRP2 for 4 – 7 days. At each time point, cells were harvested by trypsinization and counted. Soft-agar experiments were performed by resuspending 9,000 cells in a mixture of RPMI/10% FBS + 0.35% agarose. This mixture was plated onto a previously prepared layer of RPMI/10% FBS + 0.5% agarose in single well of a 6-well dish. Cells in soft-agar were fed every 3 days. Colonies were allowed to form for 14 days after plating. Colonies were counted after staining with 0.005% crystal violet in PBS. Soft-agar assays were performed in triplicate for each time point and condition tested.

C8161 transfections were carried out using GeneIn Reagent (GlobalStem). For each transfection, 2 µg of total DNA was diluted in 200 µL of OptiMEM with 3 µL of each GeneIn reagent. Approximately 10,000 C8161 cells were plated in a single well of a 6-well dish 24 hours prior to transfection. Cells were transfected with the pCMV-IRES-GFP-Puro (Origene, Rockville, MD) vector with or without the sFRP2 open reading frame (Origene). Transfection efficiency was monitored using GFP expression. Cells were selected using 700 ng/mL of puromycin 48 hours after transfection. Total viable cells were counted using trypan blue exclusion 48 hours and 7-days post transfection. Experiments were repeated in triplicate for each treatment.

5.4.5 Real-time PCR – RNA was purified using Trizol reagent according to the manufacturer's instructions (Invitrogen) with the following modification: precipitated RNA pellets in isopropanol were centrifuged for 60 minutes at 12000 g at room temperature. After NanoDrop quantification, 1 µg of cDNA was synthesized using the High Capacity cDNA Reverse Transcription Kit with RNase inhibitor (Invitrogen). Real-time PCR was

performed using the TaqMan® Universal PCR Master Mix (Invitrogen). Samples were incubated at 50°C for 2 minutes followed by 10 minutes at 95°C. Samples were then amplified at 95°C for 15 seconds followed by 1 minute at 58°C for 46 cycles. All samples were normalized to the large ribosomal protein RPLPO as a positive control. All primers were obtained from Invitrogen and assay information can be found in Appendix Table 1.15. Each biological replicate was run in triplicate for every marker assayed. All reagents were used according to the manufacturer's instructions.

5.4.6 Immunofluorescence – Immunofluorescence was performed as described previously [50]. Briefly, cells were rinsed and fixed with 4% para-formaldehyde containing 20 mM sucrose. Fixed cells were permeabilized using 0.1% Triton-X100. Prior to staining, cells were blocked using the Dako Serum Free Protein Block solution (Dako, Cambridgeshire, UK). Oct-4 (clone 10H11.2), SSEA-4 (clone MC-813-70), and SSEA-1 (clone MC-480) primary antibodies were obtained from Millipore (Billerica, MA). Cells for Oct-4 labeling were permeabilized using a 0.1% Triton X-100 solution prior to blocking. Cells were labeled with primary antibodies for Oct-4 or SSEA-4 as undifferentiated markers and SSEA-1 for differentiated cells all at concentrations concentrations of 2 µg/mL for 60 minutes at room temperature. Secondary Alexa-fluor 488 goat anti-mouse IgG and Alexa-fluor 568 goat anti-mouse IgM were obtained from Invitrogen (Carlsbad, CA). Secondary antibodies were probed at concentrations of 1 µg/mL for 60 minutes at room temperature. All products were used according to manufacturer's instructions.

5.4.7 Flow Cytometry – All reagents and probes for flow cytometry were obtained from eBiosciences (San Diego, CA) unless noted otherwise. Cells were enzymatically harvested using Accutase (Invitrogen) to obtain a single cell suspension. After centrifugation, cell pellets were resuspended in 5% FBS in PBS. Alexa-488 conjugated SSEA-4 and Alexa-647 conjugated SSEA1 were diluted into the cell mixture according to the manufacturer's instructions. Negative control samples contained respective isotype controls for the primary antibodies used. Solutions were incubated for 2 hours and analyzed using an Accuri C6 (BD Biosciences) flow cytometer after rinsing to remove unbound antibody. Populations were gated according to forward and side scatter patterns with filtering for viable cells using 7-aminoactinomycin D staining. Data was analyzed using FlowJo software (Tree Star, Ashland, OR).

5.4.8 Immunoblotting – Harvested cell pellets were reconstituted in mammalian protein extraction reagent containing protease inhibitor cocktail (Thermo Fisher, Toronto, Canada). 20 µg of protein based on Bradford assay was run on an 8% SDS-Gel. Proteins were transferred to a PVDF membrane (Millipore) and incubated in 5% milk overnight at 4°C. After rinsing in TBS containing 0.1% Tween-20, membranes were incubated for 4 hours with primary antibodies. Oct3/4, Nanog, sFRP1, and sFRP2 antibodies were obtained from Epitomics (Burlingame, CA). β-Actin antibody was obtained from Santa Cruz Biotech (Santa Cruz, CA). After rinsing, membranes were incubated with specific HRP-conjugated secondary antibodies for 1 hour. Blots were developed using Pierce ECL reagent and CL-Xposure film (Thermo).

5.4.9 Statistical Analysis – Statistical analyses were performed using GraphPad Prism software. Results are expressed as SD or SEM as indicated in figure legends. Statistical significance was determined using one-way ANOVA with Tukey post-hoc analysis. When only two samples were being compared, unpaired Students T-tests were applied. Differences were reported as follows: * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$.

Chapter 6

Discussion

6.1 Summary of Accomplishments

It is clear that the microenvironment plays a critical role in the regulation of hESC fate. Central to the potential application of hESCs in therapeutic applications are advances in controlled methods for modulating the pluripotent state. Paramount for development is increasing our knowledge of the processes eliciting control in this dynamic environment. To obtain a complete understanding of the *in vitro* stem cell niche, analysis of soluble and ECM contributors to this environment is necessary. Due to the complex requirements for the *in vitro* maintenance of hESCs, direct analysis of the ECM presents a significant challenge. To this end, we have developed proteomic methodologies for the direct study of the ECM portion of the microenvironment (Chapters 2 – 3). Additionally, we have demonstrated the application of these methods to the analysis of this complex environment, and in doing so have elucidated novel factors involved in hESC regulation (Chapters 4-5).

This chapter contains excerpts from the following paper:

Hughes, C.S., Radan, L., Stanford, W., Betts, D., Postovit, L.M., Lajoie, G.. (2012) "Mass Spectrometry-Based Proteomics Analysis of the Matrix Microenvironment in Pluripotent Stem Cell Culture". (In Preparation)

The complexity of Matrigel™ necessitates the use of quantitative proteomics techniques to study the ECM portion of the microenvironment. To this end, we have developed conditions for the application of the metabolic labeling approach, SILAC, to hESCs (Chapter 2). This new protocol eliminates conversion of isotopically labeled arginine amino acids to proline derivatives and represents a significant increase in simplicity and reduction in cost when compared with alternative methods for addressing this conversion. We also further extend our SILAC approach to a defined hESC media formulation. This defined alternative offers an attractive platform for the study of the microenvironment free of contaminating contributions from MEF feeder layers present in conditioned medium. Furthermore, the extension of this defined medium to the growth of hiPSCs presents new opportunities for the quantitative study of stem cell biology.

A secondary challenge for the analysis of the ECM portion of the microenvironment is the protein complexity of these matrices. MS-based proteomics studies consistently struggle to identify the low-abundance components of complex mixtures in the face of a large dynamic range of protein concentration. This is further complicated with ECM mixtures due to their propensity to polymerize when not chilled. Although our quantitative SILAC strategy would enable distinction between hESC and Matrigel derived proteins, the presence of candidates derived from both sources significantly increases the complexity of the CMTX solution. In order to facilitate the detection of low abundance hESC derived proteins, we have shown the benefits of using a combination of conventional proteomics techniques (Chapter 3). Upon application for the analysis of Matrigel and other cell-derived matrices, we successfully achieve significant depth of coverage in these complex samples. Furthermore, we illustrated the utility of analyzing

matrices used in stem cell culture for the elucidation of components critical for the maintenance of hESC pluripotency.

Finally, through application of the SILAC (Chapter 2) and ECM analysis methodologies (Chapter 3), we obtained a proteomic profile of a matrix layer preconditioned by hESCs (Chapter 4). We then reconcile proteomic datasets from the soluble and ECM portions of the microenvironment previously obtained. Investigation of the CMTX revealed that hESCs generate a self-sustaining niche rich in supportive factors found in Matrigel, as well as in conditioned medium. Functional validation of candidate factors illustrates the complexity of hESC-ECM interactions (Chapter 5). Taken together, these studies will aid in the development of tools for studying the complex interactions between hESCs and their microenvironment.

6.2 The hESC Niche and the ECM

One of the primary goals of research focused on the microenvironment is to elucidate all the processes involved in the control of hESC fate. The ability to control if a stem cell self-renews or differentiates is critical to the potential therapeutic application of hESCs. Parallel to this need is the ability to direct lineage specific differentiation to generate pure populations of tissue-specific cell types. Currently, hESC differentiation is directed through the use of cocktails of exogenously supplemented growth factors (reviewed in [1]). Depending on the desired cell type, multiple differing cocktails can be required dependent on the time point of the differentiation protocol [2]. Which factors are supplemented is conventionally determined through large screens of proteins involved in pathways that are known to be critical for the regulation of pluripotency. However,

many of these generated protocols struggle to produce pure populations of tissue-specific cell types. This shortcoming stems from an incomplete understanding of all of the processes contributing to hESC control within the *in vitro* microenvironment. As we have shown in this thesis, these processes can potentially be governed by interactions of hESCs or cytokines with the ECM.

6.2.1 Wnt Signaling in the Microenvironment

There are three primary pathways that are activated upon binding of Wnt ligands to their cognate receptors (For a review of Wnt signaling, see [3, 4]). The canonical pathway involves interaction of Wnt ligands at the cell surface with Frizzled (Fz)/low-density lipoprotein receptor-related protein (LRP) complexes. In the absence of Wnt, cytoplasmic β -catenin is associated with a complex containing Axin and Adenomatous Polyposis Coli (APC). This complex facilitates the phosphorylation of β -catenin by glycogen synthase kinase 3- β (GSK-3 β) resulting in its subsequent degradation. Upon binding of Wnt ligands, phosphorylation of β -catenin is inhibited allowing it to translocate to the nucleus where it regulates gene expression through interaction with lymphoid enhancer factor (LEF)/T-cell factor (TCF) transcription factors.

In the extracellular space, Wnt proteins are relatively insoluble due to the presence of a palmitoyl lipid modification. This modification has been shown to be important for the secretion, activity, and solubility of Wnt proteins as well as for their interactions with binding partners [5]. In the extracellular space Wnt signaling is antagonized through interactions with a variety of inhibitors (reviewed in [6]). The two main groups are the soluble frizzled related proteins (sFRP) and the Dickkopf (Dkk) family. Dkk proteins are

believed to inhibit canonical Wnt signaling through interaction with the LRP receptors [6]. The sFRP family is thought to bind directly to the Wnt ligands themselves, leading to a diverse array of potential roles for these proteins other than antagonism. This is emphasized by the multiple divergent roles for the sFRP family members in a variety of pathological conditions (reviewed in [7, 8]).

In mouse ESCs, activation of the canonical Wnt pathway is understood to promote the maintenance of self-renewal and pluripotency (reviewed in [9]). In human ESCs, the picture is less clear, and contrasting roles for canonical Wnt signaling have been suggested [10, 11]. However, recent data has garnered support for a model of Wnt signaling activation that supports stem cell fate determination [12, 13]. Activation of canonical Wnt signaling enhances hESC growth and survival in an undifferentiated state, as well as their differentiation. However, aberrant regulation of the canonical pathway is thought to be involved in diseases such as cancer [3]. Therefore, control over the activity of Wnt ligands in the extracellular space is potentially critical for the proper maintenance of the ES cell phenotype.

From our analysis it remains unclear what role the sFRP proteins play in the regulation of Wnt signaling in the extracellular space and the resultant changes in hESC phenotype (Chapter 5). shRNA mediated knockdown of sFRP1 or 2 gene expression or direct inhibition of sFRP1 protein using a small molecule inhibitor results in no change in expression for Oct3/4 and Nanog, hallmarks of pluripotency. Based on our findings with direct supplementation of soluble recombinant Wnt3a, it is clear that Wnt3a promotes stem cell fate determination dependent on the growth factor microenvironment. sFRP1

and sFRP2 are unable to inhibit Wnt3a induced changes when supplemented in MEF-CM. These data are potentially confounded by the presence of numerous other Wnt regulatory proteins in both hESC conditioned medium [14] and in the CMTX (Chapter 4-5), such as Cerberus. The reduction of sFRP activity through small molecule inhibition or shRNA knockdown is potentially compensated for by these other regulatory proteins or increased activity of additional sFRP family members. The effects of direct supplementation of sFRP1 and sFRP2 are also potentially reduced in this way, where other proteins can restore the proper balance of Wnt activity. The complexity and cross-talk in signaling pathways present in the microenvironment suggests that a combination of factors act on hESCs. This is highlighted by the results of our proteomics screen where other antagonists of core pluripotency pathways were identified.

6.2.2 TGF- β Signaling in the Microenvironment

In the MS-based proteomics screen of CMTX we identified factors implicated in the regulation of TGF- β pathways, specifically Lefty 1 and 2 and Cerberus proteins (Chapter 4). The TGF- β superfamily of proteins consists of over 30 members, including Activins, Nodal, and bone morphogenic proteins (BMP). TGF- β family members are directly involved in processes such as cell growth and apoptosis. Furthermore, this family has been implicated as playing a prominent role during embryonic development in processes such as gastrulation and patterning (reviewed in [15]). TGF- β signaling primarily operates via transmission of extracellular signals through complexes of type-I (activin receptor-like kinases, e.g. ALK4, ALK7) and type-II (activin receptor IIB,

ActRIIB) transmembrane receptors and their associated co-factors (e.g. Cripto). These signals are translated to phosphorylation events in different complexes of Smad proteins that in turn regulate target gene expression in the nucleus (reviewed in [15]).

TGF- β signaling is mediated through interactions between soluble factors in the microenvironment. The Lefty proteins are extracellular antagonists of TGF- β signaling that act through inhibition of the embryonic morphogen Nodal [16]. Regulation of Nodal activity through inhibition by Lefty has been shown to be critical for proper development during embryogenesis [16]. In hESCs, activation of the Smad2/3 branch of the TGF- β pathway mediated by Nodal or Activin is known to be one of the core processes critical for the maintenance of self-renewal and pluripotency [17, 18]. Defined media such as E8 and the defined SILAC medium employed here contain exogenous Activin or Nodal to facilitate the maintenance of undifferentiated hESCs [19, 20]. Activin has also been found in MEF conditioned medium screened using MS-based proteomics [14, 21]. Inhibition of Lefty proteins has been shown to promote maintenance of undifferentiated hESCs; however, correct differentiation of these cells is impaired [22]. Interestingly however, inhibition of Nodal using Lefty does not induce differentiation of hESCs [18]. Moreover, induction of Lefty has been observed to be important for exit from the pluripotent state in embryoid body formation assays [23]. Taken together, these findings indicate that Lefty functions to maintain a balance of Nodal induced TGF- β initiation in hESCs.

Detection of Lefty isoforms in CMTX illustrates that hESCs are secreting factors to generate a matrix microenvironment designed to regulate extracellular signaling

involving soluble factors. Although the direct supplementation of recombinant Lefty was not able to enhance the maintenance of an undifferentiated state in hESCs induced to differentiate, regulation of Nodal signaling by Lefty in the microenvironment has previously been observed to be facilitated through interactions with the ECM [24]. In *Xenopus* embryos, the interaction of Lefty with ECM linked heparan sulfate proteoglycans has been observed to facilitate control over Nodal signaling [24]. The ECM enhances the stability, transport, and effective range of the Lefty and Nodal proteins [24]. These effects aid in the generation of morphogen gradients important for proper development. Similar processes in the microenvironment potentially contribute to maintenance of a 'primed' hESC state, wherein control over differentiation is enhanced by interactions between Lefty and Nodal facilitated by the ECM.

The ability of Lefty containing CMTX to enhance maintenance of an undifferentiated state is potentially acting through pathways alternative to Nodal induced TGF- β activation. The positive effects of Nodal signaling on hESCs are well established [17, 18]. However, exogenous supplementation with Lefty does not induce differentiation of hESCs [18]. Expression of Nodal and Lefty proteins are known to be rapidly decreased following the induction of differentiation [25]. The presence of Lefty in the CMTX and the absence of hESC derived Nodal following differentiation potentially confer an enhancement in the maintenance of undifferentiated cells through other TGF- β pathways. BMP signaling through Smad 1/5/8 is observed to be increased specifically in differentiated hESCs [25]. Moreover, BMP signaling induced by the extracellular cytokine BMP-4 is known to induce differentiation of hESCs, and its inhibition using antagonists such as Noggin to block differentiation [26, 27]. Lefty has been observed to

inhibit BMP-4 induced TGF- β activation by blocking the phosphorylation of Smad proteins in P19 embryonal carcinoma cells [28]. In our CMTX experiments, Lefty may be acting on BMP-4 induced TGF- β signaling and thereby inhibiting differentiation resulting from activation of this pathway. This is highlighted by the presence of other factors in the CMTX that inhibit Nodal/BMP signaling, such as Cerberus.

6.2.3 New View of the hESC Microenvironment

Using the assays presented here we observed the ability of the CMTX, containing regulators of the Wnt and TGF- β pathways, to alter the behavior of hESCs in the microenvironment. However, in our recombinant and antibody blocking CMTX experiments, both of these pathways were monitored individually and neither was able to fully recapitulate the positive effect observed for hESCs on CMTX. The microenvironment is considered to be an effector of cellular change acting through a dynamic balance resulting from an array of contributors. As such, it is likely that the core pathways we have investigated here function together in the CMTX to generate the observed effect. Indeed, multiple levels of cross-talk have been suggested amongst the FGF/TGF- β /Wnt pathways [13, 29]. In hESCs, the maintenance of self-renewal and pluripotency is controlled by the co-operative activity of these three core pathways. The addition of the ECM to this model adds an additional layer of complexity, wherein proteins bound to the matrix can act to regulate individual pathways, the effects of which are subsequently potentiated through cross-talk with others. Given the known roles of the ECM in the contribution to the generation of morphogen gradients in other

developmental systems, it is not hard to envision a similar activity regulating pluripotency in the hESC niche.

6.3 Development of ECM Environments for hESCs

The ECM is one of the core elements governing cellular changes in the microenvironment. Not only can the ECM regulate cell growth, attachment, and movement, but in hESC culture can affect processes such as differentiation. The beneficial effects of the ECM are further highlighted by the positive outcome observed when *in vivo* injections directed at teratoma formation are performed using hESCs diluted in Matrigel™ [30]. The proposed mechanism for the enhancement observed in the presence of Matrigel™ is related to the reduction of apoptosis through interactions with the ECM and the potential for Matrigel to induce growth factor stimulation [30]. The xenogenic nature of Matrigel inhibits its use with injections or otherwise in potential therapeutic strategies. Developing an understanding of the processes and factors regulated by the components of Matrigel, or other hESC supportive matrices will aid in the generation of xeno-free matrices for use *in vitro* or *in vivo*.

Using the techniques presented in this thesis, analysis of the diverse range of matrices available for hESC culture will assist in the development of ECM supports suitable for a wide range of hESCs. Using MS-based proteomics we demonstrate the utility of determining the composition of cell-derived and recombinant growth matrices used in hESC culture (Chapter 3). From these studies we were able to elucidate factors directly related to the enhancement of hESC growth in *in vitro* culture. Moreover, using the methods developed and optimized here to facilitate the analysis of hESC-derived

matrices, we were able to characterize a novel self-supportive matrix microenvironment generated by the stem cells during growth *in vitro*. The findings of these works will have a direct application towards obtaining a comprehensive understanding of hESC interactions within the microenvironment. Perhaps more importantly however, the information contained in this thesis can be used to aid in the development of biomaterials designed to mimic the ECM.

In recent years, as a direct result of the potential for the application of stem cells in therapeutic applications, numerous biomaterials have been tested for their viability for the maintenance of hESCs (reviewed in [31]). Natural materials such as collagen, hyaluronic acid, and alginate have all shown promise for the control of self-renewal or differentiation of stem cells [32-34]. Synthetic materials such as PLGA and PEG have also been utilized to control the properties of stem cells *in vitro* (reviewed in [35]). Pioneering work from the Langer group was one of the first studies to analyze hESC-ECM interactions on a large-scale using synthetic polymer based arrays [36, 37]. Utilizing different combinations of acrylate, diacrylate, dimethacrylate, and triacrylate monomers, they profile over 1700 ECM interactions in a single array. In recent years, nano-scale array platforms that utilize conventional DNA spotting technology have facilitated the analysis of a wide range of biomaterials for their effect on stem cell maintenance and differentiation [38-42]. The designs of polymers or bioactive materials to be screened are typically done in a discovery type fashion, or through mimicry of known cell-ECM interactions. Elucidating core ECM factors present in cell-derived matrices can potentially aid in directing these array-based screens. By focusing on

matrices known to be beneficial for stem cell maintenance, factors identified in our proteomics screen can be used to generate biomaterials tailored for hESCs.

Aside from the ability to regulate the activity of these matrices through modulation of properties such as stiffness, size, and shape, other physical modifications can be made to promote the desired experimental outcome [35]. The addition of bioactive growth factors directly to the polymerized matrix has been used to modulate the self-renewal and differentiation of hESCs [43, 44]. Controlling the availability of these growth factors can be regulated through the addition of compounds such as heparan sulfate to the matrix [35]. Based on the findings presented here, the presence of multiple soluble growth factor binding and regulatory proteins in the matrix can regulate the differentiation of stem cells. By determining the pathways that are potentially regulated by candidate proteins identified in the CMTX, our proteomic analyses can aid in the development of biomaterials that mimic the necessary binding or cytokine requirements. Furthermore, investigating components of hESC-derived matrix microenvironments as we have attempted to do here can be completed on defined matrices instead of Matrigel. The ability to control the deposition and release of bioactive growth factors from the matrix through the use of synthetic alternatives will permit direct validation of deposited factors. Together, these complementary studies would be beneficial for determining ECM-associated regulatory proteins that can be combined with biomaterials to control pathways related to self-renewal and differentiation.

6.4 Studying hESCs using Quantitative Proteomics

With the increase in research focused on ESCs, the number of developmentally related cell types that can be successfully cultured *in vitro* is rising. It is clear that comparison of pluripotent or multipotent progenitor cells with differentiated sub-types can provide valuable information on stem cell regulation. The application of high-throughput genomic technologies in these areas has already resulted in advancement in our understanding of stem cells. However, global screening using proteomics methods has lagged behind, partially due to the difficulty in achieving cell quantities amenable to these experiments. This is particularly difficult for hESCs due to their strict culture requirements.

Application of metabolic labeling approaches such as SILAC opens new avenues for performing comparative analyses of multipotent and differentiated cell types. Utilization of our SILAC protocol provides researchers with the tools necessary to acquire the quantities of cells required, in a reproducible fashion, for proteomics experiments. Currently there is only one other example of a defined hESC culture medium amenable to SILAC experimentation presented in the literature [45]. However, as the efficiency of methods for the *in vitro* culture of hESCs continues to increase, so too will the development of enhanced media for their culture. This is highlighted by recent work from the Thomson lab where they systematically tested individual medium components to assess their necessity for the maintenance of hESCs and hiPSCs [20]. They demonstrated that the SCs could be maintained for extended periods in media containing just eight ingredients, referred to as E8 (insulin, selenium, transferrin,

l-ascorbic acid, FGF2 and TGF- β (or Nodal) in DMEM/F12). E8 has the added benefit of being serum-free, offering an attractive platform for the analysis of conditioned media from hESCs grown in feeder-free conditions. As we have demonstrated here (Chapter 2), the adaption of chemically defined culture media such as E8 to SILAC experimentation can be achieved simply by modulating the amino acid composition, even for metabolically sensitive cell types such as hESCs.

Outside of direct comparisons of pluripotent and differentiated cell types, quantitative proteomics methods like SILAC offer many other attractive research avenues in the study of hESC biology. An emerging area where quantitative mass spectrometry approaches have a direct application is in the analysis of global protein turnover in hESCs. The metabolic incorporation of the SILAC label permits time-dependent analysis of protein synthesis and degradation rates, analogous to a pulse-chase style experiment [46]. Currently there are no examples of the direct analysis of protein turnover on a global scale in mouse or human ESCs. The most comprehensive proteomics studies of hESCs and hiPSCs to date have focused on measuring abundance snapshots [47]. Recent work from the Selbach lab has demonstrated the utility of measuring protein and mRNA degradation rates to obtain a picture of global cell regulation as a function of turnover [48].

It is not hard to envision the potential applications for SILAC derived turnover measurements in hESCs or their niches. Direct examination of the pathways that feed into the maintenance of homeostasis through modulation of the synthesis and degradation of proteins on a global scale can potentially clarify the mechanisms

governing pluripotency of hESCs and preservation of a state primed for differentiation. Furthermore, metabolic labeling with SILAC can be used to unlock the potential mechanisms that regulate the switch from a primed state to differentiation in stem cell populations. When coupled with established methods for measuring mRNA turnover [49], or high-resolution screens of global translation rates using ribosome density profiling [50], the potential acquisition of a global measurement of hESC control makes the application of SILAC protocols such as those developed here (Chapter 2) an attractive platform in stem cell research. Additionally, coupling these quantitative proteomics analysis platforms to investigation of hESC niches offers the opportunity to monitor temporal signaling patterns as indicated by differential protein levels in conditioned media or matrices.

6.5 Future Applications in Stem Cell Research

6.5.1 Niches from other stem cells

The hESC niche represents a dynamic environment that is critical for control over decisions concerning cell fate and its analysis is crucial for a complete understanding of pluripotency. However, the recent expansion of research involving adult stem cells (ASC) offers new opportunities for studies directed at investigation of the microenvironment. Furthermore, the rapid expansion of derived induced pluripotent stem (iPS) cells from a variety of tissue and disease types offers interesting new avenues for study of the microenvironment. The analysis of CMTX completed here (Chapter 4) was performed on a single iPS cell line. Our findings indicate significant similarity between the hESC and iPS cell derived matrices analyzed. However, due to

the distinct differences between iPS lines dependent on their derivation method or parental cell origin [51, 52] (reviewed in [53]), expansion of our analysis to include other lines is desirable.

The application of quantitative proteomic methodologies such as those developed here (Chapter 2) also offer interesting avenues for continuing exploratory studies in stem cell niches *in vitro*. The induction of pluripotency in iPS cells is known to take upwards of 30 days following transgene expression in culture [54]. Quantitative changes of protein turnover during reprogramming coupled with temporal examination of secreted factors in the niche would provide valuable insight into processes contributing to the induction of pluripotency. The assessment of expression patterns during reprogramming of candidate proteins identified in this thesis (Chapter 4) could reveal valuable information on factors such as the sFRP, Cerberus, and Lefty proteins. With the previous knowledge that these proteins function at the crossroads of the undifferentiated and differentiated state, their examination during reprogramming could reveal distinct expression patterns that contribute to pluripotency. Additionally, these trends can be compared to data generated in this and other studies of the microenvironment to characterize their correlation to known roles in hESCs.

6.5.2 Addressing heterogeneity in stem cell cultures

Two of the core components of the microenvironment are the ECM support and paracrine/autocrine signaling regulated by soluble factors. In the hESC niche this can be expanded to include accessory or support cells that contribute to processes involved with both of the previously mentioned core components. In two-dimensional adherent

cultures *in vitro* hESCs tend to grow as tight aggregates. hESCs are refractory to passaging or maintenance as single cells. Within these cell clusters, recent work has observed the ability of hESCs to generate colony specific niches that contain signaling gradients that effect core pluripotency pathways [55]. These findings suggest that a level of cellular heterogeneity exists within hESC cultures and even within specific colonies. The non-homogeneous nature of stem cell culture has been noted before in the literature [56-60]. This variability can be the result of differences in cell cycle progression as well as spontaneous differentiation. Even in a wholly undifferentiated population, differences in core pluripotency genes such as Nanog have been observed [61]. Considering the ability of the microenvironment to elicit changes in cell behavior, differences in hESC colony specific niches can potentially be a significant contributor to this heterogeneity. By collecting data that represents an average of a heterogeneous population, the potential sensitivity of the results is limited as changes represented in a sub-type of cells will be diluted. Therefore, developing methods directed at monitoring hESC characteristics at a single-cell level are critical for in-depth microenvironment analysis.

Recent developments in methods for single-cell monitoring of global processes such as transcription and translation offer new avenues for stem cell research (reviewed in [62, 63]). Furthermore, with the development of methods for high-throughput analysis of matrices using spotted arrays (see Section 5.3), single-cell analysis of the hESC niche is now potentially viable. As such, studies directed at single-cell analysis of behavior patterns in hESC niches have been presented [55]. The work presented here offers potential extensions for modeling of single-cells in hESC niches. Using factors

identified in our proteomic characterizations of matrices (Chapter 3 – 4) in combination with micropatterning techniques for generating ECM arrays, the activity of single cells within colonies in response to seeded gradients of deposited factors could be assayed. Arrays such as these can potentially reveal the specific regulatory mechanisms of factors identified in our analysis of CMTX, such as the sFRP and Lefty proteins. The expression of Lefty B has previously been observed to change dependent on hESC colony size, indicating the potentially dynamic nature of these inhibitors [55]. Furthermore, the established gradient signaling mechanisms of both the Wnt and Nodal pathways in development indicate that a similar process may be occurring *in vitro* in the hESC niche. The ability to perform directed screens based off of factors identified in our study coupled with high-resolution single-cell data acquisition offers an attractive platform for addressing key questions concerning the hESC microenvironment.

Copyright Permissions

For Molecular and Cellular Proteomics:

http://mcponline.org/site/misc/Copyright_Permission.xhtml

These guidelines apply to the reuse of articles, figures, charts and photos in the *Journal of Biological Chemistry, Molecular & Cellular Proteomics* and the *Journal of Lipid Research*.

For authors reusing their own material:

Authors need **NOT** contact the journal to obtain rights to reuse their own material. They are automatically granted permission to do the following:

- Reuse the article in print collections of their own writing.
- Present a work orally in its entirety.
- Use an article in a thesis and/or dissertation.
- Reproduce an article for use in the author's courses. (If the author is employed by an academic institution, that institution also may reproduce the article for teaching purposes.)
- Reuse a figure, photo and/or table in future commercial and noncommercial works.
- Post a copy of the paper in PDF that you submitted via BenchPress.
 - Only authors who published their papers under the "Author's Choice" option may post the final edited PDFs created by the publisher to their own/departmental/university Web sites.
 - All authors may link to the journal site containing the final edited PDFs created by the publisher.

Please note that authors must include the following citation when using material that appeared in an ASBMB journal:

"This research was originally published in Journal Name. Author(s). Title. *Journal Name*. Year; Vol:pp-pp. © the American Society for Biochemistry and Molecular Biology."

For the Journal of Proteomics:

<http://www.blackwellpublishing.com/permis.asp?ref=0962-1075&site=1>

Permission to reproduce Wiley journal Content:

Authors - If you wish to reuse your own article (or an amended version of it) in a new publication of which you are the author, editor or co-editor, prior permission is not required (with the usual acknowledgements). However, a formal grant of license can be downloaded free of charge from Rightslink if required.

For Methods in Molecular Biology:

This is a License Agreement between Christopher Hughes ("You") and Springer ("Springer") provided by Copyright Clearance Center ("CCC"). The license consists of your order details, the terms and conditions provided by Springer, and the payment terms and conditions.

All payments must be made in full to CCC. For payment instructions, please see information listed at the bottom of this form.

License Number	2863840437193
License date	Mar 07, 2012
Licensed content publisher	Springer
Licensed content publication	Springer eBook
Licensed content title	De Novo Sequencing Methods in Proteomics
Licensed content author	Christopher Hughes
Licensed content date	Dec 16, 2009
Type of Use	Thesis/Dissertation
Portion	Excerpts
Author of this Springer article	Yes and you are the sole author of the new work
Order reference number	
Title of your thesis / dissertation	Mass Spectrometry-Based Proteomics Analysis of the Matrix Microenvironment in Pluripotent Stem Cell

Culture
Expected completion date Apr 2012

Total 0.00 USD
Terms and Conditions

If you would like to pay for this license now, please remit this license along with your payment made payable to "COPYRIGHT CLEARANCE CENTER" otherwise you will be invoiced within 48 hours of the license date. Payment should be in the form of a check or money order referencing your account number and this invoice number RLNK500734946.

Once you receive your invoice for this order, you may pay your invoice by credit card. Please follow instructions provided at that time.

**Make Payment To:
Copyright Clearance Center
Dept 001
P.O. Box 843006
Boston, MA 02284-3006**

For suggestions or comments regarding this order, contact RightsLink Customer Support: customer care@copyright.com or +1-877-622-5543 (toll free in the US) or +1-978-646-2777.

Gratis licenses (referencing \$0 in the Total field) are free. Please retain this printable license for your reference. No payment is required.

Christopher Hughes

Education

PhD in Biochemistry – University of Western Ontario, London, Canada (Jan 2009 – Current)

Masters of Biochemistry – University of Western Ontario, London, Canada (May 2007 – Jan 2009)

Honors Bachelor of Science – University of Waterloo, Waterloo, Canada (Sept 2002 – May 2007)

Stem Cell Training Course – Stem Cell Technologies, Vancouver, Canada (April 2010)

Quantitative Proteomics Workshop Short Course – ASMS 2009

FT-ICR Mass Spectrometry Workshop Short Course – ASMS 2008

Achievements and Publications

Publications:

Hughes, C.S. et al. (2012) Mass Spectrometry-Based Proteomics Analysis of the Matrix Microenvironment in Pluripotent Stem Cell Culture. (In preparation)

Presentations:

Hughes, C.S. *et al.* (2011) – HUPO 2011 – Analysis of Human Embryonic Stem Cell Depositome (Poster Number – P1346)

Hughes, C.S. *et al.* (2011) – ISSCR – Analysis of Human Embryonic Stem Cell Depositome (Poster Number – 2219)

Hughes, C.S. *et al.* (2010) – Canadian National Proteomics Network Conference – Analysis of Human Embryonic Stem Cell Depositome (Poster)

Hughes, C.S. *et al.* (2010) – HUPO 2010 – Matrigel: A complex mixture required for optimal growth of cell culture (Poster)

Hughes, C.S. *et al.* (2010) – HUPO 2010 – Analysis and quantitation of a glycogen synthase kinase-3 knockout embryonic stem cell line to a depth of >3500 proteins (Poster Number)

Hughes, C.S. *et al.* (2009) – ASMS 2009 – Analysis and quantitation of a glycogen synthase kinase-3 knockout embryonic stem cell line to a depth of >3500 proteins (Poster)

Hughes, C.S. *et al.* (2008) – ASMS 2008 – Prevention of amino acid conversion in SILAC experiments with embryonic stem cells (Oral presentation)

Awards:

NSERC Canadian Graduate Scholarship – Doctoral (May 2009 – Current)

NSERC Canadian Graduate Scholarship – Masters (May 2008 – May 2009)

NSERC Undergraduate Research Scholarship – (Jan 2006 – May 2006)

USC Excellence in Teaching Award – (2009, 2011)

Young Investigator Award – HUPO 2010

CSMS Student Travel Award – ASMS 2009

Professional Experience

Apr. - Sept. 2006 **Merck Frosst Canada** – Pointe-Claire, QC

I spent a single work term at Merck Frosst working on the drug metabolism team. My main project while at Merck involved testing and validating a new mass spectrometer ion source based on thermal desorption. I was involved in all aspects of the project from sample and instrument preparation, analysis, interpretation, and manuscript authoring. My work at Merck resulted in a publication: Wu, J. (2007) *Anal. Chem.* 79:12, 4657 – 4665.

Jan. - Apr. 2006

Radiant Technologies Inc. – Burlington, ON

I spent a single work term at Radiant working in the drug purification division. While there I would perform large column (80L) purification and separation of an active drug ingredient from natural sources. I was part of all stages of the process from crude product to purified form. My main duties were running, maintenance, packing of the large columns, and purification post-column.

Sept. 2004 - Sept. 2005

MDS Sciex – Concord, ON

I spent two work terms in the demo and projects laboratory department. While at MDS, I worked with all types of MDS Sciex mass spectrometry hardware and software as well as on HPLC hardware from a wide range of manufacturers. I completed a project profiling carcinogenic food dyes found in spices from around the world. As well, I completed another project profiling excipients from analgesic drugs in an attempt to identify counterfeit drugs. Both of these reports have been presented at conferences and are frequently used as sales information for instrumentation. I also acted in a support role providing worldwide technical support on Sciex hardware and software.

Jan. - Apr. 2004

Agriculture and Agri-Food Canada – Harrow, ON

While at Agri-food, I worked in the dry beans division. I studied bean plants under various diseased conditions in an attempt to isolate resistant varieties. Inoculated plants were analyzed visually as well as at the DNA level for changes. A secondary project I was part of involved the results of mechanical damage to seedling growth and maturity.
