Abstract

Aerodynamic drag in the atmospheric boundary layer (ABL) is affected by the structure and density of obstacles (surface roughness) and nature of the terrain (topography). In building codes and standards, average roughness is usually determined somewhat subjectively by examination of aerial photographs. For detailed wind mapping, boundary layer wind tunnel (BLWT) testing is usually recommended. This may not be cost effective for many projects, in which case numerical studies become good alternatives. This thesis examines Computational Fluid Dynamics (CFD) for evaluation of aerodynamic roughness of the built environment and complex terrain.

The present study started from development of an in-house CFD software tailored for ABL simulations. A three-dimensional finite-volume code was developed using flexible polyhedral elements as building blocks. The program is parallelized using MPI to run on clusters of processors so that micro-scale simulations can be conducted quickly. The program can also utilize the power of latest technology in high performance computing, namely GPUs. Various turbulence models including mixing-length, RANS, and LES models are implemented, and their suitability for ABL simulations assessed.

Then the effect of surface roughness alone on wind profiles is assessed using CFD. Cases with various levels of complexity are considered including simplified models with roughness blocks of different arrangement, multiple roughness patches, semi-idealized urban model, and real built environment. Comparison with BLWT data for the first three cases showed good agreement thereby justifying explicit three-dimensional numerical approach. Due to lack of validation data, the real built environment case served only to demonstrate use of CFD for such purposes.

Finally, the effect of topographic features on wind profiles was investigated using CFD. This work extends prior work done by the research team on multiple idealized two-dimensional topographic features to more elaborate three-dimensional simulations. It is found that two-dimensional simulations overestimate speed up over crests of hills and also show larger recirculation zones. The current study also emphasized turbulence characterization behind hills. Finally a real complex terrain case of the well-known Askervein hill was simulated and the results validated against published field observations. In general the results obtained from the current simulations compared well with those reported in literature.

Keywords: Computational fluid dynamics, Aerodynamic roughness, Complex terrain, Atmospheric boundary layer, Parallel CFD, Turbulence modeling

Co-Authorship Statement

In Chapter 3, a conference paper titled 'Application of an artificial neural network model for boundary layer wind tunnel profile development' is extracted and published with Simon Levin, who provided the BLWT data for training and validation of the ANN model.

Other papers have been extracted from the cores of Chapters 3,4,5 and submitted for publishing in Journal articles.

Acknowledgements

I would like to thank my major advisor Dr. Girma T. Bitsuamlak for supervising my work here at Western and also at FIU where the research is started. This work would not have been possible without his active support and daily involvement. I would also like to express my sincere gratitude to Dr. Ashraf El Damatty, Dr. Horia M. Hangan, Dr. Fernando Miralles, Dr. Arindam G. Chowdhury and Dr. Ping Zhu for their constructive input in the completion of this research.

I would like to acknowledge the Civil and Environmental Engineering Department at Western and FIU, CEATI International Inc., and the National Science Foundation (NSF) for their financial support of my doctoral research.

I would also like to thank the SHARCNET and MAIDROC high performance computational facility centers that were instrumental for the completion of the study. The help and the moral support I have received from my friends and colleagues is also appreciated.

Finally, I would like to thank my parents and sisters for their unconditional love, encouragement and support to my academic career.

Nomenclature

α	Power law coefficient
Δ	LES filter width
ΔS	Relative speed up ratio
Δt	Time step
ϵ	Turbulent energy dissipation rate
\hat{g}	Peak factor
κ	von Karmann constant
λ_f	Frontal area density ratio
λ_p	Planar area density ratio
μ	Dynamic viscosity
ν	Kinematic viscosity
ν_t	Turbulent viscosity
Ω	Vorticity
\bar{U}	Mean wind speed
ϕ	Any flow variable
ρ	Density of air
τ	Surface shear stress
$\tau_{Reynolds}$	Surface Reynolds shear stress

$\tau_{xy}, \tau_{xz}, \tau_{yz}$ Surface shear stresses on different planes

A_d Total area of obstacles

A_f Frontal area of obstacles

A_p Planar area of obstacles

c, d Inverse power law coefficients of ASCE-7

C_D Drag coefficient

C_s Smagorinsky constant

C_{ks} Roughness constant

Co Courant number

d Displacement height

F Body force

f_c Coriolis parameter

G Gradient height

g Gravitational acceleration 9.8 m/s^2

H Height of obstacle such as hill or blocks

I Integral time scale

I_u Longitudinal turbulence intensity

I_v Vertical turbulence intensity

I_w Transverse turbulence intensity

k Turbulent kinetic energy

K_s Sand grain roughness

L_u Longitudinal length scale of turbulence

l_{mix}, l_m Mixing length

M_t	Topographic modification factor
p	Pressure
P_e	Peclet number
Re	Reynolds number
Ro	Rossby number
T	Deviatoric component of stress tensor
U	Instantaneous wind speed
u'	Fluctuating component of wind speed
U_+	Dimensionless velocity
U_*	Friction velocity
U_p	Horizontal velocity component at the first near wall cell
V	Vertical velocity component
v'	Fluctuating component of vertical wind speed
W	Transverse velocity component
w'	Fluctuating component of transverse wind speed
x	Longitudinal axis
X_f	Fetch length
y	Transverse axis
y_+	Dimensionless wall coordinate
Y_p	Perpendicular distance to the wall from nearest cell
z	Vertical axis
z_0	Surface roughness length
z_{ref}	Reference height at which wind speed is measured

Chapter 1

Introduction

1.1 Overview

Computational wind engineering (CWE) is an inter-disciplinary field that uses Computational Fluid Dynamics (CFD) as the basic tool for studying wind effects on structures and the built environment in general. Some commonly conducted CWE studies include design of buildings for wind loads, assessment of wind hazards due to hurricanes and tornadoes, wind energy production assessment, pollutant dispersion in the built environment etc. Advances in computing technology allow for conducting bigger and more refined simulations with in a short time, thus CFD programs should be written to exploit future computing hardware. New numerical model development and validation with experiment is also an important aspect of CWE. The current work focuses on aspects of CWE regarding atmospheric simulations in the boundary layer and exploiting future computing hardware to accelerate CFD simulations. The particular subject of study is estimation of aerodynamic roughness, which is important in the development of models that represent atmospheric processes ranging from the microscale to the mesoscale (Hansen 1993).

1.1.1 Methods for investigation of atmospheric flow over topography

Numerical modeling of the atmosphere has been successfully used for weather prediction (NWP) since it was first introduced by Richardson (1922). One such NWP model is the Weather Research and Forecasting (WRF) model that is used for weather forecasting as well as research in extreme weather conditions such as hurricanes. NWP simulations concern the upper part of the atmosphere and usually have resolutions in the order of 5km. The resulting resolution is usually too coarse to fully understand flow behavior near the ground in a complex

terrain or urban exposures, and as such cannot be directly used for wind engineering purposes that require more detail about wind flow characteristics. Despite these limitations, mesoscale ($\geq 5km$) simulations can be used as boundary conditions for detailed microscale ($\leq 5km$) simulations. Also if the terrain is flat and has no obstacles, extrapolation of results from a height of 4km to the ground may be acceptable (Rasoulli 2010). However that is rarely the case, and such extrapolations on complex terrain are often incorrect. Therefore it is necessary to conduct micro-scale simulations that take in to consideration topographic features and built environment as a whole when detailed wind flow characteristics are required, which is the topic of the current research.

Among experimental methods in wind engineering, Boundary Layer Wind Tunnel (BLWT) testing is industry accepted and most widely used for studying wind flow characteristics in an area of size 5-30 km, mainly because it is relatively cheaper and takes less time compared to field investigations. Numerical simulation is an attractive alternative to BLWT that can further reduce the associated cost and time of investigation. BLWT studies over scaled models of microscale size have been used to obtain detailed wind maps. Many such studies have been carried out at University of Western Ontario BLWTs. A recent study conducted on complex terrain used recent technology for instrumentation, namely Particle Image Velocimetry (PIV), to make simultaneous measurements of the wind field (Rasoulli 2010). Commonly used instrumentation methods, such as hot-wire anemometers and Laser Doppler Velocimetry (LDV), are limited to point measurements unlike the PIV method. The PIV method, despite low sampling rate, has been found to give comparable results with the other instrumentation techniques. The major problems in BLWT testing are model preparation, terrain roughness modeling, and instrumentation.

Field observations of wind characteristics using cup-anemometers placed at specific locations usually take months to complete and are also expensive. Moreover data is gathered only at specific locations in the area, hence the data for rest of the study area have to be extrapolated from those few point measurements at meteorological towers. However field measurements have been successfully used to measure maximum wind speed up factors over hills, escarpments, ridges and other topographic features. The results from these experiments are incorporated in building codes and standards such as American Society of Civil Engineers - 7 (ASCE7) and National Building Code of Canada (NBCC). Extensive field measurements over a real complex terrain is rarely conducted due to associated high cost and time needed for the investigation, but in some cases such data is necessary for benchmarking CFD simulations and BLWT testing. For example, Taylor & Teunisson (1986) conducted extensive field measure-

ments over the Askervein hill which is now commonly used as a benchmark for validating complex terrain CFD codes. Larger scale field studies have been conducted by Grant & Mason (1990), that have studied boundary layer structure over complex terrain by flying balloons at high altitudes and taking simultaneous measurements.

1.1.2 Effect of roughness on atmospheric boundary layer flow

A typical urban surface is extremely complex, with towns and cities consisting of large buildings with various shapes, sizes, and distributions which protrude into the atmosphere and interfere with the atmospheric aerodynamic and radiative heat transfer processes (Arnfield 2003). According to the modeling results of Coceal & Belcher (2005), either a change of building density or a change of building height has a direct impact on the mean flow, with the largest difference occurring near ground level. Buildings exert a resistive drag on the air flow and also complicate interactions through turbulent wakes and mutual sheltering. Therefore the relationship between wind profiles, roughness length and surface morphological characteristics is important. Surface roughness characteristics of an urbanized area can be predicted from wind speed data obtained from meteorological towers (EPA 1987). Wind speed measurements at different locations and height can be collected for long periods of time from which roughness parameters can be calculated.

In current practice, codes and building standards such as ASCE7-05 provide 3-s gust basic design wind speeds for open terrain conditions at 10m elevation, derived largely from meteorological stations at nearby airports. The wind speed at a particular study site will then have to be derived from the basic wind speeds through proper exposure corrections that reflect the roughness of the ground surface. The ground surface roughness lengths are usually estimated visually by examining aerial photographs or satellite images for each wind direction. These visually estimated values will be used in the logarithmic wind velocity profiles at a particular study site. For inhomogeneous upwind terrain condition and dense urban areas this task is even more complicated. Usually simplistic formulas are used to approximate the drag force based on average frontal and planar area of the obstacles (Counihan 1971, Lettau 1969, MacDonald et al. 1998, Theurer 1993). Some wind consulting offices use the Engineering Science Data Unit (ESDU) wind speed model (ESDU-82026 1993). ESDU uses equations fitted to data obtained by the Deaves & Harris (1978) numerical model over changes in surface roughness using a very simplified form of flow equation. An equivalent roughness can be obtained by considering the fetch length and associated roughness length for a particular wind direction. This equivalent roughness is then applied at the floor of a wind tunnel to generate wind test

profiles. In some case the change of roughness can be dramatic. For example, in downtown Miami the characteristic of the wind coming from the ocean will experience a sudden change from open (ocean) to urban (coastal community) and then to suburban within a few miles. These local, small scale roughness changes have significant effect on the velocity as well as turbulence profile (Wang & Stathopoulos 2007a).

1.2 Objectives and scope

The major objective of this thesis is to evaluate aerodynamic roughness of the built environment and complex topography by conducting micro-scale numerical simulations. To achieve this goal several specific goals will be pursued.

1. To develop a high performance CFD software tailored for Atmospheric Boundary Layer (ABL) simulations over the built environment and complex topography. The program will be parallelized using Message Passing Interface (MPI) to run on a cluster of processors such as the Shared Hierarchical Academic Research Computing Network (SHARCNET) cluster at Western. Latest technology in High Performance Computing (HPC), namely Graphic Processing Units (GPUs), will be exploited using NVIDIA's Compute Unified Device Architecture (CUDA). Different turbulence models suitable for ABL simulation will be implemented and tested for suitability of complex terrain simulations. The turbulence models to be implemented include linear mixing-length model, many Reynolds Averaged Navier-Stokes (RANS) models including k-epsilon and RNG k-epsilon, and the Smagorinsky Large Eddy Simulation (LES) model. The code will be validated against well known benchmark cases including problems specific to wind engineering. The scope of the program does not include mesh generation for complex terrain even though structured mesh generation for simple models is supported. Instead the program imports mesh from advanced meshing software such as 'snappyHexMesh' of OpenFOAM or Gambit meshing software of ANSYS Fluent. The program will use flexible polyhedral meshing format that are robust for CFD simulations and also allow for easy refinements in regions of interest.
2. To analyze the effect of roughness on wind speed and turbulence using CFD simulations. Different levels of complexity of roughness element configuration will be considered. First simplified models with regularly arranged blocks, similar to the case in a BLWT, will be tested for wind coming from different directions. The simulation results will then

be compared against empirical formulas that use average frontal and planar area density ratios. Then the problem of multiple roughness patches on the upstream side of a building will be investigated. It is known that the roughness patches closest to the building have the most effect on wind loading (pressure distribution). In literature this effect has been tested mainly in BLWT but numerical modeling attempts were usually limited to simplified 2D simulations that model the effect of roughness using empirical formulas. This work will investigate 3D explicit modeling of roughness elements. First a Virtual Boundary Layer Wind Tunnel (V-BLWT) will be simulated by replicating all the roughness features such as spires, barrier and roughness blocks to examine the effect of each roughness element. Then spires and barrier will be dropped in the latter simulations, with the blocks remaining as the only roughness feature. Instead a fully developed boundary layer profile is directly applied at the inlet to account for the effect of the removed roughness features. This setup will be used to evaluate the effect of multiple roughness patches on wind profile using many test setups found in literature. Furthermore for roughness blocks that are arranged in a regular manner, the inherent symmetry is exploited to reduce the computational domain to a single row of blocks. Finally the complexity of the test models will be increased further so that they become more and more representative of a real urban environment. A semi-urbanized model from CEDVAL-LES (2011) will be used for validation against BLWT data.

3. To analyze the effect of topographic features on wind flow using CFD simulations. Topographic features are responsible for most of the modification of ABL flow. This fact is recognized in building codes and standards through specification of wind speed up factors based on the slope and height of orography for simple hill, escarpment and valley geometries. Most codes do not have recommendations for multiple topographic features placed one after the other. This work will extend the work done by Bitsuamlak et al. (2004) on multiple topographic features using 2D simulations to a more elaborate 3D CFD simulations and using various turbulence models. Comparisons will be made with results available in literature. Then simulation on a real complex topography for which field measurements are available will be conducted for validation. Parametric studies will be conducted for different resolutions of grid, different turbulence models and dimension of the computational domain.

The thesis is organized as follows. Following the introduction in Chapter 1, brief literature review is carried out on the effect of roughness and topographic features in Chapter 2. The chapter also discusses background on CFD and its applications in wind engineering. Most

relevant literature to the objectives of this thesis are discussed at the beginning of the following sections. Chapter 3 discusses the implementation and validation of a high performance CFD software using C++ and MPI/CUDA for parallelization. Chapter 4 analyzes the effect of roughness on wind speed using different arrangement of roughness elements. After gaining enough experience with simplistic models, a full virtual wind tunnel is simulated using different roughness features through which the effect of multiple roughness patches is assessed. Then the complexity of the model is increased further to an idealized built environment to complete the study on urban flow characterization. Chapter 5 discusses the study on the effect of topographic features on wind flow. Simulations on 2D and 3D isolated and multiple hills are carried out . Speed up factors are calculated along lines at different heights which is a useful information for design of long-span structures such as transmission towers. The turbulence structure behind hills is examined using different turbulence models. Chapter 6 summarizes the findings and conclusions of this research work.

Chapter 2

Background

2.1 Atmospheric boundary layer

The Atmospheric Boundary Layer (ABL) is the lowest portion of the atmosphere (1-2 km) that is under the direct influence of the surface of the earth and responds to surface forcing in an hour or less. It is one order of magnitude smaller than the troposphere ($\sim 10km$), that consists of about 80% of the atmosphere, and two orders of magnitude smaller than the atmosphere ($\sim 100km$). In this region flow quantities display rapid fluctuations, unlike in the free atmosphere that is turbulence free. The terrain shape, roughness, thermal conditions, evaporation are some factors that affect behavior of the ABL. The free atmosphere, shown in Fig. 2.1, is the region above the ABL where the effect of surface friction is negligible and the wind is geostrophic, i.e. purely driven by pressure gradient and Coriolis force. The transition zone between the ABL and free atmosphere, from 100m to 1km, is known as the Ekman layer (Outer layer). It is a part of the ABL because surface friction still plays a role, but the effect of Coriolis force can no longer be ignored as in the surface layer. Usually Boundary Layer Wind Tunnel (BLWT) can not accommodate for Coriolis force hence the height up to which ABL can be simulated accurately is limited to 100m. However micro-scale simulations on complex terrain that fall in the Ekman layer and upper portions of the ABL should incorporate Coriolis effect.

A typical characteristic of an ABL flow, compared to uniform flow, is the development of a gradient in the tangential wind speed due to a no-slip condition at the surface. The dragging action of the surface on the wind, also known as aerodynamic drag, takes away momentum from the wind causing a velocity (momentum) deficit near the surface. The effect extends few hundred meters above the surface in which wind speed increases from zero at the ground to a maximum value at the gradient height above which it remains constant with height. The

Figure 2.1: Structure of ABL (Craστο (2007))

roughness of the surface determines the gradient height above which the effect of surface drag is negligible. The power-law and log-law are commonly used to approximate mean wind speed profiles within the surface layer for given surface roughness conditions.

2.2 Modification of ABL by topographic features

Topographical features such as escarpments, embankments, ridges, cliffs and hills can have a more profound effect on the flow in the ABL than any other single factor. It is known that wind speed increases significantly at the top of hills and ridges as shown in Fig.2.2. This phenomenon is exploited in wind energy to place wind turbines at optimal locations for maximum power production. Wind speed increases up the slope and reaches maximum at the crest or slightly upwind of it. Depending on the degree of steepness of the slope, flow separation may occur on the leeward side. It can also occur on the upstream side or any other location where there is a significant change in slope.

Building codes such as American Society of Civil Engineers - 7 (ASCE7) take into consideration the speed up effect over hills by the use of topographic multipliers (M_t in equation 2.1). The value of M_t is calculated from coefficients ($K_1 = f(H)$, $K_2 = f(x)$, $K_3 = f(z)$) that are read

Figure 2.2: Speed up on isolated hill (NBCC 1995)

from a table for given dimensions of a topographic feature.

$$M_t = \frac{U_z(\text{at topographic feature})}{U_z(\text{at flat ground upstream})}$$

$$M_t = 1 + K_1 K_2 K_3 \quad (2.1)$$

ASCE7 states that wind speed-up effects shall be included in the design when all the following conditions are met.

1. The hill, ridge, or escarpment is isolated and unobstructed upwind by other similar topographic features of comparable height for 100 times the height of the topographic feature (100H) or 2 mi, whichever is less. This distance shall be measured horizontally from the point at which the height H of the hill, ridge, or escarpment is determined.
2. The hill, ridge, or escarpment protrudes above the height of upwind terrain features within a 2 mi radius in any quadrant by a factor of two or more.
3. The structure is located in the upper one-half of a hill or ridge or near the crest of an escarpment.
4. $H/L \sim 0.2$ and H is greater than or equal to 15 ft (4.5 m) for Exposures C and D and 60 ft (18 m) for Exposure B.

It is clear that the code is rather limited and does not extend beyond simple topographical features. Other codes such as NBCC also have similar limitations. These codes usually recommend BLWT experiments for complex terrains that do not meet the criteria.

Wind speed up over topography has both a good and bad side to wind engineers. The increase in wind speed over hills and escarpments causes structural failures if not properly accounted for. The wind load increases in proportion to the square of wind speed ($\sim U^2$), thus a 20% increase in wind speed translates to a 40% increase in wind load. For this reason, buildings and standards such as NBCC and ASCE7 provide guidelines for calculating wind speed up over idealized topography. Some of the orographic features for which codes provide guidelines are shown in Fig. 2.3. Most building codes do not have provisions for multiple

Figure 2.3: Hills, escarpments and valleys of different slope

hills and valleys placed consecutively. The wind speed typically reduces from the second hill towards associated with an increase in turbulence (Miller & Davenport 1998). When hills are placed side by side, funneling effects could significantly increase wind load for a structure placed in between the hills. Similar scenario is also observed inside a valley as shown in Fig. 2.4. These cases are not covered well in building codes and standards. An advantage of wind speed up over topographic features is that wind energy production can be maximized by placing wind turbines at locations where the wind speed is maximum (e.g. crest of hills) and the turbulence intensity is lowest. It is common to conduct Computational Fluid Dynamics (CFD) simulations to get a detail wind map of the area for micro-siting (e.g. Uchida & Ohya (2008)). For these reasons, wind farm locations are usually located along shorelines, at highest elevations and area at which the surface cover is minimum (e.g. open roughness).

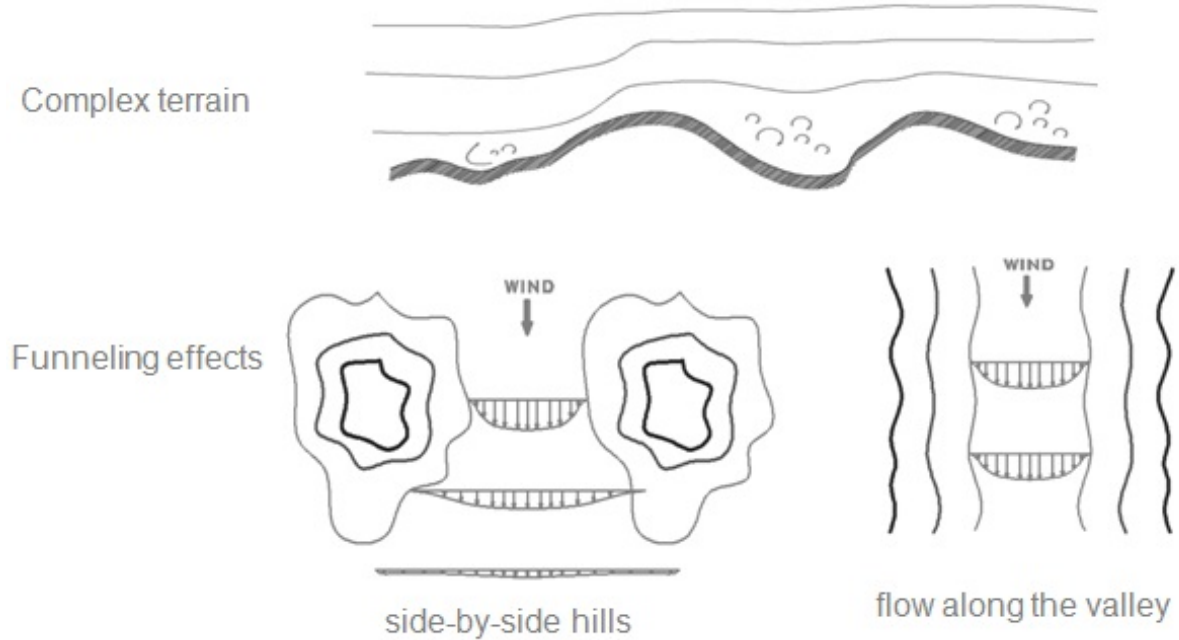

Figure 2.4: Double hills, funneling between two hills, and speed up inside a valley

2.3 Modification of ABL by surface roughness

Aerodynamic roughness comprises of both the effect of the terrain surface and its roughness elements. For a no-slip surface condition, the wind velocity drops from a large value at the free stream to zero at the surface, with in what is known as a boundary layer. The vertical gradient of horizontal velocity is a function of surface roughness. If the surface is smooth, the boundary layer is very thin. However as the surface roughness increases, the surface shear stress and hence velocity deficit in the wind profile also increase. A rough surface imposes larger aerodynamic drag than a smooth surface. For turbulence generated by wind shear, the magnitude of the surface Reynolds stress can be used as a scaling parameter. The shear stress and friction velocity are defined as shown in equations 2.2 and 2.3. The friction velocity U_* is incorporated in the log-law wind speed model as a scaling term.

$$|\tau_{Reynolds}| = [\tau_{xz}^2 + \tau_{yz}^2]^{1/2} \quad (2.2)$$

$$U_*^2 = |\tau_{Reynolds}|/\rho = [\overline{u'w'^2} + \overline{v'w'^2}]^{1/2} \quad (2.3)$$

There is a disparity in the definition of roughness parameters z_0 and d . Panofsky & Dutton (1984) believed that the surface roughness length z_0 represents the size of the eddies produced

Table 2.1: Revised Davenport roughness classification (Wieringa 1992)

Class	Z_0 (m)	Type	Landscape description
1	0.0002	Sea	open water, tidal flat, snow with fetch above 3 km
2	0.005	Smooth	featureless land, ice
3	0.03	Open	flat terrain with grass or very low vegetation, airport runway
4	0.1	Roughly open	cultivated area, low crops, obstacles of height H separated by at least $20 H$
5	0.25	Rough	open landscape, scattered shelter belts, obstacles separated by $15 H$ or so
6	0.5	Very rough	landscape with bushes, young dense forest etc separated by $10 H$ or so
7	1.0	Closed	open spaces comparable with H , eg mature forest, low-rise built-up area
8	≥ 2	Chaotic	irregular distribution of large elements, eg city center, large forest with clearings

from the wind moving over a rough surface: the larger the eddies the larger the z_0 and vice versa. It can also be defined as the height above the physical surface at which flow starts to occur (Gardner 2004, Stangroom 2004). At this height z_0 , the velocity is theoretically zero even though turbulence maybe present. Roughness length can be as high as 5m in city centers and large forests (Hansen 1993, Wieringa 1992). Building codes and standards such ASCE7-02 provide tables from which values of z_0 and α can be read based on land-use categories. This method can be quite effective in establishing representative roughness lengths (Hansen 1993). Hansen also suggests that this method can be expanded to include terrain features such as hills in a form (pressure) drag contribution. Three roughness categories (namely open, suburban and urban) are commonly considered for the purpose of determining wind loads on structures. Davenport et al. (2000) has proposed fine grained classification of terrain roughness using eight classes. Wieringa (1992) updated the Davenport roughness classification as shown in Table 2.1

There is also some disparity in the definition of the displacement height. This thesis uses the definition that the zero plane displacement height d is the height above the surface at which turbulent exchanges begin to occur, and is comparable to the depth of trapped air (Hansen 1993, Monteith 1965, Stangroom 2004, Thom 1972). In a closed city center, the density of the obstacles may prevent any flow effects from occurring between the buildings, thereby forming a canopy layer where the air is effectively trapped inside. A phenomenon known as ‘skimming flow’ occurs, where the ground plane is effectively displaced up by an amount d in to the rough-

ness elements. The displacement height does not change the shape of the velocity profile but only displaces it upward by an amount d . The roughness length in this case is measured from the plane of zero-displacement or in other words at $z_0 + d$ above the ground. Both roughness length and displacement height are directly incorporated in the log-law wind speed model. The power law model has a similar parameter (α) to reflect the effect of surface roughness on wind speed.

Raupach et al. (1991) defines rough flow as one whose shear stress is dominated by drag of roughness elements, compared to smooth flow whose shear stress is dominated by viscous drag. A rough ABL flow has the following layers that are depicted in Fig. 2.1.

1. Roughness sublayer in which velocity is influenced by the roughness elements. It is about 2 to 3 times the average height of roughness elements (H). Within this region a canopy layer may be present when the roughness elements are big; forest canopy, urban canopy etc. As discussed in previous sections, the velocity is zero at height of $d + z_0$.
2. Surface layer ($\sim 100m$) in which wind speed varies only with height, i.e. horizontally homogeneous, as governed by the log-law. The shear stress within this region is constant.

2.4 ABL stratification and stability

Atmospheric stability refers to the resistance of the atmosphere to vertical motion. Temperature usually decreases at a roughly constant rate, commonly known as lapse rate, as one goes away from the surface of earth. This situation leads to an unstable atmospheric condition due to lighter air being at the bottom of cooler air. The lighter air moves upwards and denser air moves downwards due to the action of gravity. A circulation within the ABL ensues as long as the surface keeps being heated. This is the case in the day time where the sun continuously heats the surface of the earth. During the nighttime, the earth loses its heat through radiation and the air at the bottom also cools down thereby a stable ABL is formed.

Stability plays an important role on wind flow over hills and other topographic features where the air is forced to move upwards. As the wind moves towards the crest on the upwind side, whether the flow remains attached or separated afterwards depends on stability. In a stable condition, the air remains attached to the surface because it has higher density than the surrounding air at the crest. For a neutral condition where the gradient of temperature is zero, the wind moves straight horizontally once it reaches the crest. For an unstable condition, the

wind moves straight upwards until it reaches heights where the surrounding air has the same temperature as the moving air parcels. Flow over a hill for the the three ABL stability cases, namely stable, unstable and neutral, are shown in Fig. 2.5.

Figure 2.5: Effect of stability on wind flow over hill

A neutral ABL is assumed in this work because vertical velocity is negligible compared to horizontal velocity for moderate to high wind speeds. Therefore the governing wind flow equations used for this work ignore stability effects by making hydrostatic assumption Stan-groom (2004), Xabier (2009). For situations where buoyant forces are important, it can be incorporated by introducing density variations due to temperature. An important simplification known as Boussinesq’s approximation allows density variations to be ignored in all parts of the governing equations except where they are multiplied with gravity. Despite the serious simplification, the model is found to be very accurate for buoyancy driven flows in the ABL. As a result, buoyancy effects can be incorporated to the governing equations as a body force.

2.5 Coriolis force

Earth’s rotation introduces fictitious forces on a moving mass of air that exist only in a rotating frame of reference. These forces are known as Coriolis and Centrifugal forces. The Centrifugal force acts outwards and is usually ignored in ABL simulations. The Coriolis force acts perpendicular to the velocity of wind and deflects it either to the right or left depending on location (latitude (ϕ)). The bulk of moving air is deflected to the right of its direction of motion on the northern hemisphere, to the left of its direction of motion on the southern hemisphere, and remains unaffected on the equator. The wind speed also affects the amount of deflection because the object has to be in motion to experience these fictitious forces. Similar to Reynolds number (Re), a parameter known as the Rosby number (Ro) is defined to quantify the magnitude of Coriolis force relative to inertial forces.

$$Ro = \frac{U}{Lf_c} \quad (2.4)$$

where f_c is the Coriolis parameter $f_c = 2\Omega\sin\phi$, Ω is angular velocity of earth's rotation, ϕ latitude, and L is length scale. A small Rossby number of $Ro \sim 1$ indicates dominance of Coriolis force over inertial forces, hence its contribution can not be ignored. Before conducting micro-scale simulations on a hill or any other topographic feature, the Rossby number should be calculated to check whether the effect of Coriolis force can be ignored or not.

2.6 Statistics on wind turbulence

Most engineering flows around bluff bodies, such as buildings and other structures with sharp edges, are turbulent. A laminar flow becomes turbulent above a certain critical Reynolds number. Reynolds number is defined as the ratio of inertial forces to viscous forces.

$$Re = \frac{\rho UL}{\mu} \quad (2.5)$$

Turbulent flows are intrinsically unsteady even with constant imposed boundary conditions. A turbulent flow has the following characteristics:

1. *Irregularity*: Turbulent flow consists of eddies of different size (scale) ranging from the largest eddies whose size is dictated by the geometry (boundary layer thickness), down to the smallest energy dissipating eddies of Kolmogorov scale whose size is a function of viscosity of the fluid.
2. *Diffusivity*: As a flow becomes more turbulent, the boundary layer thickness also increases. Rapid mixing and increased mass, momentum, heat transfer occurs. A flow that is irregular but does not spread (not diffusive) is not turbulent.
3. *High Reynolds number*: Turbulent boundary layer flow occur at high Reynolds number in the order of $10^5 - 10^6$ or higher, where the inertial terms dominate viscous terms. At very low Reynolds numbers, viscous forces dominate inertial forces, and the resulting flow is known as creeping flow (Stokes flow).
4. *Three dimensional and anisotropic*: Turbulent flows consist of rotational vortices. Vortex stretching is at the core of the turbulent energy cascade in which energy is transferred from large to small eddies.
5. *Dissipative*: The smallest scales dissipate kinetic energy into internal energy. Unless the flow is maintained by incoming flow at boundaries turbulence will eventually die out.

Figure 2.6: Time series of wind turbulence (left) and its spectrum (right) (Stull 1988)

Wind flow is turbulent and hence can only be described using statistical methodology. A time series of wind speed and its frequency content are shown in Fig. 2.6. The mean and root mean square (RMS) fluctuations of wind are usually used to describe wind intensity. Field observations using cup anemometers mounted on meteorological towers can provide point measurements at high frequency, that go a long way to characterize wind flow in an area. The fluctuating component of velocity is usually specified via turbulence intensity, in which the fluctuating component is normalized with the mean velocity.

$$I_u = \frac{\sigma_u}{U} \quad (2.6)$$

$$U' = U + \hat{g}\sigma_u \quad (2.7)$$

In building codes and standards, the peak wind load to be used for design purposes is calculated from a peak factor (g), mean wind speed and RMS fluctuation. Different averaging times can be used to calculate the mean wind speed. Peak 3-sec gust, 5-sec gust, 1min, 10 min, 1 hour averages are commonly used for different purposes in wind engineering. Wind speed averaged over 3 sec can be 1.53 times as large as the hourly average. Mean wind speed in the ABL tend to follow a standard Gaussian distribution while peak values follow extreme value distributions. Thus given records of wind speed from field observations, the probability of occurrence of any wind speed can be determined from the properties of the underlying distributions. Peak factors are used in building codes and standards to calculate peak wind loads.

2.6.1 Spectral content of wind

The largest scales of turbulence extract kinetic energy from the mean flow. Through the cascade process this energy is transferred to progressively smaller scales until it is totally dissipated to internal energy. All scales of turbulence dissipate some amount of energy through friction but it is assumed that about 90% of the energy is dissipated at the smallest Kolmogorov scales. For a given rate of energy dissipation ε per unit mass and kinematic viscosity ν , the velocity, time and length scales of the smallest eddies are as follows

$$U = (\nu\varepsilon)^{1/4}, L = (\nu^3/\varepsilon)^{1/4}, T = (\nu/\varepsilon)^{1/2} \quad (2.8)$$

The energy dissipation ε at the smallest scales can be estimated from that obtained from the largest scales of turbulence. Kolmogorov introduced the idea that the smallest scales of turbulence are the same for every turbulent flow while the largest scales are affected by geometry. In wave number space the energy of eddies from κ to $\kappa + d\kappa$ can be expressed as $E(\kappa) d\kappa$

The total kinetic energy contained in all eddies can be found by integrating over the whole wave number space. The wave number of an eddy is proportional to the inverse of its radius ($\kappa \sim 1/r$)

$$K = \int_0^{\infty} E(\kappa) d\kappa \quad (2.9)$$

In the intermediate range (inertial range) the energy coming from the largest eddies is in equilibrium with the energy transferred to the smaller eddies. The inertial region exists for all fully turbulent flows (high Re). Kolmogorov, through dimensional analysis, came up with a relation for the energy contained by eddies in the inertial region. The energy in this range exhibits what is known as a ‘ $-5/3$ decay’:

$$E(\kappa) = \text{constant} * \varepsilon^{2/3} * \kappa^{-5/3} \quad (2.10)$$

The Kolmogorov law is often used in experiment, large eddy simulation and direct numerical simulation, to verify that a flow has become fully turbulent.

To understand the turbulence (fluctuations) in wind better, it is convenient to transform wind speed measurements in time domain to the frequency domain using Fourier decomposition. The resulting spectral density function provides a description of the frequency content of wind speed fluctuations. The most commonly used spectrum for longitudinal velocity component is the von Karman-Harris spectral density shown in Fig.2.7. The spectral density equations for

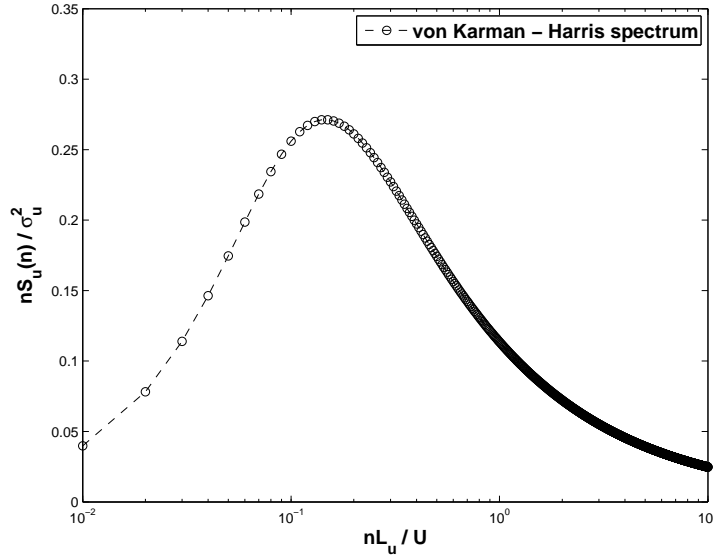

Figure 2.7: The von Karman-Harris spectra for longitudinal wind speed

the three velocity components are

$$\frac{nS_u(n)}{\sigma_u^2} = \frac{4n_u}{(1 + 70.8n_u^2)^{5/6}} \quad (2.11)$$

$$\frac{nS_v(n)}{\sigma_v^2} = \frac{4n_v(1 + 755.2n_v^2)}{(1 + 283.2n_v^2)^{11/6}} \quad (2.12)$$

$$\frac{nS_w(n)}{\sigma_w^2} = \frac{4n_w(1 + 755.2n_w^2)}{(1 + 283.2n_w^2)^{11/6}} \quad (2.13)$$

where $n_i = nL_i/U$

The time scale of turbulence is calculated by integrating auto-correlation of fluctuations at a fixed location. The integral time scale indicates the rate at which turbulence decays at a given location.

$$f(\tau) = \frac{\overline{u'(t)u'(t + \tau)}}{\overline{u'^2}} \quad (2.14)$$

$$I = \int_0^{\infty} f(\tau) d\tau \quad (2.15)$$

Another important property of wind turbulence in relation to wind loading on structures concerns its spatial variation. If the wind speeds at two different heights do not reach peak values simultaneously, it is possible to get a reduction in design wind loads. Cross-correlation of velocity components at different heights reveal approximate size of coherent structures or

eddies. The length scale of turbulence L_u is calculated by first calculating cross-correlation coefficients using equation 2.16 and then calculating the area under the curve by integration.

$$f(\zeta) = \frac{\overline{u'(x)u'(x+\zeta)}}{\overline{u'^2}} \quad (2.16)$$

$$L_u = \int_0^\infty f(\zeta) d\zeta \quad (2.17)$$

2.6.2 Mean wind speed and turbulence intensity models

2.6.2.1 The log law model

Wieringa (1993) proposed a semi-empirical equation for wind speed in neutral conditions and homogeneous roughness, commonly known as the log-law model. The model has some theoretical basis because it can be derived from mixing length theory making reasonable simplifying assumptions. It gives good estimates of wind speed within the inertial sublayer i.e. with in the lowest 100m of ABL. The aerodynamic roughness length (z_0) is used as a correction for the effect of roughness.

$$U(z) = \frac{u_*}{\kappa} \left[\ln \left(\frac{z-d}{z_0} \right) \right] \quad (2.18)$$

The model can be modified to account for atmospheric stability by adding an extra term to it.

$$U(z) = \frac{u_*}{\kappa} \left[\ln \left(\frac{z-d}{z_0} \right) + \psi(z, z_0, L) \right] \quad (2.19)$$

where L is the Monin-Obukhov stability parameter. Similarly Deaves & Harris (1978) modified the model to account for Coriolis effect and make it applicable in the outer region as well.

$$U(z) = \frac{u_*}{\kappa} \left[\ln \left(\frac{z-d}{z_0} \right) + 5.75 \left(\frac{z}{G} \right) - 1.88 \left(\frac{z}{G} \right)^2 - 1.33 \left(\frac{z}{G} \right)^3 + 0.25 \left(\frac{z}{G} \right)^4 \right] \quad (2.20)$$

where $G = u_*/6f_c$ is the gradient height. The equation can be simplified to

$$U(z) = \frac{u_*}{\kappa} \left[\ln \left(\frac{z-d}{z_0} \right) + \frac{34.5 f_c z}{u_*} \right] \quad (2.21)$$

The corresponding equation for turbulence intensity is

$$I_u(z) = \frac{k}{\ln \left(\frac{z-d}{z_0} \right)} \quad (2.22)$$

where k is a coefficient dependent on roughness. It takes values of 1, 0.92, 0.88 for smooth, open and closed roughness respectively.

2.6.2.2 The power law model

An alternative wind speed model for the upper portion of the surface layer is the power law model. This simpler wind speed formula is commonly used in wind power calculations in which wind turbines reach heights of $\geq 50m$. Given wind speed measurements at a reference height (usually 10m), the power law can be used to calculate wind speed at any other height using the following equation. Because the power law index α is usually chosen to fit the upper portion of the surface layer better, its prediction in the lowest portion could be relatively poor compared to that of the log-law. The power law index α is a function of roughness of terrain and turbulence. This method does not have a theoretical background unlike the log-law.

$$U(z) = U_{ref} \left(\frac{z-d}{z_{ref}} \right)^\alpha \quad (2.23)$$

Similarly an inverse power law equation is used to estimate turbulence intensity profile in ASCE 7. The coefficients c and d are dependent on the roughness of the terrain and can be read from a table.

$$I_u(z) = c \left(\frac{z}{z_{ref}} \right)^{-d} \quad (2.24)$$

2.7 Surface roughness models

Aerodynamic roughness can be estimated analytically, experimentally (full scale and wind tunnel) and numerically. A brief review of literature of roughness estimation is given in the following sections.

2.7.1 Empirical formulas

For well defined obstacle shapes, surface roughness parameters can be determined from density of obstacles, frontal (wall) area and/or planar (floor) area densities. Grimmond & Oke (1999) review various empirical models to determine aerodynamic characteristics of a site through analysis of its surface form (morphometry). Different roughness models have been proposed in literature to determine roughness parameters z_0 and d based on average area density of obstacles. This section discusses some of well known empirical formulas for estimating z_0 .

A simple approximation for z_0 can be obtained from average height of obstacles: buildings, bridges, crops, forests etc. A value of $c = 0.1$ have been found to give good results in many situations however it is established that z_0 is generally not constant.

$$\frac{z_0}{H} = c \quad (2.25)$$

Theurer (1993) noted that z_0 and d are related to two secondary parameters of the obstacles.

$$\lambda_f = \frac{A_f}{A_d} \quad (2.26)$$

$$\lambda_p = \frac{A_p}{A_d} \quad (2.27)$$

Lettau (1969) provided an empirical formula to determine z_0 from frontal area density ratio of obstacles

$$\frac{z_0}{H} = 0.5\lambda_f \quad (2.28)$$

Peterson (1994) tested this model in wind tunnel and found good agreement when roughness elements do not interfere strongly with each other. For λ_f or λ_p greater than 20 to 30 % , the model fails to give good predictions due to interference between obstacles and development of displacement height d that is not accounted for in Lettau's expression. For example when the surface is completely covered with obstacles ($\lambda_p = 1$), Lettau's expression predicts a maximum roughness length. But in reality a new smooth surface displaced with a height of $d = H$ is formed and $z_0 \rightarrow 0$. Raupach (1992) have shown that peak value of roughness length occur in the range of $0.2 < \lambda_f < 0.3$, with $z_0 \rightarrow 0$ as $\lambda_f \rightarrow 1$.

Counihan (1971) measured z_0 in wind tunnel from velocity profiles over regular arrays of cubic elements and arrived at an expression that includes the effect of limited fetch length.

$$\frac{z_0}{H} = 8.2 \frac{H}{X_f} + 1.08\lambda_p - 0.08 \quad (2.29)$$

X_f is the fetch length. In Counihan's experiment $A_f = 0.6 A_p$ from which λ_f can be obtained with which it is better correlated than it is with λ_p . For large fetch lengths, his equation reduces to

$$\frac{z_0}{H} = 1.08\lambda_p - 0.08 = 1.08\lambda_f - 0.08 \quad (2.30)$$

He claimed this expression is valid $0.06 < \lambda_f < 0.15$. Similar results as that of Lettau's are obtained for $\lambda_f < 0.06$. Both the above models fail to capture the non-linear reduction of $\frac{z_0}{H}$

Figure 2.8: Roughness length and displacement height for square and staggered blocks (Peterson 1994)

as λ_f goes beyond 0.3. Hall et al. (1996) conducted wind-tunnel experiments over arrays of 0.1m cubes placed in a regular and staggered manner. They measured mean velocity profiles for $X_f \sim 22H$ and varying λ_p , and calculated z_0 and d using similar methods as that used by Peterson (1994). The variation of these parameters with λ_p is shown in Fig. 2.8. Theurer (1993) found expressions for z_0 and d from full scale measurements in cities and wind tunnel experiments.

$$\frac{d}{H} = 1.67\lambda_p \quad (2.31)$$

$$\frac{z_0}{H} = 1.6\lambda_f(1 - 1.67\lambda_p) \quad (2.32)$$

These equations are valid for up to $\lambda_p < 0.6$. Theurer limited λ_f to 0.25 to avoid skimming flow effects. For cubical obstacles Theurer's expression for z_0 becomes quadratic with a peak value of 0.24 as show in Fig. 2.9. All of the above methods fail to perform adequately in urban areas where λ_f exceeds 20%.

MacDonald et al. (1998) proposed an improved model which tackles the following limitations of the Lettau's model: low roughness element densities, lack of non-linear decrease of z_0 at high area density, drag differences caused by different obstacle shapes or layouts. The model is derived from Lettau's expression which they proved can be derived from fundamental principles assuming negligible wake interference between surface obstacles. Then the mean velocity approaching each obstacle can be obtained using log-law, which is the main reason

Figure 2.9: Comparison of different empirical models for roughness length

why the Lettau's expression fails to give good results for high area density ratios, in which wake interference effect is significant. The final expression after including the drag effect by different obstacle shapes is given below

$$\frac{z_0}{H} = \exp\left(-\left(0.5 \frac{C_d}{k^2} \lambda_f\right)^{-0.5}\right) \quad (2.33)$$

For $C_D = 1.2$ (Engineering Science Data Unit (ESDU) recommendation for cube) and $\kappa = 0.4$, the above expression is simplified

$$\frac{z_0}{H} = \exp\left(-\left(0.52 \lambda_f\right)^{-0.5}\right) \quad (2.34)$$

This expression shows better agreement with the Counihan's relation as shown in Fig. 2.9. However it still predicts monotonic increase of z_0 with λ_f . Hall et al. (1996) have shown that z_0 reaches a peak around $\lambda_f = 20\%$ from wind tunnel experiments. The derivation is redone with the logarithmic law which considers the effect of displacement height d .

$$\frac{z_0}{H} = \left(1 - \frac{d}{H}\right) \exp\left(-\left(0.5 \frac{C_d}{k^2} \left(1 - \frac{d}{H}\right) \lambda_f\right)^{-0.5}\right) \quad (2.35)$$

Jackson (1981) has shown that the minimum displacement height is the height of an equivalent surface obtained by flattening out the obstacles into a smooth one with a uniform cross-

Figure 2.10: Displacement height for different convexity

sectional area, $\frac{d}{H} \geq \lambda_p$. Approximate values for d can be obtained by the following equations that satisfy the requirement that $d = 0$ at $\lambda = 0$, and $d = H$ at $\lambda=1$. The parameter A controls the convexity of the curve as shown in Fig. 2.10.

$$\frac{d}{H} = 1 + A^{-\lambda}(\lambda - 1) \quad (2.36)$$

Using this model, MacDonald et al. (1998) found excellent agreement with Hall's wind tunnel data collected for staggered array obstacles. However the square array data is over-predicted due to enhanced sheltering effect. Various correction factors on the drag coefficient can be applied to account for different obstacle shapes and flow conditions: factor for velocity profile shape (k_s), incident turbulent intensity (k_i), turbulent length scales (k_l), incident wind angle (k_θ), and round corners (k_r).

$$C'_d = C_d \beta = C_d k_s k_i k_l k_\theta k_r \quad (2.37)$$

This modified drag coefficient can be used to determine z_0 . Using $\beta = 0.55$, they were able to get good fit to the wind tunnel data for the staggered array.

The empirical roughness models we have discussed so far are summarized in Table 2.2. For a terrain with high density of obstacles of uniform height, 'skimming flow' occurs in which the roughness length continuously decreases to zero while the displacement height increases. The Lettau (1969) and Counihan (1971) models disregard this effect, hence their use is limited to

Figure 2.11: Roughness length for different convexity

Table 2.2: Summary of empirical formulas for roughness parameters

Model	$\frac{z_0}{H}$	$\frac{d}{H}$
Lettau (1969)	$0.5\lambda_f$	None
Counihan (1971)	$1.08\lambda_f - 0.08$	None
Theurer (1993)	$1.6\lambda_f(1 - 1.67\lambda_p)$	$1.6\lambda_p$
MacDonald et al. (1998)	$(1 - \frac{d}{H}) \exp(-0.5 \frac{c_d}{k^2} ((1 - \frac{d}{H})\lambda_f)^{-0.5})$	$1 + A^{-\lambda}(\lambda - 1)$

low density of obstacles not more than 30%. Peak values of z_0 occur approximately at area density ratio of 20%.

2.7.2 BLWT methodology

Peterson (1994) conducted wind tunnel tests on different models to evaluate surface roughness parameters from observed velocity profiles. Using the database of wind tunnel tests on three refinery models and two uniform roughness modes, the Lettau, Counihan and simplified Counihan models are evaluated. Among the seven different methods tested to determine roughness length z_0 from velocity profiles, only two were deemed adequate. Using statistical analysis to evaluate predicted roughness by the above mentioned methods, he found out that the Lettau model provides good estimates within a factor of 0.5-1.5 and 95% confidence.

First profiles of mean wind speed and turbulence intensity are obtained at several locations on the center line, left and right of center line. Then three different methods are used to

determine roughness length from velocity profiles.

1. The first method uses best fit to the logarithmic profile without displacement height.

$$\ln(z) = \frac{k}{u^*} u(z) + \ln(z_0) \quad (2.38)$$

a linear fit can be done to obtain z_0 and u^* simultaneously.

2. EPA (1987) on-site meteorological program provides the following relation for determination roughness length from turbulence intensity measurements.

$$z_0 = \frac{z}{\exp(\frac{u}{u^*})} \quad (2.39)$$

for $20z_0 < z < 100z_0$.

3. Lo (1990)'s method: Technically this is the best method to estimate the actual roughness length. However it has deficiencies in that the estimation is based on measurements at only two heights, which can introduce large errors from small statistical errors. By applying the logarithmic profile with displacement height at two points Lo arrived at the following equations using normalized variables with respect to U_{n+1} and Z_{n+1} .

$$z_0 = \frac{(z_n - d)^\alpha}{(1 - d)^\beta} \quad (2.40)$$

$$(1 - A - d)\ln(1 - d) - (1 - d) + (A - 1 + d)[\alpha \ln(z_n - d) - \beta \ln(1 - d) + \frac{(z_n - d)^\alpha}{(1 - d)^\beta}] = 0 \quad (2.41)$$

$$\alpha = \frac{1}{1 - u_n}, \beta = \frac{u_n}{1 - u_n}, \text{ and } A = \int_0^1 U(z) dz \quad (2.42)$$

The solution proceeds by first solving iteratively for the displacement height from the second equation, and then the roughness length is determined from the first equation. Peterson also discussed other methods which can be used for roughness evaluation, among which two are found to be adequate. One of them is Lo's method with some modifications to avoid the problem of statistical errors.

Zaki et al. (2010) conducted wind tunnel measurements of roughness parameters of building arrays with random geometries. The randomness is featured in the form of vertical ran-

domness of height of blocks, and horizontal randomness of the rotation angle of each block. The study has found that the ‘skimming flow’ effect observed at high area density ration with uniform height elements is absent when the height of roughness elements show variations. This effect is attributed to the fact that flows around the taller blocks do not interfere with each other due to large separation on average, and also because randomly rotated blocks are less streamed than a regular arrays.

2.7.3 CFD methodology

Many researchers have used CFD to study aerodynamic drag using different arrangement of obstacles: shapes, size and layouts. The height and arrangement of roughness elements in wind tunnels is fixed in accordance with the required roughness that produces a desired velocity and turbulence intensity profiles at the turntable. When the terrain has multiple roughness patches or obstacle shapes are not clearly defined, analytical methods are difficult to use and in general do not give good results. In that case CFD can be used to conduct simulations, from the results of which can be estimated roughness parameters for different angle of wind attack. Explicit roughness modeling, as opposed to implicit modeling via wall functions, is used throughout this work (Chapter 4) to investigate the effect of homogeneous and inhomogeneous roughness on wind profiles.

Idealized models can be used to replace a complex built environments with simplified models that have equivalent aerodynamic roughness. Usually cubes with a regular or staggered arrangement and certain packing density are used in areas where resolving detailed flow characteristics is not required. This homogeneous model is exploited in CFD and Wind tunnel models where the area with in a certain radius of the study object is modeled as perfectly as possible, while the rest of the area is replaced with blocks that have similar aerodynamic properties. The next higher level modeling adds desired features of typical urban environment which is heterogeneous and morphologically consistent with the actual environment. This kind of models have been used in urban pollution and pedestrian comfort studies using CFD (e.g. (CEDVAL-LES 2011)).

Rasheed (2010) conducted CFD simulations to compare complex urban environment with a simplified model consisting of regular array of cubes. This is similar to the case in BLWT where the less important buildings away from the test building are modeled with regular array of roughness blocks. This transformation is necessary to take advantage of existing urban parameterization models that are developed for regular array of obstacles. The simplification also helps in increasing quality of meshes because the usually problematic tetrahedral meshes can

be avoided. He found that the stream wise velocity components for the two models show good agreement but turbulent kinetic energy profiles show significant differences.

To summarize the above reviews,

1. Most empirical models fail to correctly predict roughness parameters for high area density ratios. The Macdonald model seems to give the best results in this regard and can be modified to account for other factors through the inclusion of drag coefficient.
2. Wind tunnel testing and full scale testing have been used to study and validate roughness models. In most BLWT testing of a built environment, detailed wind flow characteristics are sought inside the built environment instead of just average roughness parameters.
3. Simplification of model by transformation to an equivalent regular array of blocks can be helpful if mean quantities are of the most interest.

2.8 Computational wind engineering

CFD can be used to analyze problems involving complex flow by solving governing partial differential equations of fluid flow. In wind engineering, experimental methods such as full scale and boundary wind tunnel tests have been the most successful ones so far. In other related fields such as aeronautical and mechanical engineering, CFD has been highly successful.

Computational wind engineering (CWE) is relatively young compared to other fields where CFD has made considerable progress. One cannot ignore the ever increasing computational power of computers which has motivated use of complex mathematical models that allow accurate flow predictions. For instance, Large Eddy Simulation (LES) has been mostly unused for high-Reynolds number flows due to its high computational demand. Nowadays it is becoming more and more common due to availability of high end computers and improvements in CFD modeling techniques. The commonly used Reynolds Averaged Navier-Stokes (RANS) models are known to give poor results in adverse pressure gradient flows, but LES gives very good results for separated flows that dominate bluff body aerodynamics.

CWE have also proven to be a reliable supplement to experimental methods. For instance it has been successfully used in the design and daily tests of the Wall of Wind (WoW) facility at Florida International University (Bitsuamlak 2006). Other applications where it has proven successful include: prediction of pedestrian level wind flows (Blocken & Carmeliet 2004), estimation of wind load on main wind force resisting system (Wright & Easom 2003), and

simulation of flows over complex topography for micro-siting (e.g. using Wind Atlas Analysis Application Program (WAsP)). A review of the current state of art in CFD for wind engineering applications is summarized in (Bitsuamlak 2006, Dagneu & Bitsuamlak 2013).

2.9 Overview of CFD

The governing equations of fluid flow are the Navier-Stokes equations for momentum conservation and the continuity equation for mass conservation. These equations are coupled and non-linear that makes obtaining analytical solution very difficult, if not impossible, for most practical engineering problems. Also most flows of wind engineering interest are turbulent in nature, which is inherently chaotic, hence seeking for closed form solutions for these problems is rather meaningless. Statistically averaged solution of turbulence can be obtained by the use of so called ‘turbulence models’. RANS have proven to be quite successful in this aspect for many engineering problems. An engineer is usually satisfied with the averaged property of the flow in many cases. For those particular cases where accurate results are required, better turbulence models can be used to capture instantaneous properties of turbulence at least for the largest eddies. A method exists that is able to capture all eddying motions down to the smallest scales (Kolmogorov scales), but it has a huge computational demand for many high-Re flows that are common in wind engineering. This aspect of compromise between accuracy and computational requirements manifests itself in other stages of CFD as well.

The mathematical model consists of governing partial differential equations of conservation laws and specified boundary conditions. Usually the equations are solved numerically by first dividing the whole domain into smaller regions and then forming linear equations that relate the quantities in each cell. There are mesh free methods that can solve the equations directly on the specified geometry without the need for discretization but these methods are still in development stage and not commonly used. The discretization method gives a set of algebraic equations at a number of discrete points in space and time. The Finite Volume Method (FVM), Finite Element Method (FEM) and the Finite Difference Method (FDM) are a few of these numerical methods. The most commonly used discretization method for fluid flows is FVM. Its popularity comes from the fact that conservation of mass and momentum is achieved in each cell during all stages of solving. The conservative nature of FVM is more appealing to engineers and gives a certain level of confidence on the results obtained from simulation carried out on coarse grids. Another advantage of the FVM over FDM is the relative ease in which it can be used on unstructured grids. Ideally structured meshes are preferable for fluid flow

simulations, but that is rarely the case in many practical problems.

2.9.1 Governing equations

The governing equations relevant to wind flow over complex terrain and built environment are described in this section. Many conservation laws applicable to other fields of engineering are excluded from the discussion. Thus an incompressible and dry atmosphere that is neutrally stratified is assumed.

2.9.1.1 Mass conservation law

The principle of mass conservation states that the fluid going out of a closed system is equal to the fluid getting into the system. This principle is expressed by the continuity equation shown below

$$\frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} + \frac{\partial W}{\partial z} = 0 \quad (2.43)$$

The above expression assumes that the density of the fluid is constant. This assumption is acceptable for wind engineering applications. Boundary layer wind flow is usually incompressible even in the case of many extreme cases like hurricanes and cyclones. In aerospace applications, where the fluid is compressible, the form of the continuity equation which conserves ρU is used instead.

2.9.1.2 Momentum conservation law

This law states that if a closed system is not affected by external forces, its total momentum can not change. This law is basically an expression of Newton's second law to fluid motion. When Newton's law is combined with the assumption that the fluid stress is the sum of diffusive viscous stress which is proportional to velocity gradient, and a pressure term, it gives rise to a set of equations known as the Navier-Stokes equations. These equations are used to describe the physics of fluid flow such as weather, ocean currents, pipe flow, and air flow in and around a moving or stationary obstacle.

$$\rho \frac{DV}{Dt} = -\nabla p + \nabla \cdot T + \vec{F} \quad (2.44)$$

$$\rho \left(\frac{\partial V}{\partial t} + V \cdot \nabla V \right) = -\nabla p + \nabla \cdot T + \vec{F} \quad (2.45)$$

The right hand side represents the forces applied on a closed domain of fluid. Surface forces applied due to the normal pressure gradient and viscous shear stresses are explicitly represented. The additional term on the right hand side \vec{F} represents body forces per unit volume. For instance, it can be used to represent the effect of gravity and Coriolis force as shown in Eq.(2.46)-(2.48). For large scale movement of air in the atmosphere and oceanic movements, Coriolis force is an important contributor and is included in weather prediction systems.

$$\frac{dU}{dt} = \frac{-1}{\rho} \frac{\partial p}{\partial x} + fV + \tau_{vx} \quad (2.46)$$

$$\frac{dV}{dt} = \frac{-1}{\rho} \frac{\partial p}{\partial y} + fU + \tau_{vy} \quad (2.47)$$

$$\frac{dW}{dt} = \frac{-1}{\rho} \frac{\partial p}{\partial z} - g + \tau_{vw} \quad (2.48)$$

The hydrostatic assumption, where the atmosphere is assumed to be free from vertical acceleration, is commonly used in wind engineering. As discussed in section 2.4, temperature variations affect density of air and thus non-hydrostatic model of the atmosphere is appropriate for meso-scale or global simulations in meteorological applications.

$$0 = \frac{-1}{\rho} \frac{\partial p}{\partial z} - g \quad (2.49)$$

The left hand-side of Eq.(2.44) is momentum in material derivative form. This is an important concept in fluid dynamics where the Eulerian frame of reference is commonly used. Changes in fluid properties at a fixed location are observed instead of following trajectory of particles as in Lagrangian frame of reference. However once the solution is obtained through Eulerian frame of reference, trajectories (streamlines) can be computed for visualization purposes.

At very low Reynolds numbers, viscous forces dominate inertial forces, and the resulting flow is known as creeping flow (Stokes flow). The limiting case of Navier-Stokes equations where the inertial terms are dropped, for flow approaching $Re \rightarrow 0$, form the Stokes equations. The other limiting case where the viscous terms are dropped instead, for flow approaching $Re \rightarrow \infty$, result in the Euler equations. The flow in the upper portions of the atmosphere can be modeled using Euler equations, but inside the ABL viscous effects cannot be ignored, hence full Navier-Stokes equations should be solved there.

2.9.2 Turbulence models

A major problem with the otherwise very important set of equations is difficulty of getting a closed form solution except for very simple cases. This is due to the convective acceleration term $V \cdot \nabla V$ in Eqs.(2.45) that introduces non-linearity and also couples all components of velocity. As a result the vast majority of flows can be studied only numerically after discretization of the domain and governing equations. Steady state solutions are usually sufficient for most wind engineering applications. However in cases where peak values of pressure and velocity are required, unsteady solutions can be carried out using unsteady RANS (uRANS) or LES turbulence models. The numerical solution of turbulent flows is extremely difficult. The most straight forward solution of turbulent flows involves using a very fine mesh and a laminar flow solver (i.e. no turbulence model) to resolve all flow scales, also known as Direct Numerical Simulation (DNS). The smallest mesh size required to resolve all flow scales is proportional to Kolmogorov length scale η .

$$\eta = \frac{(v^3)^{1/4}}{\epsilon} \quad (2.50)$$

The number of floating point operations required for a DNS solution is proportional to cube of Reynolds number (Re^3), resulting in very high computational cost. The most powerful computers cannot solve practical flows with large Reynolds number which in the case of wind engineering is in the order of $Re \sim 10^6$. Hence this method is rarely used in practice and its use is limited to fundamental research in developing and verifying new turbulence models. RANS equations are used in practice where knowledge of average quantities is sufficient. LES is a computationally expensive alternative that is starting to gain ground for studying bluff body aerodynamics. DNS, which do not use turbulence models, have only been carried out for very simple cases. Moreover the engineer is mostly interested in the mean quantities of flow parameters and sometimes in peak values, and not in instantaneous values. Hence it is convenient to break down the turbulent quantities into mean and fluctuating components using Reynolds decomposition. Different turbulence models are discussed in the following sections.

2.9.2.1 Reynolds Averaged Navier Stokes

For a steady flow the mean can be calculated over an infinite Δt or a value large enough that exceeds the time scales of the largest eddies. For unsteady flow, the average of instantaneous values of the flow quantity over a large number of repeated identical experiments, so called ensemble average, is used.

$$U = \bar{U} + u \quad (2.51)$$

$$p = \bar{p} + p \quad (2.52)$$

Using the Reynolds decomposition for all variables and substituting into the instantaneous Navier Stokes equations, modified equations for the mean values can be obtained which has an additional term that accounts for the effect of turbulent fluctuations on the mean flow. This new equations are the RANS equations.

$$\nabla \cdot \bar{U} = 0 \quad (2.53)$$

$$\frac{\partial \bar{U}}{\partial t} + \nabla \cdot (\bar{U}\bar{U}) = g - \frac{1}{\rho} \nabla \bar{p} + \nabla \cdot \nu \nabla \bar{U} + \overline{U'U'} \quad (2.54)$$

The new term that appears on the right hand side is the Reynolds stress tensor $\mathbf{R} = \overline{U'U'}$ which depends on the velocity fluctuations induced by turbulence. The Reynolds stress tensor is a symmetric tensor with six components which are unknown. But we have only four equations (three momentum equations for each direction and continuity equation). This problem is known as the turbulence closure problem. To close the system of equations turbulence models are used to model the Reynolds stress tensor in terms of known quantities. RANS turbulence models can be categorized as:

- Linear eddy viscosity models
- Non-linear eddy viscosity models
- Reynolds stress models

2.9.2.2 Linear eddy viscosity models

The Reynolds stress tensor \mathbf{R} is computed using the Boussinesq assumption which prescribes linear relation between \mathbf{R} and viscous stresses.

$$-\rho \overline{U'U'} = 2\mu_t S - \frac{2}{3}\rho k \mathbf{I} \quad (2.55)$$

where S is the mean strain rate and k is the mean turbulent kinetic energy.

$$\mathbf{k} = \frac{\overline{U' \cdot U'}}{2} \quad (2.56)$$

$$\mathbf{S} = \frac{(\nabla U + (\nabla U)^T)}{2} - \frac{\nabla \cdot U}{3} \quad (2.57)$$

The new viscosity term ν_t is called turbulence viscosity (eddy viscosity). It can be solved in many ways by solving additional transport equations. Earlier models approximated turbulence viscosity directly from the flow variables without solving additional equations.

1. Zero equation models:

The eddy viscosity is computed using an algebraic equation to close the system of equations. No additional transport equations are solved hence the name zero-equation. One such model for boundary layer type flows is the mixing length model developed by Prandtl. Using dimensional analysis

$$\nu_t (m^2/s) \sim U (m/s) * l (m) \quad (2.58)$$

where U and l are characteristics of the largest turbulence scales. In the mixing length model velocity gradient is used as the velocity scale.

$$\nu_t = l_{mix}^2 \left| \frac{\partial U}{\partial y} \right| \quad (2.59)$$

A problem with this model is that the mixing length is unknown; hence the model is hardly used in practice nowadays. There are other algebraic models commonly used in aerospace engineering to get quick results when robustness in design iterations is more important than capturing all details of turbulence. The Baldwin-Lomax and Cebeci-Smith are such models which prescribe the eddy viscosity in terms of local boundary layer velocity profile.

2. One equation models:

All zero equation models can not properly account for history effects of turbulence due to convection and diffusion of turbulent kinetic energy. The one equation models solve a transport equation, which is usually turbulent kinetic energy k . Prandtl's one equation model is shown below.

$$\mu_t = \rho k^{1/2} l \quad (2.60)$$

$$\frac{\partial k}{\partial t} + \nabla \cdot (\rho \mathbf{V} k) = \nabla \cdot \left(\left[\mu_{lam} + \frac{\mu_t}{\sigma_k} \right] \nabla k \right) + \mu_t G - \rho C_D \frac{k^{3/2}}{l} \quad (2.61)$$

where G is the turbulence generation rate $G = 2\mathbf{S} \cdot \mathbf{S}$ and $C_D = 0.08$, $\sigma_k = 1$.

The last two terms on the right hand side account for production and destruction of turbulent kinetic energy respectively. The length scale is, for example, taken to be proportional to the

boundary layer thickness. However, the main disadvantage of one equation models is that the length scale is not universal for all type of flows.

3. Two equation models:

Two equation models are most commonly used RANS models in industry. Usually one of the equations solved is turbulent kinetic energy k as was the case for one equation models. The other equation is solved to determine the length scale of turbulence, which was a major problem of the one equation models. The turbulent dissipation ϵ or specific dissipation ω are common choices for the second transport equation. The standard k-epsilon model equation for high Reynolds number flow are shown below

$$\mu_t = \rho C_\mu \frac{k^2}{\epsilon} \quad (2.62)$$

$$\frac{\partial k}{\partial t} + \nabla \cdot (\rho \mathbf{V} k) = \nabla \cdot \left(\left[\mu_{lam} + \frac{\mu_t}{\sigma_k} \right] \nabla k \right) + \mu_t G - \rho \epsilon \quad (2.63)$$

$$\frac{\partial \epsilon}{\partial t} + \nabla \cdot (\rho \mathbf{V} \epsilon) = \nabla \cdot \left(\left[\mu_{lam} + \frac{\mu_t}{\sigma_\epsilon} \right] \nabla \epsilon \right) + C_{1\epsilon} \mu_t G \frac{\epsilon}{k} - C_{2\epsilon} \rho \frac{\epsilon^2}{k} \quad (2.64)$$

$$C_{1\epsilon} = 1.44, \quad C_{2\epsilon} = 1.92, \quad C_\mu = 0.09, \quad \sigma_k = 1.0, \quad \sigma_\epsilon = 1.0 \quad (2.65)$$

Wilcox proposed a series of k-omega models that solve specific dissipation (omega) equation to determine length scales. Omega is proportional to the ratio of ϵ and k i.e. $\omega \propto \epsilon / k$. This helps in regions of low turbulence where both ϵ and k goes to zero. In the standard k-epsilon equation the non-linear term (ϵ^2/k) causes stability problems as k approaches zero.

$$\mu_t = \frac{k}{\omega} \quad (2.66)$$

$$\frac{\partial k}{\partial t} + \nabla \cdot (\rho \mathbf{V} k) = \nabla \cdot ([\mu_{lam} + \sigma^* \mu_t] \nabla k) + \mu_t G - \rho \beta^* \omega k \quad (2.67)$$

$$\frac{\partial \omega}{\partial t} + \nabla \cdot (\rho \mathbf{V} \omega) = \nabla \cdot ([\mu_{lam} + \sigma \mu_t] \nabla \omega) + \alpha \mu_t G \frac{\omega}{k} - \rho \beta \omega^2 \quad (2.68)$$

$$\beta = \frac{3}{40}, \quad \beta^* = \frac{9}{100}, \quad \alpha = \frac{5}{9}, \quad \sigma = \frac{1}{2}, \quad \sigma^* = \frac{1}{2}, \quad \epsilon = \beta^* \omega k \quad (2.69)$$

The Boussinesq approximation has an inherent weakness manifested in commonly used two

equation models. In strongly accelerated / decelerated flows and flows with strong curvature the assumption is not valid. Hence the models are incapable of correctly predicting strongly rotating flows. Usually an overproduction of turbulent kinetic energy is observed in those regions. To solve this problem, different modifications to two equation models have been proposed. Normally turbulent kinetic production P in the k equation is specified as

$$P = 2\mu_t(S.S) \quad (2.70)$$

Kato & Launder (1993) proposed an ad-hoc modification to this term by introducing vorticity Ω into the equation. The modified P equation is

$$P = 2\mu_t \left(\sqrt{(S.S) * (\Omega.\Omega)} \right) \quad (2.71)$$

This modification can be applied to all two equation models to alleviate the problem of over production of turbulent kinetic energy in strongly rotating zones. Other modifications on the standard k -epsilon equation to include swirling component of the flow resulted in two modified turbulence models Realizable k -epsilon and RNG (Renormalization Group) k -epsilon. The effect of spin on turbulence, which was missing from the standard k -epsilon model, is incorporated in the equations.

2.9.2.3 Non-linear eddy viscosity models

The linear Boussinesq approximation is dropped in favor of a non-linear relation that includes vorticity to improve the poor performance observed in the two equation model near flow stagnation zones. Hence the Reynolds stress is rewritten as

$$-\rho \overline{U'U'} = 2\mu_t f(S, \Omega, \dots) \quad (2.72)$$

2.9.2.4 Reynolds stress models (RSM)

This is the most elaborate RANS turbulence model which directly calculates Reynolds stresses without the need of modeling. Transport equation for the Reynolds stress (six) is solved together with an equation for dissipation rate (one). The seven additional transport equations make the method very expensive compared to the two equation models, however the benefit obtained from correct solution in rotating flows may balance the cost in some cases. A detailed discussion of this method can be found in Launder et al. (1975).

Figure 2.12: The law of the wall expressed with wall coordinates y^+ and U^+

2.9.2.5 Modeling flow near wall

Close to walls where turbulence is generated, a fine mesh should be used to resolve the details of turbulent motion due to the prevailing sharp gradients. This imposes heavy computational requirements even when using two equation RANS models. The behavior of fully developed turbulent boundary layer flow near wall regions is well established from experiments. Hence, a significant saving on computation can be obtained by developing wall models (wall functions) to predict the near wall behavior for high Reynolds number flows. The law of the wall was first published by Theodore von Karman. The flow adjacent to the wall is dominated by viscous stresses (linear sub-layer) while the one on the top is dominated by turbulent Reynolds stresses (log law layer). In the middle is a buffer layer where both stresses are equally important. For a smooth no-slip wall the logarithmic law of the wall is shown in Fig.2.12. The equations describing the flow near wall are prescribed using dimensionless quantities u^+ and y^+ . The viscous and log-law layer are separated at y^+ value of about 11.

$$y^+ = \frac{u_* y}{\nu} \quad (2.73)$$

$$u^+ = \frac{U}{u_*} \quad (2.74)$$

$$u^+ = \begin{cases} y^+, & \text{viscous layer} \\ \frac{1}{\kappa} \ln(Ey^+), & \text{log-law layer} \end{cases} \quad (2.75)$$

where y the perpendicular distance between the nearest wall and center of nearest cell. For smooth walls values of $E = 9.8$ and $\kappa = 0.41$ are commonly used. In high Reynolds number RANS models, the production and rate of dissipation of kinetic energy are calculated and fixed at the nearest cell to the wall. During the solution phase, the turbulent kinetic energy k from the previous iteration is used to calculate a wall function friction velocity u^* as follows. This is a different friction velocity than atmospheric boundary layer friction velocity used in the log-law.

$$u^* = C_\mu^{1/4} k^{1/2} \quad (2.76)$$

Then the turbulent dissipation (ε) or specific dissipation (ω) rates can be calculated as follows to be used for k-epsilon and k-omega models respectively.

$$\varepsilon = \frac{u^{*3}}{\kappa y} \quad (2.77)$$

$$\omega = \frac{u^*}{\kappa y \sqrt{C_\mu}} \quad (2.78)$$

Then a Dirichlet boundary condition is applied at the nearest cell to the wall with the above values. The turbulent energy production at the walls is calculated using an eddy viscosity coefficient

$$\mu_t = u^* \frac{y^+}{u^+} \quad (2.79)$$

The log-law can be modified for rough wall surfaces by adding an extra term on the right hand side ΔB which is a function of sand grain roughness K_s . Nikurdase (1933) conducted extensive experiments on rough wall surfaces and found out that the log-law has still the same slope when plotted on semi-log scale i.e $1/\kappa$. The plot is just shifted by an amount ΔB which is 0 for smooth walls.

$$u^+ = \frac{1}{\kappa} \ln(Ey^+) - \Delta B \quad (2.80)$$

For fully rough flow with ($K_s^+ \geq 90$), the following approximation for ΔB is suggested by Cebeci and Bradshaw. K_s^+ is dimensionless sand grain roughness ($K_s u^* / \nu$).

$$\Delta B = \frac{1}{\kappa} \ln(1 + C_{ks} K_s^+) \quad (2.81)$$

2.9.2.6 Large eddy simulations

In LES, the small universal eddies are filtered out and modeled using sub-grid scale models (SGS models). This filtering process can be thought of as separating the velocity field into a resolved and sub-grid component. The filtering operation is convolution of velocity with a filtering kernel G .

$$\bar{u}_i(\vec{x}) = \int G(\vec{x} - \vec{\epsilon})u(\vec{\epsilon})d\vec{\epsilon} \quad (2.82)$$

$$u_i = \bar{u}_i + u'_i \quad (2.83)$$

The simplest kernel is a box filter which results in the grid itself acting as a spatial filter. That means the values of velocity on the grid are the filtered values. This implicit filtering is easy to program and is commonly used. For dynamic SGS models explicit filtering with a different filtering kernel such as Gaussian filter is used. Applying the filtering on the Navier-Stokes equation results in filtered equations with an addition stress term (SGS stress).

$$\frac{\partial \bar{u}_i}{\partial t} + \bar{u}_j \frac{\partial \bar{u}_i}{\partial x_j} = -\frac{1}{\rho} \frac{\partial \bar{p}}{\partial x_i} + \frac{\partial}{\partial x_j} ([\nu + \nu_t] \frac{\partial \bar{u}_i}{\partial x_j}) \quad (2.84)$$

The sub-grid scale turbulence models usually employ the Boussinesq hypothesis to calculate the deviatoric part of the SGS stress.

$$\tau_{ij} - \frac{1}{3} \tau_{kk} \delta_{ij} = -2\mu_t \bar{S}_{ij} \quad (2.85)$$

The sub-grid scale turbulent viscosity for the Smagorinsky - Lilly model

$$\mu_{sgs} = \rho(C_s \Delta)^2 |\bar{S}| \quad (2.86)$$

where the filter width $\Delta = (Volume)^{1/3}$ and the constant $C_s = 0.1 - 0.2$

2.9.3 Finite volume discretization

The three most common ways of discretizing the governing equations are the Finite Difference Method, Finite Volume Method and Finite Element Method. In FDM the partial derivatives are replaced with terms usually taken from truncated Taylor series. Its disadvantage is difficulty of applying the method to an irregular grid. The FVM and FEM work with integral forms of the governing equations, and thus can be easily extended to support irregular grids. Moreover the

FVM balances fluxes across faces of cells and hence governing conservation equations (mass, momentum and energy) are always satisfied locally and globally at any stage of the solution. This property makes FVM preferable for engineers which are used to conservation laws. In FEM Galerkin's method of weighted residuals, where the weights have the same form as the shape function, is used. FEM is more mathematically involved than FVM and also the terms of the algebraic equations does not have any physical significance unlike the FVM approach. All approaches can be viewed as variations of method of weighted residuals: FDM as collocation method using Dirac-Delta weights where $w_i = 1$ at nodes and zero everywhere else, FVM as a subdomain method where $w = 1$ in a subdomain and the integral of the weighted residual is forced to zero for each subdomain, and FEM as the Galerkin variation of weighted residuals. From here only the FVM approach is discussed.

In FVM, the differential form of a general transport equation is converted to integral form by integrating over a closed control volume

$$\frac{\partial \rho \phi}{\partial t} + \nabla \cdot (\rho \phi \mathbf{u}) = \nabla \cdot (\Gamma \nabla \phi) + S_\phi \quad (2.87)$$

$$\oint \frac{\partial \rho \phi}{\partial t} + \oint \nabla \cdot (\rho \phi \mathbf{u}) = \oint \nabla \cdot (\Gamma \nabla \phi) + \oint S_\phi \quad (2.88)$$

The volume integrals for the convection and diffusion terms can be re-written into a surface integral form by using Gauss's theorem

$$\oint \nabla \cdot \mathbf{a} dV = \oint \mathbf{n} \cdot \mathbf{a} dA \quad (2.89)$$

$$\frac{\partial}{\partial t} \left(\oint \rho \phi dV \right) + \int_A \mathbf{n} \cdot (\rho \phi \mathbf{u}) dA = \int_A \mathbf{n} \cdot (\Gamma \nabla \phi) dA + \oint S_\phi dV \quad (2.90)$$

where \mathbf{n} the surface normal vector. For transient simulation, integration in time is applied on top. Because time is a one way coordinate, solution marches forward from initial prescribed conditions at t_0 . Temporal discretization is division of the total time in to small time steps of Δt .

The accuracy of the discretization method depends on the assumed variation of ϕ in space and time around the center of the control volume. If a stepwise profile, where a constant value of ϕ is assumed throughout the control volume, a first order accurate discretization scheme is arrived. To get second and higher order accuracy, a profile assumption, such as piece wise linear, that couples the values of ϕ in adjacent control volumes is required. Not all terms of

the equation above have to be discretized the same way. For instance, the convection term is usually discretized with first order accurate stepwise profile, while the diffusion term uses second order accurate piece wise linear profile. Which ever method is used, the model should posses certain properties to be useful.

1. Consistency: Truncation error should vanish as $\Delta t \rightarrow 0$ and $\Delta x \rightarrow 0$
2. Stability: Errors in the course of the simulation should not magnify, and cause divergence.
3. Conservation: Conservation of physical quantities on both local and global scales.
4. Boundedness: Solutions must lie within proper bounds dictated by the boundary values.
5. Realizability: The solutions obtained should be realistic

2.9.3.1 Convection discretization

As mentioned before, Gauss's theorem can be used to convert the volume integral into a surface integral with interpolated quantities at the surface (Jasak (1996))

$$\begin{aligned} \oint \nabla \cdot (\rho U \phi) dV &= \sum S \cdot (\rho U \phi)_f \\ &= \sum S \cdot (\rho U)_f \phi_f \\ &= \sum F_f \phi_f \end{aligned} \quad (2.91)$$

where F represent the mass flux though the face, and S the surface normal vector with magnitude equal to the area of the face.

$$F = S \cdot (\rho U)_f \quad (2.92)$$

Three basic discretization schemes are considered below. ϕ_f represents the value at the shared face between two control volumes P and N.

1. Central difference scheme (CDS) : Second order accurate but unbounded

$$\phi_f = f_x \phi_P + (1 - f_x) \phi_N \quad (2.93)$$

2. Upwind scheme (UDS): Bounded but first order accurate

$$\phi_f = \begin{cases} \phi_P, & F \geq 0 \\ \phi_N, & F < 0 \end{cases} \quad (2.94)$$

3. Blended scheme (BS): A compromise between accuracy and boundedness by blending the above two methods

$$\phi_f = \gamma\phi_P + (1 - \gamma)\phi_N \quad (2.95)$$

4. Hybrid scheme: Picks either of CDS or UDS depending on how strong convection is compared to diffusion. The Peclet number is defined as $P_e = F/D$ where D is diffusion conductance $D = \gamma/\delta x$. The method takes advantage of the good properties of CDS and UDS; it is bounded and has better accuracy than UDS, however its accuracy is still first order.

$$\phi_f = \begin{cases} CDS, & |P_e| \leq 2 \\ UDS, & |P_e| > 2 \end{cases} \quad (2.96)$$

5. Total Variation Diminishing (TVD) schemes: The schemes discussed so far are either unbounded (e.g. CDS) or of first order accuracy (e.g. Hybrid). There is a need for high resolution(HR) schemes that are bounded and non-oscillatory. These schemes are especially important for shock predictions, in which all the previous schemes can give false predictions when used on coarse grids. A class of HR schemes known as TVD schemes start from implicit UDS scheme for the sake of boundedness, and then add explicit source term (difference of higher order scheme (HOS) and UDS scheme) to improve accuracy in each iteration via what is known as a ‘deferred correction’ approach. In this sense, all the previous convection discretization schemes are implicit because the final values are obtained after exactly one iteration without correction. Deferred correction can also be used in other situations where it is difficult or impossible to handle terms implicitly. For example non-orthogonality of mesh can be handled by starting from the assumption of orthogonality and then adding explicit corrective terms in every iteration. Before the time step is updated to the next one, the deferred corrections should be iterated until convergence (or acceptable level of accuracy) with the only changes coming from deferred corrections.

$$\phi_f = UDS \quad (2.97)$$

$$S_u = \sum [(HOS - UDS) * F] \quad (2.98)$$

If the HOS is CDS then the TVD scheme becomes a bounded central difference scheme. Other TVD schemes are Linear upwind scheme (LUD), Monotone Upstream-centered

Schemes for Conservation Laws (MUSCL), VanLeer etc.

2.9.3.2 Diffusion discretization

The diffusion term is discretized similarly with the central difference scheme.

$$\begin{aligned} \oint \nabla \cdot (\rho \Gamma_\phi \nabla \phi) dV &= \sum S \cdot (\rho \Gamma_\phi \nabla \phi)_f \\ &= \sum (\rho \Gamma_\phi)_f S \cdot (\rho \Gamma_\phi)_f \end{aligned} \quad (2.99)$$

where the surface gradient is approximated by

$$S \cdot (\nabla \phi)_f = |\mathbf{S}| \frac{\phi_N - \phi_P}{|\mathbf{d}|} \quad (2.100)$$

For non-orthogonal meshes such as tetrahedrons and pyramids, a deferred correction approach is used as discussed in the previous section. \mathbf{S} is split into two components one always parallel to the line connecting the centroids (Δ) and another chosen in different ways (\mathbf{k}).

$$\mathbf{S} \cdot (\nabla \phi)_f = \Delta \cdot (\nabla \phi)_f + \mathbf{k} \cdot (\nabla \phi)_f \quad (2.101)$$

$$\mathbf{S} = \Delta + \mathbf{k} \quad (2.102)$$

This splitting can be done in three different ways

1. Minimum correction: makes the correction as small as possible by making Δ and \mathbf{k} orthogonal to each other, i.e. $\Delta \cdot \mathbf{k} = 0$.
2. Orthogonal correction: This approach keeps the contribution of ϕ_P and ϕ_N same as that on an orthogonal mesh despite the amount of non-orthogonality, i.e. $|\Delta| = |\mathbf{S}|$.
3. Over-relaxed: This approach increases the contribution of ϕ_P and ϕ_N with non-orthogonality in such a way that $\mathbf{S} \cdot \Delta = 0$.

The non-orthogonal correction may not preserve boundedness of a scheme, hence the correction should be limited or completely abandoned if preservation of boundedness is more important (Jasak 1996).

2.9.3.3 Source term discretization

Source term may have non-linear terms which need transformation to linear forms (linearization). For example, the $k - \epsilon$ turbulence mode has a highly non-linear dissipation term in the

transport equation for dissipation ϵ . The linearization can be carried out in many ways that give different values of S_u and S_p . Convergence rate and stability of solution depends on the selected linearization scheme.

$$S_\phi(\phi) = S_u + S_p\phi \quad (2.103)$$

$$\oint S_\phi(\phi) dV = S_u V_P + S_p V_P \phi_P \quad (2.104)$$

2.9.3.4 Temporal discretization

Temporal discretization of spatial derivatives can be carried out in three ways.

1. Implicit: Current values of ϕ are assumed to persist through out the time step. The advantage of this method is that it is bounded and unconditionally stable, however since the unknown current ϕ values are coupled with each other, a set of simultaneous equations need to be solved at each time step.
2. Explicit: Old values of ϕ are assumed to persist through the time step. The new ϕ values depend only on the old values, hence explicit updates can be carried out. However it comes with a price of using small time step Δt to insure stability of solution. The Courant number $Co = U.\Delta t/\Delta x$ should be less than one for stability.
3. Crank Nicholson: A linear variation of ϕ between old and new values is assumed within the time step to get a second order accurate scheme. It is unconditionally stable but unbounded. Patankar (1980) notes that unconditionally stability refers to the fact that the oscillations will eventually die out, not to the absence of them

The above discretization concern the time at which the values of spatial derivatives are to be evaluated. The first time derivative itself use implicit first order Euler scheme, that becomes second-order accurate if the Crank Nicholson scheme is used for the spatial derivatives.

$$\frac{\partial}{\partial t} \oint \rho\phi dV = \frac{(\rho\phi V)_i - (\rho\phi V)_{i-1}}{\Delta t} \quad (2.105)$$

Higher order Runge-Kutta or other implicit/explicit time integration schemes can be used for more accuracy. First and second time derivatives can also be discretized with backward differencing scheme that require values of ϕ in the previous two time steps. This results in second order scheme for the first derivative and only first order for the second derivative.

$$\frac{\partial}{\partial t} \oint \rho\phi dV = \frac{3(\rho\phi V)_i - 4(\rho\phi V)_{i-1} + (\rho\phi V)_{i-2}}{2\Delta t} \quad (2.106)$$

$$\frac{\partial}{\partial t} \oint \rho \frac{\partial \phi}{\partial t} dV = \frac{(\rho \phi V)_i - 2(\rho \phi V)_{i-1} + (\rho \phi V)_{i-2}}{\Delta t^2} \quad (2.107)$$

2.9.4 Boundary conditions

Boundary conditions are required to obtain a well-posed problem and complete the solution. The basic boundary conditions are the Dirichlet type where the value of ϕ is prescribed and the Neumann type where the value of the gradient $\nabla\phi$ is prescribed. Other boundary conditions can be derived from these basic boundary conditions. Some of those implemented in the software are discussed below

1. Dirichlet: Fixed values applied on faces of a boundary. This include different profiles such as uniform, power-law, log-law, parabolic etc. In addition, these boundary conditions have turbulence intensity parameters to change their values with time. The fluctuations can take on a prescribed turbulence intensity profile or simple random fluctuations about a mean value of ϕ . Correlated fluctuations such as one that satisfies the von Karman spectrum can also be imposed but are not implemented in current software.
2. Neumann: The value of ϕ at the boundary face is calculated from its value at the adjacent cell center and the specified gradient.

$$\phi_b = \phi_P + \mathbf{d}_n \cdot (\nabla\phi)_b \quad (2.108)$$

The value at the boundary ϕ_b can be eliminated from the set of equations by substituting the above equation for a given value of gradient.

3. Symmetry: When the domain is symmetrical in geometry and boundary conditions, the flow is also symmetrical with no flux through the symmetry plane. Hence this boundary condition sets the normal component $\nabla\phi_n$ to 0. In this case ϕ_b can not be eliminated from the set of equation, hence a deferred correction approach is used instead such that the boundary condition is obeyed gradually with iterations.
4. Cyclic: This boundary condition is applied when the domain wraps around and the value at one end is the same as the value at the other. This is implemented the same as the Neumann methods above where half of the cells in the boundary are used as inputs to the other half for all flow quantities.

5. Ghost: When a decomposed domain is solved in parallel, the values at the boundary are exchanged through ghost cells. This is similar to cyclic boundary condition but is a two way update.
6. Derived: Other derived boundary conditions such as Robin, turbulence generating wall boundary conditions etc.

2.9.5 Calculation of flow field

Once the set of algebraic equations relating values of ϕ at control volume centers are obtained, we set out to solve the equations but there are some more difficulties to overcome. First the convective acceleration term in the momentum equations, i.e. ‘velocity being transported by itself’, results in non-linear terms with squared velocities. However this non-linearity is not a problem for iterative solvers that work on linearized equations formed from guessed values U . In other words one of the U ’s is treated explicitly and is no more different than other coefficients. What is problematic is the apparent absence of an equation for obtaining pressure, that appears only in the momentum equation. If the pressure was specified directly, the momentum equation could be solved with no difficulty. Instead the pressure field is indirectly specified through the continuity equation, which couples pressure and velocity.

For efficiency reasons segregated solvers are commonly used. Each component of velocity and pressure (via continuity equation) are solved separately. This decoupling of pressure and velocity can sometimes result in few problem that are discussed later. To ensure convergence towards a solution, a strategy to iteratively link the equations is required. If direct methods are used, all the components can be solved simultaneously. However the cost of direct solution is significantly larger than that of iterative solvers both in terms of memory and floating point operations.

A related problem is the representation of the pressure gradient term. If both u and p are stored at the centers of same control volumes, part of the pressure gradient term will cancel out. This results in a situation where pressure is being effectively solved at twice a coarser grid than velocity. This is a partial decoupling of pressure and velocity which can result in unrealistic oscillating solutions between alternating grids (checkerboard pattern). This problem can be solved by storing pressure and velocity at adjacent grid points (staggered grid) to prevent the decoupling. This has been the preferred method for decades but it is problematic for implementation in non-orthogonal and unstructured grids. Also two grids have to be maintained for solution of velocity and pressure.

In collocated grid arrangement, all the variables are stored at the same location and is very convenient for programmers. Collocated grids have become popular since the discovery of Rhie and Chow interpolation for pressure velocity coupling. The velocity at the faces is interpolated in such a way that pressure and velocity remain coupled. This method is usually seen as a correctional approach between the pressure gradient at the face and the interpolated pressure gradient (Ferziger & Peric (2001))

$$u_j = u_j - \Delta \left(\frac{1}{A_p^{u_j}} \right) \left(\frac{\partial p}{\partial x_j} - \overline{\left(\frac{\partial p}{\partial x_j} \right)} \right) \quad (2.109)$$

First the momentum equations are solved with old pressure values. This stage is the momentum prediction step which is necessary when there are other scalar transport equations to be solved. To solve for pressure using continuity equation the pressure contribution to momentum is separated from the rest. Following Ferzigers notations

$$[U] = \frac{H}{A} - \frac{1}{A} \nabla [p] \quad (2.110)$$

$$U_* = \frac{H}{A} \quad (2.111)$$

H represents contributions from neighboring cells, previous time step, other sources but the pressure gradient term. Applying the divergence operator to the above equation, and setting the left hand side to 0 due to continuity, we arrive at pressure Poisson equation

$$\nabla \cdot ([U_*]) = \nabla \cdot \left(\frac{1}{A} \nabla [p] \right) \quad (2.112)$$

Once the pressure equation is solved, velocity that satisfy continuity can be obtained by adding back the pressure contribution. This is the explicit velocity correction step.

The two commonly used segregated solvers are Semi Implicit Method for Pressure Linked Equations (SIMPLE) for steady state simulations and Pressure Implicit with Splitting Operators (PISO) for transient simulations. The major difference between these two methods is that PISO solves the pressure equation more than once, while SIMPLE relies on a severe under-relaxation of pressure equation for convergence. For steady state simulations, non-linearity of the system becomes more important than pressure-velocity coupling since changes of ϕ between successive iteration is large anyway.

Chapter 3

Implementation of 3D CFD program

The basics of the Computational Fluid Dynamics (CFD) program developed in this work is briefly described in the following sections. The program solves continuum mechanics problems using the Finite Volume Method (FVM). An Object Oriented Programming approach (OOP) using C++ is used which is inspired by the design of OpenFOAM (Jasak et al. 2007, OpenFOAM 2013, Weller et al. 1998). This helps to significantly reduce the time required to write new solvers for any Partial Differential Equation (PDE). The code developed in this work is about 7300 lines and is available in Appendix C.2. The development started from the lowest units of tensor and field manipulations. The reason for this choice is to gain expertise in developing CFD software and also have the utmost freedom in implementing performance enhancements using latest technology such as Graphic Processing Units (GPUs). The code has been parallelized to run on a homogeneous cluster of Central Processing Units (CPUs) and also on a single GPU. Validation is an important step in development of any CFD program. Therefore for every new feature added to the program, such as turbulence models or new discretization methods, validation has been carried out with well known benchmark cases. Some of the test cases are described at the end of the chapter.

3.1 Tensors

Problems in continuum mechanics can be concisely expressed using tensors and associated linear field operations. For example the second order stress and strain tensors can be represented by a 3×3 array. The program represents tensors using template classes with parameters describing the rank of a tensor and a parameter specifying storage for each element of the tensor. Storage can be either single precision or double precision. Common operations for all rank

tensors such as addition, subtraction, dot product etc are optimized by unrolling loops to allow parallel operations on each element of the tensor. Use of templates for representing tensors allows production of optimized code for each instance of the template with as little effort as possible. In older CFD codes using FORTRAN, separate code had to be written even for the case of increasing the precision of solution.

An example illustrating this advantage is shown below for calculating the dot product of any size tensor.

```

1  template <int N>
2  struct Unroll {
3      static FORCEINLINE Scalar dot(const Scalar* p, const Scalar* q) {
4      return (*p) * (*q) + Unroll<N - 1>::dot(p + 1, q + 1);
5      }
6  }
```

Operations specific to a given rank tensor such as finding the transpose, symmetric, skew tensors of a second rank tensor are implemented taking into consideration the known size and nature of the tensor. For example, most tensors encountered in fluid mechanics are symmetric which reduces the number of elements that need to be stored from nine to six. Such optimization are taken advantage of whenever possible.

Some of the implemented tensor operations are:

1. Inner product: The dot product on two vectors, double inner product on two second rank tensors and triple inner product on third rank tensors all give a scalar. This is concisely implemented as shown in the above code snippet. Other inner products yield vectors and tensors that requires special handling. For example, inner product of a vector and second rank tensor gives a vector, and that of two second rank tensors yield a second rank tensor.
2. Outer product: The outer product of two vectors yield a second rank tensor while that of a vector and second rank tensor give a third rank tensor.
3. Exclusive operations to a tensor of given rank :
 - First rank tensors: Cross product
 - Second rank tensors: Transpose, symmetric and skew components, hydrostatic and deviatoric components etc.

$$\begin{aligned}
 A &= 1/2 * (A + A^T) + 1/2 * (A - A^T) &= \text{symm}(A) + \text{skew}(A) \\
 A &= A - 1/3(\text{trace}(A)) + 1/3(\text{trace}(A)) &= \text{dev}(A) + \text{hyd}(A)
 \end{aligned}
 \tag{3.1}$$

3.2 Fields

A tensor represent values of physical quantities or their derivatives at a point in space and time. Solution of a PDE such as the Navier-Stokes equations involves discretization of the domain into what is commonly known as a grid or mesh. The set of tensors of each point in the domain forms a tensor field of the physical quantity over the mesh that varies both in space and time. Thus a tensor field is implemented as an array (vector) of tensors of size equal to the number of nodes or faces of the mesh. The values may be stored at cell centers, vertices or face centers. All tensor operations for single grid points are extended for the tensor fields as well. Important differential operations on tensor fields that are required to formulate any PDE are described in the following paragraphs.

1. Gradient: The derivative (gradient) of a continuously differentiable scalar field gives a second rank tensor field (vector field) .

$$grad(s) = \nabla s = \left(\frac{\partial s}{\partial x}, \frac{\partial s}{\partial y}, \frac{\partial s}{\partial z} \right) \quad (3.2)$$

Similarly the gradient of a second or higher rank tensor field can be derived by taking the gradient of each scalar component to get a tensor field one rank higher.

2. Divergence: Divergence operation on a vector field gives a scalar field that represents the net outward flow at each grid point.

$$div(v) = \nabla \cdot V = \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} \quad (3.3)$$

Similarly the divergence of a second rank or more tensor field yields a tensor field one rank lower.

3. Curl: The curl of a vector field represent the rotation (vorticity) of the flow field.

$$curl(v) = \nabla \times V = \left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z}, \frac{\partial u}{\partial z} - \frac{\partial w}{\partial x}, \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right) \quad (3.4)$$

4. Laplacian: Laplacian is the divergence of gradient of a tensor field.

$$lap(S) = \nabla \cdot \nabla S = \nabla^2 = \frac{\partial^2 S}{\partial x^2} + \frac{\partial^2 S}{\partial y^2} + \frac{\partial^2 S}{\partial z^2} \quad (3.5)$$

5. Temporal derivative: The total derivative measures the rate of change of a quantity ϕ as an infinitesimally small volume of material (particle) moves .

$$\frac{D\phi}{Dt} = \lim_{\Delta t \rightarrow \infty} \frac{\Delta\phi}{\Delta t} \quad (3.6)$$

In fluid mechanics the rate of change observed at a fixed point in space, i.e spatial time derivative $\partial\phi/\partial t$, is preferred

$$\frac{D\phi}{Dt} = \frac{\partial\phi}{\partial t} + U \cdot \nabla\phi \quad (3.7)$$

3.3 Equation discretization

The partial differential equations for fluid flow can be compactly expressed by field operators discussed in the previous section. Equation discretization involves conversion of components of the PDE (first time derivative, convection, diffusion and source term) into linear algebraic equations. Also non-linear source terms have to be converted in to an equivalent linear form. The final set of equations can then be represented in matrix form as

$$[A]\{\phi\} = \{B\} \quad (3.8)$$

where $[A]$ is a matrix of coefficients , ϕ is a vector of the unknown quantity at cell centers and b is a vector of source terms.

A field operation can be explicit in which case a tensor field is transformed into another without contributing to the coefficient matrix. The gradient (∇), divergence ($\nabla \cdot$) and curl ($\nabla \times$) operation are examples of such explicit operations. On the other hand, the operation can be implicit in which case values of ϕ at neighboring cells are coupled through the coefficient matrix A . The coefficient matrix is extremely sparse with zeros filling up most of the matrix. This is because when two cells do not share the same face the corresponding coefficients are both set to zero . Various specialized methods for efficient storage and solution of sparse matrices are available. The storage method used in this work is suitable for polyhedral meshes in which a control volume can contain any number of faces. After finite volume discretization, coefficients are obtained for each cell : a_p for the parent cell and a_n for each of the neighboring cells sharing a face with the parent.

$$a_p\phi_p = \sum a_n\phi_n + S \quad (3.9)$$

The sparse matrix format used in this study stores a_p and a_n separately in different scalar fields. Hence the non-zero elements are not stored resulting in tremendous saving of memory, and also solution with fixed point iterative methods becomes straight forward. This form of matrix representation is not suitable for computations on the GPU, hence another type of representation known as Compressed Sparse Row (CSR) is used instead. CSR is a popular general purpose format that stores non-zero values and corresponding column indices.

Finite volume discretization integrates each term of the PDE in a control volume. The volume integration is converted into a surface integral (summation) over the faces of the polyhedral mesh.

$$\oint_V \nabla * \phi dV = \oint_S dS * \phi = \sum S * \phi \quad (3.10)$$

where S is the surface area vector and $(*)$ represents any tensor operation.

3.4 Overview of components of CFD tool

A short summary of the components of the developed CFD program is given in the following sections. The software is developed in C++ using an object oriented programming approach (OOP). Classes are provided for different field calculus such as divergence, laplacian, temporal derivative etc. This makes the software suitable for solving PDE other than Navier-Stokes equations. Templates are extensively used to avoid duplication of code. The design of the program keeps the implementation of the physics (Navier stokes equations, turbulence model etc) isolated from other parts of the program, so that different mathematical models can be tried conveniently.

3.4.1 Partial differential equation solvers

Writing solvers for many PDEs becomes easy once the basic field and tensor operations are programmed. These include divergence, laplacian, temporal derivative, gradient among others. Some of the PDE solvers implemented that were necessary for this work are briefly described as follows

3.4.1.1 Wall distance solver

It is necessary to calculate the distance of a grid cell to the nearest wall for some turbulence models and other applications. This can be obtained by solving a differential equation first proposed by Spalding (1994). The following equations are solved with boundary conditions

Figure 3.1: Contour map of wall distance from the surface of a 2D hill

for ϕ set as Dirichlet at ground surface and Neumann elsewhere.

$$\nabla \cdot \nabla \phi = -V \quad (3.11)$$

Then the distance to nearest wall is calculated as

$$y = \sqrt{\nabla \phi \cdot \nabla \phi + 2\phi} - |\nabla \phi| \quad (3.12)$$

These two equations are implemented as follows. This is the simplest solver implemented but other complex solvers do not pose more difficulty.

```

1 void Mesh::calc_walldist(Int step,Int n_ORTHO) {
2   ScalarCellField& phi = yWall;
3   /*poisson equation*/
4   ScalarFacetField one = Scalar(1);
5   for(Int k = 0;k <= n_ORTHO;k++)
6     Solve(lap(phi,one) == -cV);
7   /*wall distance*/
8   VectorCellField g = grad(phi);
9   yWall = sqrt((g & g) + 2 * phi) - mag(g);
10  /*write it*/
11  yWall.write(step);
12 }

```

An example simulation result using this solver for a 2D hill is shown in Fig. 3.1.

3.4.1.2 Potential flow solver

In potential flow theory, the velocity field is assumed to be gradient of velocity potential $V = \nabla \phi$ and also that the fluid is inviscid (no viscosity $\nu = 0$) and irrotational (no vorticity $\nabla \times V = 0$).

For an incompressible flow where $\nabla \cdot V = 0$, the previous two equations reduce to a single Laplace equation from which all flow parameters can be determined

$$\nabla \cdot \nabla \phi = 0 \quad (3.13)$$

The specified initial flow field will inevitably not satisfy continuity due to imposed boundary conditions ($\nabla \cdot V \neq 0$), hence a pressure Poisson equation is solved and the velocity is corrected with the gradient of p , which is the velocity potential ϕ . At the end of solution, continuity equation will be satisfied so that $\nabla \cdot V = 0$. This solver can be used for initializing flow field as exemplified by its use in OpenFOAM (2013).

$$\begin{aligned} \nabla \cdot \nabla p &= \nabla \cdot U \\ U &= \nabla p \end{aligned} \quad (3.14)$$

3.4.1.3 Parabolic diffusion solver

The parabolic heat equation is solved using implicit or explicit temporal discretization schemes. The steady state version drops the temporal derivative to become Laplace's equation for temperature, in which case under-relaxation is necessary to avoid divergence of solution.

$$\frac{dT}{dt} = -\alpha * \nabla \cdot \nabla T \quad (3.15)$$

3.4.1.4 Transport equation solver

Once the flow field (velocity) field is established, transport of pollutants, dies and even turbulent flow quantities themselves (k and $epsilon$) can be obtained by solving a 'transport' equation for any tensor.

$$\frac{\partial \epsilon}{\partial t} + \nabla \cdot (\rho V \epsilon) = \nabla \cdot \mu \nabla \epsilon \quad (3.16)$$

3.4.1.5 Navier-Stokes solver

The details of this solver will be explained in the following sections but it basically solves transport equation for momentum and the continuity equation. Source terms in the form of surface and body forces such as pressure gradient, Coriolis force and others are added to the momentum transport equations. Different turbulence models are used for closure.

$$\frac{\partial V}{\partial t} + \nabla \cdot (VV) = -\nabla p + \nabla \cdot \nu \nabla V + F \quad (3.17)$$

3.4.2 Meshing

The issue of mesh generation is a vast topic beyond the scope of this study however we give a glimpse of what is required. It is known that the quality of mesh plays a major role in the quality of simulation results. For finite volume discretization, Hexahedral elements are known to give much better results compared to tetrahedrals. Hexahedral grid leads to faster solutions and requires lower cell count than tetrahedral grid, while keeping the same quality of results. Unfortunately most of the existing grid generation software is adapted to finite element codes in which tetrahedral elements are popular. Tetrahedral grid can be generated for a complex terrain using algorithms such as Delaunay triangulation. This has proven to be successful in the finite element field, but not so much in the finite volume field mainly due to the problems mentioned above. It is also very difficult, if not impossible, to generate Hexahedral meshes for an irregular geometry. Tetrahedral meshing of an irregular geometry is relatively easy and many free software are available for that purpose. Automatic hexahedral mesh generation suitable for finite volume solutions is still an active research area. This study does not attempt to produce a grid generator for complex surfaces but simply adds support to import grid from other grid generating software. For 2D grids, body fitted grid methodology using transfinite interpolation is used which has proved rather useful in some of the 2D hill simulations. The same method is used for simple 3D mesh generation when the surface is not too complex. This tool was enough for most of the study cases considered in this research such as simple rectangular buildings, staggered/regular array of cubes etc. To improve quality of grid with elongated and skewed cells, special care is taken during the discretization steps to account for mesh non-orthogonality and skewness as suggested in Jasak (1996).

3.4.3 Solution and turbulence modeling

Boundary layer wind flow is incompressible even in the case of many extreme cases such as hurricanes and cyclones. Like many other engineering flows, it is also of a high Reynolds type flow. Hence the program is geared towards solving an incompressible Navier Stokes equation at high Reynolds number. An incompressible pressure based solver is used as opposed to a general type compressible density based solver. The Navier Stokes equations are non-linear and coupled at the same time. Both problems can be tackled using segregated iterative solvers, in which partial solution of velocity and pressures are sought one after the other. For this study, the Semi Implicit Method for Pressure Linked Equations (SIMPLE) and Pressure Implicit with Splitting Operators (PISO) algorithms are implemented.

The linear solvers that are implemented include Successive Over Relaxation (SOR), Pre-conditioned Conjugate Gradient (PCG) and Preconditioned Bi Conjugate Gradient (PBiCG) methods. An algebraic multi grid solver (AMG) is planned for the future. The turbulence model implemented include many high-Re versions of Reynolds Averaged Navier-Stokes (RANS) models and the Smagorinsky Large Eddy Simulation (LES) model. The standard k-epsilon model has proven to be a cost effective solution to many wind engineering flows. However it fails to give accurate results in regions of flow separation such as at corners of buildings. Many large scale experiments have been conducted at the Wall of Wind (WoW) facility at FIU which consistently demonstrated this deficiency of RANS models. LES models, including the simplest one implemented in this study (Smagorinsky model), have shown good agreements with experimental data. The use of sub-grid scale (SGS) two equation models without the use of wall functions gives the best results, but the temporal and spatial resolution requirements for high-Re flows limits its applicability.

3.4.4 Parallelization

Even for simulation on a simple cubical building, the computational demand may be very high depending on the accuracy required (Kose & Dick 2010). Flow around bluff bodies is extremely unsteady and turbulent and require fine resolution in both time and space. For instance, Lim et al. (2009) used about 10 million cells to model a flow around a single building for a flow with a Reynolds number of 20,000. This Reynolds number (Re) is in fact too low compared to typical values of a few millions in wind engineering. Hence simulation of realistic situation would require much more grid cells. The demand for simulations on complex terrain is even more severe. Therefore parallel computing can be helpful in a wide spectrum of flow problems.

The CFD software developed is parallelized using the Message Passing Interface (MPI) communication protocol to exchange information between different sub-domains. The communication is kept as low as possible to account for the relatively slow Ethernet network connections that are common in commodity clusters. The software is also parallelized to run on the state-of-the-art High Performance Computing (HPC) technology using General Purpose Graphic Processing Units (GPGPUs). A speed up of up to 100 times as fast as a serial version has been reported in literature (Julien & Senocak 2009). However this was for simple benchmark problems that are not representative of simulations carried out in practical wind engineering. Nowadays, regular desktop computer with GPUs of up to thousands of cores can be bought for couple of hundred dollars and give cluster-level performance. The top-most supercomputers in the world use both GPUs and CPUs to reach peak performance in the order of

peta FLOPS (Meuer 2013).

3.5 Development of high performance CFD code

Large scale simulation of wind flow over complex topography requires tremendous amount of computational resources: CPU hours and memory. Also the use of mesh refinement close to walls or use of more complex turbulence models, for example LES instead of K-epsilon model, will add to the computational demand. As mentioned before, even simulations around a single building may require tens of millions of grid cells to fully resolve the flow. Hence it is usually necessary to take a cut in accuracy of flow simulations close to walls by assuming the law of the wall to hold there. Parallel computation on cluster of machines can help to get quick results without degrading quality of results.

3.5.1 Domain decomposition

Complex terrain simulations produce mega bytes of data at each time step of the simulation, making it impossible to simulate the whole domain all in one computer. The high performance CFD software uses domain decomposition methods in which each processor takes care of part of the terrain, while exchanging information during the solution stage. Domain decomposition is a ‘divide and conquer’ strategy that is commonly used when either the problem is too big to fit in memory or the sub-domains are easily solved than the original. The method is extensively used in aerospace engineering to conduct finite element and finite volume CFD simulations on parts of an air-plane. The program uses a non-overlapping domain decomposition methods to parallelize the solution of the Navier Stokes equations. The details of the parallelization are given in the following sections.

3.5.2 Platform for high end simulation

From 2009-2012, the Tesla-128 cluster at Florida international university is used for development and validation of the code. The cluster is composed of 64 nodes as shown in Fig. 3.3, each with a fast Ethernet interface and a gigabit Ethernet interface. All 64 nodes are connected by a 48-way fast Ethernet switch. From May 2012 onwards, the multi-institutional Shared Hierarchical Academic Research Computing Network (SHARCNET) is used. It is much more powerful than the Tesla cluster and also have GPU clusters on which the code is tested.

Figure 3.2: MAIDROC tesla cluster at FIU with $2 \times 64 = 128$ cores

Figure 3.3: SHARCNET cluster, a network of high-performance computers

3.5.3 Parallel computing

Coarse grained parallelism in a distributed memory cluster is traditionally achieved by domain partitioning strategies. The whole domain is partitioned into smaller sub-domains which are assigned to one processor in a cluster. In this study a non-overlapping type of domain decomposition method is implemented where information such as pressure and velocity is exchanged at the boundary through ghost cells during the calculation phase. The MPI is used to exchange information between sub-domains.

GPGPU are overtaking CPUs in the HPC market. They are especially suitable for solving linear system of equations such as those obtained from fluid flow problems. Julien & Senocak (2009) reported speed ups of up to 100 times compared to a CPU implementation. The program is parallelized using NVIDIAs Compute Unified Device Architecture (CUDA) programming toolkit to harness the fine grained parallelism offered by GPUs. Both methods of parallelization are combined at the solver level so that a mixed CPU-GPU computation is possible. Finally the speed up numbers obtained for different size problems are compared.

3.5.3.1 Coarse grained parallelism

Parallel computing using domain decomposition (DD) methods have been used extensively in finite element methods used in aerospace engineering. Even when the computational resources were very limited, the decomposed sub-domains are solved one by one on a regular desktop computer by imposing special boundary conditions suitable for the kind of problem being solved. Some of the non-overlapping DD methods are the Dirichlet - Neuman, Neumann-Neumann, and other adaptive variations of these methods suitable for hyperbolic convection problems. While the motivation for these methods was to solve large size problems which do not fit in the memory space of a desktop computer, our motivation in this study is to exploit concurrency using a cluster capable of holding the whole computational domain. Thus synchronization between the sub-domains is done while all sub-domains are being solved simultaneously. The domain partitioning strategy adopted in this study is done in two ways. First synchronizing all the working processors at each and every iteration of the solver using barriers *MPI_Barrier()*. Gropp et al. (1999) describes a way of parallelizing Poisson equation using this method. An asynchronous communication method is also implemented and tested in this study. The details of this unique implementation is given later in this chapter.

3.5.3.2 Fine grained parallelism

GPUs are the latest technology in HPC that broadens the scope of graphic co-processors to number crunching besides rendering graphics. GPUs with hundreds of processors are very cheap to set up compared to cluster of CPUs. GPGPU computing is at its infancy compared to distributed computing using MPI. However, excellent acceleration of the fluid simulations on GPUs have been reported in many fields including wind engineering (Corrigan et al. 2009, Julien & Senocak 2009, Selvama & Landrus 2010).

The first generation of GPGPUs were difficult to program because one has to use graphics rendering operation to do number crunching as well. This changed with the introduction of NVIDIAs CUDA programming language and OpenCL which are extensions to traditional programming languages such as C. NVIDIAs CUDA programming language is used to parallelize three solvers SOR, PCG and PBiCG. These three solvers are used to solve incompressible Navier-Stokes equations, Poisson pressure equation and transport equations used in turbulence modeling. Among the above equations, the solution of the elliptic Poisson-pressure equation is the most time consuming which makes it a good candidate for computation on the GPU. All of the solvers mentioned can be implemented on the GPU with relative ease, but in some cases sacrifices are made for ease of implementation and better parallelization. Algorithms that are hard to parallelize on the GPU include pre-conditioners of the Incomplete Cholesky type. Selvama & Landrus (2010) reported speed up of up to 24x using a simple Jacobi preconditioner thus that is also used in our program. Corrigan et al. (2009) reported a speed up of upto 33x times over the equivalent serial code on an unstructured grid. Use of shared memory and coalesced memory access are reported to accelerate GPU solver significantly, but no attempt is made in this study to optimize implementations to the fullest. In general structured grid solvers have a regular memory access pattern that can be exploited during optimization, but unstructured grid requires re-numbering to ensure two neighboring cells remain close in memory. Most of the comparisons in literature on CPU vs GPU computations are done on structured grid that heavily benefit from the above memory optimization techniques, hence those reported numbers may not be representative of expected performance on practical problems that use unstructured grids.

3.5.4 Relaxation algorithms

Relaxation methods are iterative methods suitable for solving sparse linear systems of equations. Although they are hardly used for solving system of equations all by themselves, they

can be good preconditioners for other methods that have fast convergence properties. All relaxation algorithms can be formulated as updates of a solution vector starting from initial guess x_0 as follows

$$x^{(k+1)} = Tx^{(k)} + c \quad (3.18)$$

Given a decomposition of matrix $A = L + D + U$, the most common relaxation methods namely Jacobi, Gauss-Seidel and Successive over relaxation (SOR) are formulated as follows.

Jacobi:

$$x^{(k+1)} = D^{-1}(b - (U + L)x^{(k)}) \quad (3.19)$$

Gauss-Seidel:

$$x^{(k+1)} = (L + D)^{-1}(b - Ux^{(k)}) \quad (3.20)$$

SOR:

$$x^{(k+1)} = (1 - \omega)x^{(k)} + (\omega)x_{GS}^{(k)} \quad (3.21)$$

Jacobi is inherently parallel because the new values are computed solely from old values. The stencil used to compute new value of the j th component x_j^k depends on the type of differential equation being solved, nonetheless all the values are taken from the old iteration. This method is easily parallelizable with the only challenge coming from stencils which have points lying in a different processor. The Gauss-Seidel method uses values from the current iteration as they become available, adding to the challenge of parallelization. Depending on the order of computation, different results can be obtained leading to different Gauss-Seidel methods. This is problematic for validation of parallelly computed results against serially computed results. However Gauss-Seidel method has superior convergence properties than Jacobi, and is proven to converge twice as fast asymptotically. The SOR method is an extension of Gauss-Seidel method that tries to further accelerate convergence by over-relaxation. It combines newly computed values and old ones with a factor $\omega > 1$. The method is equivalent to the basic Gauss-Seidel for $\omega = 1$.

The sequential nature of Gauss-Seidel can be broken by selecting specific order of computation that allows for parallel computation. One such method is the wavefront ordering where all points on the same diagonal are calculated in parallel. The downside of this method is that it is difficult to load balance because of unequal length of the diagonals. The degree of parallelism increases from the shortest diagonals at corners to the longest diagonal in the middle. Another alternative is to use graph coloring algorithms to form computation stencils of nodes containing of only one color. For example in simple two dimensional grid for solving Poisson equation, red-black coloring of adjacent nodes give 5-point stencils of same color neighbors.

First updates for stencils with red points at the center are done parallelly and then the same can be done for the black nodes. A third alternative is to not care about order of updates at all. This method is sometimes known as chaotic relaxation Chazan & Miranker (1969). The stochastic behavior limits analysis of convergence properties. The method may also diverge solely due to the way updates are done, even though the convergence conditions of the Gauss Seidel method are met.

SOR is convergent for $0 < \omega < 2$ for symmetric positive definite (SPD) matrices. A value of $\omega = 1.7$ gives good acceleration for many problems, while maintaining convergence properties. However we are mostly interested in faster convergence rather than just convergence, thus higher values may be used. A symmetric version of the method does a forward SOR sweep followed by another sweep in reversed order. This usually converges slower than standard SOR with optimal ω value. The motivation for this method is the symmetry of the iteration matrix which allows it to be used as a pre-conditioner for SPD matrices. The convergence rate of fast solvers such conjugate gradient method (CG) and generalized minimal residual (GMRES) is highly dependent on the condition number of the matrix. Infact all the above relaxation methods are too slow for practical calculations so they are mostly used as preconditioners or as smoothers to remove low frequency errors.

3.5.5 Preconditioning

Matrix preconditioning is a procedure to reduce the condition number of the matrix so that it becomes more suitable to numerical algorithms. The preconditioner M is usually a partial inverse of the matrix itself that can be calculated fast enough. The range of possible preconditioners is from the identity matrix I to the actual matrix inverse itself A^{-1} . The former is a no preconditioning case, while the later is an extreme case where the solution can be found in one iteration. There are a bunch of preconditioners in between with different cost-to-benefit ratio and suitability for parallelization. The procedure of preconditioning is outlined in algorithm 1 with one of fastest solvers for sparse linear systems: the preconditioned conjugate gradient method. The preconditioning is applied on the residual by multiplication with the preconditioner M^{-1} . In practice this procedure is done in such way that neither the matrix M nor its inverse need to be stored, because it will be dense even for sparse matrix A . Also the matrix is not inverted, rather forward and backward substitutions are used to solve triangular system $Mz_{k+1} = r_{k+1}$ where M is usually some incomplete LU-factorization of A . For diagonally dominant matrices, the Jacobi preconditioner $M = D$ is effective. The preconditioner scales rows of the matrix such that elements on the diagonal are one. This method is good for parallel precon-

Algorithm 1 Preconditioned conjugate gradient**procedure** PCG(A) $r \leftarrow b - Ax_0$ $z_0 \leftarrow M^{-1}r_0$ $p_0 \leftarrow z_0$ **while** $r \neq \text{small}$ **do** $\alpha_k \leftarrow \frac{r_k^T z_k}{p_k^T A p_k}$ $x_{k+1} \leftarrow x_k + \alpha_k p_k$ $r_{k+1} \leftarrow r_k - \alpha_k A p_k$ $z_{k+1} \leftarrow M^{-1}r_{k+1}$ ▷ Preconditioning: solve $Mz_{k+1} = r_{k+1}$ $\beta_k \leftarrow \frac{z_{k+1}^T r_{k+1}}{z_k^T r_k}$ $p_{k+1} \leftarrow z_{k+1} + \beta_k p_k$ **end while****return** x **end procedure**

ditioning because a processor can compute relevant slice of the preconditioner by itself. Also sequentially computed result will be exactly the same as its parallelly computed counter part which may be an important advantage during solver development stage. The symmetric gauss siedel preconditioner is given in equation 3.22. Here L and U are not exact LU decompositions but the upper and lower triangular parts of $A = L + D + U$. Thus usually only the inverse of the diagonal is stored, and that is usually done for efficiency reasons i.e. to avoid division in the inner loops.

$$M = (D + L)D^{-1}(D + U) \quad (3.22)$$

Similarly the SSOR preconditioner can be formulated by introducing ω . Optimal value of ω will lead to lower number of iterations for solution.

$$M = \frac{1}{2 - \omega} \left(\frac{D}{\omega} + L \right) D^{-1} \left(\frac{D}{\omega} + U \right) \quad (3.23)$$

The SSOR preconditioner is among the best general preconditioners for sparse matrices, and usually gives much better results than the Jacobi preconditioner. However it is very difficult to parallelize due to the sequential nature of gauss-siedel sweeps. So far the preconditioners discussed formulate M from components of A itself: D, L, U. Better preconditioners can be obtained by conducting an incomplete factorization of A.

$$M = L_* D_* U_* \quad (3.24)$$

The standard LU or Cholesky factorization is followed with dropping of elements that do not have a corresponding entry in A. If all such elements are dropped i.e. no fill-ins allowed, the preconditioner so obtained is ILU-0. For SPD matrices the cholesky decomposition is applied in a similar manner. Incomplete factorization methods require separate storage of the preconditioner matrix, which in the case of 0 fill ins is same size as the matrix A itself, but are among the best general preconditioners for sparse matrices. Better preconditioners that do not preserve the same sparsity as matrix A can be obtained, but the cost-benefit ratio should be examined because the factorization stage consumes significant amount of time. To avoid computation and storage of off-diagonal elements, one could opt for finding incomplete factorization of only the diagonal elements. This method, also known as the D-ILU, assumes the off diagonal components are same as the original matrix A and the preconditioner becomes

$$M = (D_* + L)D_*^{-1}(D_* + U) \quad (3.25)$$

3.5.6 Parallel implementations

The suitability of relaxation algorithms and preconditioners for parallel implementation has been discussed in the previous sections. The Jacobi sweeps are the simplest to parallelize but even those are not embarrassingly parallel due to the need for values of neighboring points which could be in a separate processor. A 5-point stencil with off processor neighbors is shown in Fig. 3.4. If the value of the neighbor on core 2 is fetched every time it is needed, the parallel performance will degrade due to frequent small chunk exchanges. This problem can be solved by exchanging values for a layer of cells around the boundary, *halo* layer, at once. With this change, the calculation for a stencil at the border become exactly same as those in internal cells. After each Jacobi sweep, each processor updates values at the halo layer from the neighboring processor. Wide halo layers (two or more halos) may be used when the stencil encompasses neighbors two or more steps away from the central cell. Thicker layers also help to reduce the communication overhead since the inner halo layer's values can be locally updated without exchanging data in every iteration (Fredrick & Marc 2010). With this approach and an n-halo layer, communication need to be done only once every n-th iteration. Information exchange can be done using MPI_send call with a corresponding MPI_receive in each processor ordered in such a way that when one processor sends halo layer values, the other should await for the message with a corresponding receive call. Besides the complication associated with order of messages, this blocked communication method adds additional synchronization points that are avoidable. Minimizing synchronization points is

Figure 3.4: A 5-point stencil with halo layer for exchanging information between processors

crucial for good performance in massively parallel systems. Both problems can be solved using asynchronous communication via `MPI_Isend` and `MPI_Irecv` calls as outlined below. The synchronization is done once with an `MPI_Waitall` call at the end instead of being at every send and receive call as in the synchronous case.

Algorithm 2 Asynchronous communication

```

procedure EXCHANGE
  for all to  $\leftarrow$  neighbors do
    MPI_Isend(to)
    MPI_Irecv(to)
  end for
  MPI_Waitall()
end procedure

```

The difficulties associated with parallelizing Gauss-Siedel and SOR algorithms have been discussed in previous sections. Using graph coloring algorithms, one sweep of SOR can be broken down to two or more equivalent sweeps that can be applied in parallel. The wavefront method exploits parallelizability on the diagonals as shown in Fig. 3.5. A source of concern with these methods is load balancing of work between different processors. The coloring algorithm should ensure approximately equal amount of nodes is assigned to each color on all processors, otherwise the time spent waiting for other processors to finish their share of work becomes a bottleneck. The wavefront method is predisposed to have unequal work at different diagonals thus it inherently suffers from this problem. An advantage of wavefront method over graph coloring is that it preserves the original order, and thus have the same convergence rate as its sequential counterpart. It is known that re-ordered gauss siedel converges slower than the

sequential counterpart that has a natural ordering. The first sweep in a red-black Gauss-Seidel is basically a Jacobi iteration since no values from the current iteration are used. Thus the overall red-black algorithm will have convergence rate equivalent to a Jacobi-GS sweeps. The wavefront method uses values from the current iteration, but it offers significantly less parallelization than graph coloring algorithms do. Asynchronous Gauss Siedel (chaotic) relaxation may be easier alternative that can avoid the above complications if convergence can be ensured somehow. Besides ease of implementation, asynchronous method do not need to exchange halo layer values at every iteration thereby completely avoiding the associated latency. Synchronization is avoided at all stages of solution, however the method may take larger number of iterations to converge, or sometimes not converge at all. Halo layers are updated randomly, i.e. as the neighbor processor sends them, therefore it is difficult to analyze convergence property of chaotic relaxation methods. Parallelization of PCG solver involve different stages with varying

Figure 3.5: Red-black colored graph for parallel Gauss-Siedel

degree of difficulty. These stages are outlined in the pseudo code below in algorithm 3. The scalar operation SAXPY ($y \leftarrow \alpha * x + y$) is embarrassingly parallel with no communication required whatsoever. However matrix-vector product and preconditioning stage are very difficult to parallelize and are usually bottlenecks of performance. The EXCHANGE operation at the beginning makes sure that halo layers have the latest values before local matrix-vector multiplications are done. The operation has an implicit barrier at the end that further adds to synchronization overheads. The local DOT products can be done in parallel however the ensuing summation of local products i.e. REDUCE operation introduces many synchronization points. This operation is commonly done through smart algorithms that are able to do the calculation in $O(\log_2(N))$ time. The matrix preconditioning stage is difficult to parallelize except for the simplest case where Jacobi preconditioner is used. Due to complexity of implementing a parallel preconditioning algorithm that gives same result as its sequential counterpart, domain decomposition method with local matrix preconditioning are commonly used. Similar to the

case with asynchronous gauss siedel method, this may result in more number of iterations for convergence.

Algorithm 3 Parallel PCG

```

EXCHANGE(p)
z ← M * p
oor ← DOT(p, z)
oor ← REDUCE(oor)
 $\alpha \leftarrow \frac{o_r}{oo_r}$ 
x ← SAXPY(x, p, alpha)
r ← SAXPY(r, z, -alpha)
z ← M-1 * r
oor ← or
or ← DOT(r, z)
or ← REDUCE(type, or)
 $\beta \leftarrow \frac{o_r}{oo_r}$ 
p ← SAXPY(p, z, beta)
  
```

3.5.7 Asynchronous implementation

In the previous section different methods of implementing a parallel algorithm that strictly follow the same computational path as the sequential counterparts have been discussed. The work associated for strict implementation of this requirement can sometimes be overwhelming. At times a significant reduction in complexity can be achieved by relaxing this requirement. For example opting for asynchronous gauss siedel avoids the need for complex algorithms such as graph coloring and wavefront method. Local preconditioning through domain decomposition avoids the need for a parallel ILU preconditioner with graph coloring or wavefront method. The number of synchronization points introduced for parallelizing PCG solver also suggests scalability issues on massively parallel systems. Given all the above problems, it is worthwhile to investigate asynchronous algorithms. In these methods, each processor does its own calculations with no synchronization whatsoever. As long as halo layers are updated regularly, one processor could be solving fluid equations while the other solves solid equations, one processor could be using PCG and the other SOR etc.. This complete freedom comes at the price of increased number of iterations or even divergence of solution, non-reproducibility in the sense that sequential computation follows different path than its parallel counterpart. However its advantage regarding scalability can be a deciding factor with the ever increasing computational power with thousands of processors, and load balancing problems due to non-uniformity of clusters. An asynchronous implementation of solvers is outlined in algorithm 4. Processors do

not exchange information at designated synchronization points, unlike the case of synchronous computation where information is exchanged at the end of each iteration and other places. Each processor continually probes for messages from its neighbors by `MPI_iprobe`. When a processor receives a halo layer data from neighboring processor, it sends back data of its own halo layer at the shared boundary or an `END` message to indicate convergence on its local problem. Each processor also keeps count of how many of its neighbors reached convergence and then stops calculations when all of them and itself reach convergence.

Algorithm 4 Asynchronous solution

```

Initialize halo layer exchange
nConverged = 0
while converge is not reached do
  Do one sweep of solver asynchronously: Jacobi,SOR, PCG etc.
  while nConverged ≠ nNeighbors do
    MPI_iprobe(message)
    if message is NULL then
      Do nothing
    else if message is HALO then
      MPI_recieve(HALO)
      Update halo layer
      Calculate residual
      if Converged then
        if END not sent before then
          MPI_send(END)
          Mark we have sent END message
        end if
      else
        MPI_send(HALO)
      end if
    else if message is END then
      MPI_recieve(END)
      nConverged = nConverged + 1
      if END not sent before then
        MPI_send(END)
        Mark we have sent END message
      end if
    end if
  end while
end while

```

3.5.8 Scalability study

Scalability study with number of computing units is a necessary step to evaluate the efficiency of parallelization. A badly parallelized program can give very poor performance due to poor algorithm, nature of the problem, communication latency etc Numerical calculations in CFD usually give good parallel speed ups due to the relative ease CFD can be parallelized. An embarrassingly parallel problem does not incur any performance loss due to communication alone. However, CFD computations do require communication of pressure, velocity and other quantities at the boundaries of the domain and quite frequently too. For an iterative solver, communication at each step of the iteration is usually necessary.

3.5.8.1 Coarse-grained scalability study

The speed up of the coarse grained parallelism using message passing was tested on a cluster of the following specification; 2 cores per node, AMD 1.6GHz 2GB RAM, fast Ethernet connection. The lid-driven problem is run with a grid 256 x 256 decomposed into sub-domains. Run time is measured from the start of loading the cases to end of iterations. The loading time is decreased from the total run time which otherwise would have biased the result. For example, the one node test took too long to load the case compared to that of sixteen node case as shown in the table 3.1. The speed up to 16 processors is very good but it starts to flatten out onwards as evidenced by the 36 processors case. The total number of cells is 64k which is relatively small, hence better speed up numbers are expected with cases of bigger size. The cavity problem is run again with a grid of 1024 x 1024 resulting in a total of 1 million cells. As expected, much better scaling numbers are obtained for larger number of processors due to a larger computation to communication ratio. The 36 processors case showed an improvement of 50%, and the 25 processor case a 16% increase. The single processor case could not solve this bigger problem due to memory constraints; hence the percentages are calculated relative to 16 processors case. This test demonstrates an advantage of domain decomposition to solve large problems which are impossible to do on one processor. And also the point where the scaling shows diminishing returns differs based on the problem size.

3.5.8.2 Fine grained scalability study

Speedup test for the fine grained parallelism is conducted on an Intel quad core with one Nvidia Quadro FX 3700m workstation GPU and Intel Core 2 quad 3.0 GHZ cpu. The GPU has 128 processors and 1 GB memory. The test is done separately for the SOR and conjugate gradient

Table 3.1: Speed ups for 256 x 256 case

Processors	Time(ms)	Speed-up
1	1427135	1.00
2	772862	1.85
4	427012	3.34
9	198425	7.19
16	124985	11.42
25	92477	15.43
36	84422	16.90

Table 3.2: Speed ups for 1024 x 1024 case

Processors	Time(ms)	Speed-up	Improvement
16	4100112	1	
25	2819571	1.45	15.61%
36	2037217	2.01	51.98%

Figure 3.6: GPU speed up relative to CPU for fixed number of iterations

solvers. In general, the SOR solver shows a much better scaling than the PCG solver because it does more iteration per time step. In each time step, matrices are copied from the CPU to the GPU which severely degrades performance. To compensate for this latency the solver should be doing many iterations in each time step. Otherwise most of the number crunching will be done by the CPU and performance may not improve at all or even degrade in some cases. A steady-state problem getting close to overall convergence or a transient problem with very small time step (e.g. LES simulations) are some examples where GPU may not scale well. Pre-allocation of workspace once on the device (for all the matrices and vectors that will be used inside the iterations) and updating directly on the device has been used by Julien & Senocak (2009) to avoid this latency.

For a 3D lid driven cavity test with a grid of $128 \times 128 \times 32$, a speedup in the range of 1.3 - 5 relative to the single CPU is obtained on the machine specified above. This is rather disappointing compared to what is reported in literature, but it should be noted that the number of iterations done per time step was relatively small in both cases especially towards the end. To illustrate this point, the above problem is solved with fixed number of iterations per time as shown in Fig. 3.6. Latency between host and device memory and between shared and global memory in the device are bottlenecks for GPU solvers. Both optimizations were not done for our implementation.

3.5.9 Validation with benchmark problems

3.5.9.1 Lid-driven cavity

The well known lid-driven cavity test is used to validate the implementation of both fine grained and coarse grained parallelism. The streamline plots for this two dimensional flow at different Reynolds number and a grid of 128×128 are shown in Figs. 3.7-3.8. Botella & Peyret (1998) conducted spectral analysis of the lid-driven cavity flow for CFD benchmarking purpose. Plots of u on vertical section and v on horizontal section show excellent agreement as shown in Fig. 3.9. Streamlines and pressure contours for higher Reynolds number are also compared with the plots found in Goyon (1996). The flow structure for the primary and secondary vortices shows very good similarity. Validation of the parallel code for both CPU and GPU implementations is done indirectly by comparing the result of decomposed cases against the serial code's result, which is already validated. Different problems with different number of sub-domains have been tested and the results are in good agreement which proved that both parallel implementations are correct. For illustration, a 2D and 3D lid-driven cavity problems

Figure 3.7: Streamlines for different Reynolds numbers showing progressive formation of eddies at the bottom right corner \rightarrow bottom left corner \rightarrow top right corner

Figure 3.8: Streamlines (left) and pressure contours (right) of lid-driven cavity flow at $Re=1000$

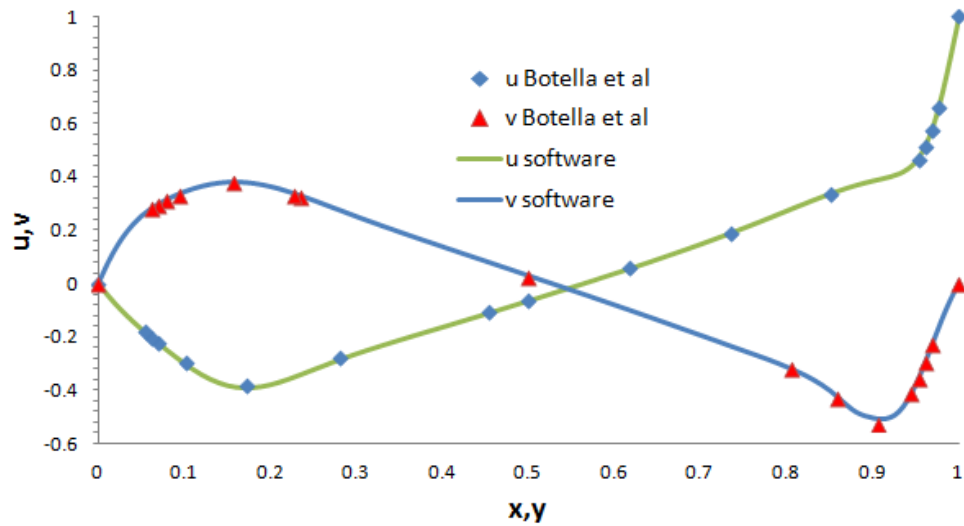

Figure 3.9: Horizontal(u) and vertical(v) velocity profiles along mid vertical and horizontal sections respectively

Figure 3.10: Solution of 3D lid-driven cavity problem solved parallelly with 16 sub-domains (left), and the resulting 3D iso-surface plot that shows the flow pattern (right)

are solved decomposed into 16 sub-domains as shown in Fig. 3.10. In all cases, no mismatches are observed at interfaces, that indicate iterations in each sub-domain have been done until full convergence is reached. The implementation has also been tested on more complex problems with unstructured mesh. The result found from the asynchronous implementation are in agreement with that of synchronous implementation in all cases. As discussed in previous sections, asynchronous algorithm may sometimes diverge where a synchronous algorithm would not, and this has been observed in some of the other tests

Figure 3.11: Grid for a cube in a boundary layer case of Kose & Dick (2010)

3.5.9.2 Flow around a bluff body

The RANS and LES turbulence models are validated with a practical wind engineering application of flow around a bluff body, namely a cube immersed in a boundary layer. The external pressure distribution around the cube is sought using RANS and LES turbulence models. The setup used for this test is similar to the one used by Kose & Dick (2010); cube height $H = 4$ cm, bulk velocity 10 m/s and molecular viscosity at 10^{-5} kg/ms, and $Re = 40000$. The mesh consists of about 200000 cells. The cells are expanded away from the cube as shown in Fig. 3.11. Appropriate boundary conditions are applied as specified in Kose & Dick (2010); Richard and hoxey inlet profiles for $k - \epsilon$ model and a turbulent inlet with random fluctuations for the LES model, symmetry boundary condition on the left, right and top walls, a pressure-outlet condition, and simulations are carried out using standard k-epsilon and Smagorinsky LES turbulence models. A Smagorinsky LES model with a time step of 2×10^{-4} sec is used for the simulation.

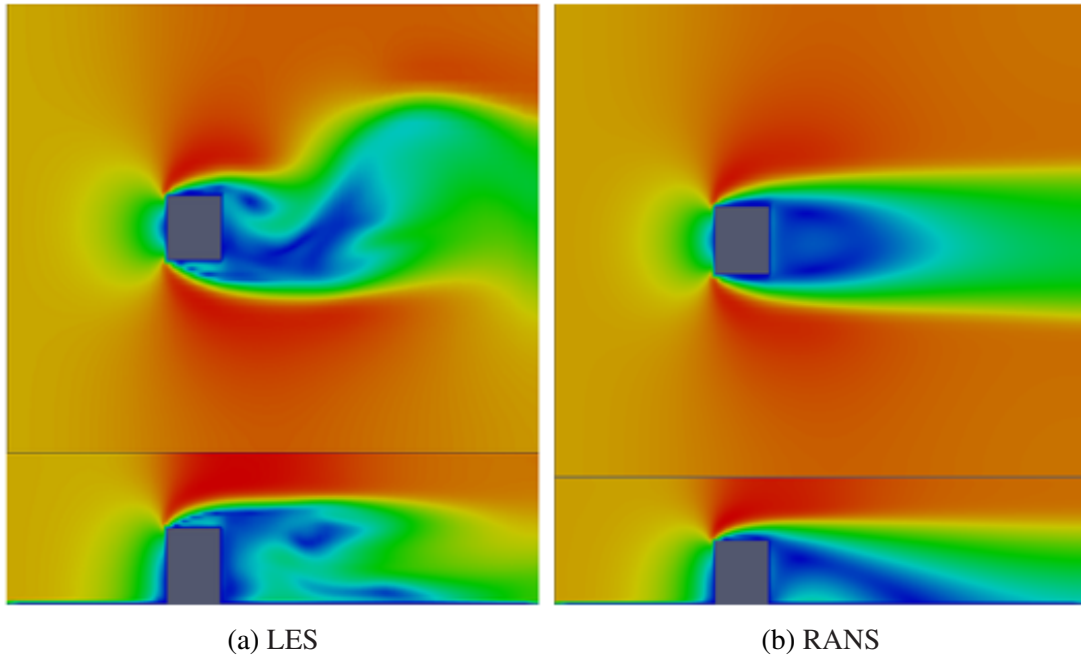

Figure 3.12: Plots of instantaneous and mean velocity contours showing vortex shading behind the cube

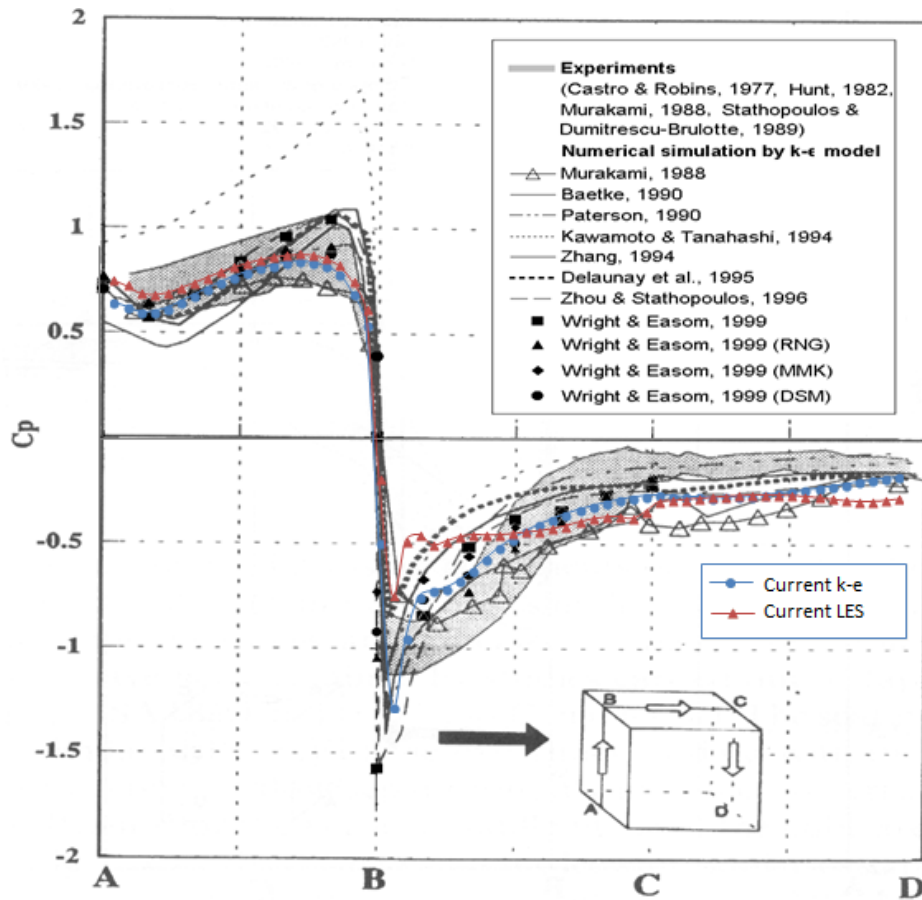

Figure 3.13: Pressure coefficients along vertical section of cube. Adapted from Bitsuamlak et al. (2010)

Formation of Karman vortex street behind the cube is captured by the simulation as shown in the instantaneous profile of Fig. 3.12. Pressure coefficients are calculated for a vertical section passing through center lines of the front, top and back faces of the cube. From LES simulations pressure values can be obtained at any instant of time, while RANS gives only time averaged (mean) pressure values. The pressure values are normalized by the dynamic head according to Eq. 3.26. The reference pressure P_0 is usually taken as atmospheric pressure.

$$C_p = \frac{P - P_0}{\rho U^2} \quad (3.26)$$

The pressure coefficient (C_p) distributions from the current study are shown in Fig. 3.13 along with other experimental and CFD investigations by many researchers including Bitsuamlak et al. (2010). The results from the current CFD study on the upstream side of the onset of flow separation lie with in the shaded area that signifies limits of acceptable range. The current standard k-epsilon model over shoots at the leading edge, where flow separation occurs, similar to the results of Wright & Easom (2003) who used the same turbulence model. This confirms the suspicion that RANS models can indeed have problems at flow separation zones. On the other hand, the current LES model gives reasonable values even at the leading edge. On the top wall, the current LES model seem to underestimate the suction pressure compared to $k - \epsilon$. This could be due to the use of a simple LES model with a constant C_s that needs to be adjusted based on the flow behaviour.

Chapter 4

Numerical evaluation of roughness effects

Atmospheric Boundary Layer (ABL) flow is affected by aerodynamic roughness that consists of the effect of surface cover (roughness) as well as the shape of the terrain (topography). This chapter examines the effect of roughness alone by conducting Computational Fluid Dynamics (CFD) simulations over various roughness setups. Given velocity and turbulence intensity measurements at a certain location, it is possible to determine roughness parameters z_0 and d by fitting suitable profiles of either the log-law or power-law type. Some methods of fitting, with different degrees of accuracy, have been discussed in section 2.7.2. Therefore the task of determining roughness parameters can be considered to be equivalent to determining velocity and turbulence intensity profiles either from field observations or numerical simulations, which is the case in the current work. The investigation of roughness effects is conducted beginning from the lowest level of complexity, namely a flat terrain, and progresses to the case of a real built environment. Each model will be validated against existing literature and wind tunnel tests when available.

1. Complexity 0: Preliminary investigations on an empty domain
2. Complexity 1: Regularly arranged array of blocks similar to that used in wind tunnels. Empirical formulas for estimating roughness parameters based on density of obstacles are compared with current CFD results.
3. Complexity 2: The effect of inhomogeneous roughness, i.e. multiple roughness patches upstream of a site, is evaluated using three dimensional CFD simulations and results are compared against existing wind speed models. The simulations are carried out in a Virtual Boundary Layer Wind Tunnel (V-BLWT) by duplicating all roughness features used namely spires, blocks and barrier. Sixty nine cases tested by Wang & Stathopoulos

(2007a) in wind tunnel are simulated and results are compared with wind speed models.

4. Complexity 3: The flow characteristics in a semi-idealized urban environment is studied by conducting model scale simulations and results are compared with existing Boundary Layer Wind Tunnel (BLWT) test data
5. Complexity 4: Simulations over a real urban environment are conducted in an area in Downtown Miami. There is usually a lack of validation data for such kind of simulations thus the only qualitative discussion of results is made.

Finally Artificial Neural Network (ANN) are considered as an alternative to setup roughness features in an actual BLWT for a required wind profiles at the turn table. A neural network is trained with half of the dataset obtained from Rowan Williams Davies and Irwin Incorporation (RWDI), and then the model is tested for prediction ability on the rest of the dataset.

4.1 Complexity 0: Empty domain

CFD enjoys a wide spread use in the wind engineering community however many parameters that influence the simulation results are not well understood (Franke & Hirsch 2004). A rather trivial case that is commonly used to demonstrate disparity between simulation results of different CFD software is the case of an empty domain. Since there are no obstacles, the characteristics of the wind should be maintained along the whole length of the domain. It may seem at first that simulation on an empty terrain is trivial but is quite challenging. The problem stems from difficulty of achieving horizontally homogeneous flow unless proper boundary conditions are used (Blocken et al. 2007, Hargreeves & Wright 2007, Richards & Hoxey 1993). This investigation also helps to outline the steps involved in a typical Computational wind engineering (CWE) simulation.

4.1.1 Computational domain

The computational domain used for this experiment is the same as the one used by Hargreeves & Wright (2007). It has dimensions of 5000m X 100m X 500m. The domain is meshed with 500x50x5 cells and the mesh is expanded in the the vertical direction in such a way that the the size of nearest cell to the ground is 1m. This satisfied the $Y_p > K_s$ criterion for roughness conditions of $z_0 = 0.01m$. A reference wind speed of 10m/s at a height of 6m is used. Different boundary conditions at the ground surface, inlet and top of the domain are tested until

a horizontally homogeneous flow is obtained using k-epsilon turbulence model. Hargreeves & Wright used commercial CFD software CFX and Fluent to demonstrate the problem of ABL simulations on an empty fetch. Boundary conditions are modified progressively through user defined functions (UDF) until a horizontally homogeneous flow is obtained for all flow quantities (U, k and ϵ). Here similar procedure is followed to check if the software developed in this work can overcome the problem.

4.1.2 Boundary conditions

Boundary conditions are very important for any CFD simulation because they are cutoff planes that divide the area we are interested in simulating from that we do not want to include in the simulation. In other words they are used to incorporate the influence of the surrounding to our model. The type of boundary condition also affects the placement of the cutoff planes relative to the central region where obstacles are placed. For example, it is well known that use of symmetry boundary condition at the top and sides of the domain introduces artificial accelerations unless blockage ratio is kept to a minimum. The computational domain is usually divided into three regions (Blocken et al. 2007), namely, the central region where the obstacle is modeled as best as possible, and the upstream and downstream regions where the effect of obstacles is modeled by regular roughness elements. The other issue concerns consistency of boundary conditions with the wind profiles specified at the inlet and the turbulence model (O'Sullivan et al. 2011, Richards & Hoxey 1993).

At the inlet of the computational domain fully developed equilibrium velocity and turbulence intensity profiles are applied. The inlet profiles should be consistent with the upstream surface roughness characteristics (Miller & Davenport 1998, Wieringa 1993), and they should be maintained within the computational domain until the flow reaches the face of the test building. This is very important for determination of wind load on buildings, that will be significantly different if, for instance, a uniform velocity profile is used instead of logarithmic profile. A peculiar problem in ABL simulations is that maintaining horizontal homogeneity is very difficult to achieve with current breed of CFD software. Richards & Hoxey (1993) have investigated this problem thoroughly and suggested boundary conditions (Eqs. 4.1-4.3) to be specified at the inlet that will ensure horizontal homogeneity for the standard k-epsilon turbulence model. Their formulas have been used by the wind engineering community for many years. However, it is not enough to specify just inlet conditions to get a stream-wise homogeneous flow. The wall functions used at the surface should be compatible with the roughness of the upstream fetch outside the domain. Otherwise an internal boundary layer will develop

starting from the inlet at which the roughness change occurs.

$$u = \frac{u^*}{\kappa} \ln \frac{z + z_0}{z_0} \quad (4.1)$$

$$k = \frac{u^{*2}}{\sqrt{C_\mu}} \quad (4.2)$$

$$\epsilon = \frac{u^{*3}}{\kappa(z + z_0)} \quad (4.3)$$

Richards & Hoxey found that the transport equations for the standard k-epsilon model can be satisfied with above relations only when a different σ_ϵ is used than the standard value of 1.3. The formula for calculating σ_ϵ given vonKarman constant is

$$\sigma_\epsilon = \frac{\kappa^2}{(C_{\epsilon 2} - C_{\epsilon 1}) \sqrt{C_\mu}} \quad (4.4)$$

Nikurdase's modified log-law equations 4.5-4.6 are used as rough wall functions in many CFD code. As described in Blocken et al. (2007), the first cell's center should be placed higher than the equivalent sand grain roughness height i.e. $Y_p > K_s$. This constraint is in conflict with using a fine mesh close to walls where high velocity gradients are present.

$$u^+ = \frac{1}{\kappa} \ln(Ey^+) - \Delta B \quad (4.5)$$

$$\Delta B = \frac{1}{\kappa} \ln(1 + C_{ks}K_s^+) \quad (4.6)$$

For a horizontally homogeneous flow, i.e. one in which same velocity profile is maintained, the wall function should approximately yield the same profile as the inlet profile as specified by Richards and Hoxey.

$$\begin{aligned} u^+ &= \frac{1}{\kappa} \ln \frac{z+z_0}{z_0} \quad , \text{ Inlet} \\ u^+ &= \frac{1}{\kappa} \ln \left(\frac{Ey^+}{1+C_{ks}K_s^+} \right) \quad , \text{ Wall} \end{aligned} \quad (4.7)$$

Equating the above two equations we get relations between K_s and z_0

$$\frac{z + z_0}{z_0} = \frac{Ey^+}{1 + C_{ks}K_s^+}$$

$$\frac{z}{z_0} = \frac{E y}{C_{ks} K_s}$$

$$K_s = \frac{E z_0}{C_{ks}}$$

$$K_s \sim 20 z_0 \quad (4.8)$$

At the sides and top of the domain, a symmetry boundary condition that prevents inflow or outflow is usually applied. This boundary conditions results in a parallel flow at the boundary which could sometimes lead to artificial acceleration if enough space is not provided between the obstacles and the boundary plane. To solve this problem the domain is sized in such a way that blockage ratio is set at a certain limit below which the effect is minimal. Another solution is to replace the boundary condition with one that allows flow outwards through the boundary (Franke & Hirsch 2004).

The common use of symmetry boundary condition at the top of the boundary is rather unfortunate since it ignores the contribution of geo-strophic wind in driving the ABL flow. Many researchers have noted that use of symmetry boundary condition results in stream-wise gradients of velocity profile. However there are many reasons why symmetry is assumed in many wind engineering problems. The major physical reason is that log layer in the ABL extends only up to a certain depth above which the gradient of velocity becomes zero. Also it is not known a priori what the values would be set at the top if symmetry boundary condition is not used. A shear stress boundary condition ($\tau = \rho u^2$) should be applied at the top to get a homogeneous (non-decaying) profile (Hargreeves & Wright 2007, Richards & Hoxey 1993). Another approach used by Blocken et al. (2007) is to apply Dirichlet boundary condition for velocity and turbulence quantities at the top.

4.1.3 Simulation for different cases

Simulations are conducted by varying the boundary conditions at the ground, inlet and top of the computational domain, and the results are examined with regard to maintaining a horizontally homogeneous flow. The four different test cases considered are briefly described in the following sections.

Case 1 - Incompatible wall roughness

The first case applies the Richard and Hoxey boundary conditions at the inlet but assumes a smooth ground surface thereby creating a situation where the surface roughness exhibits a sud-

den change at the inlet. Due to this incompatibility, stream wise gradients are observed in the profiles of U , k and ϵ as shown in Fig.4.1. Close to the ground, both the velocity profile and turbulence dissipation show large changes as one goes downstream; while the profiles towards the top remain somewhat constant. On the other hand, the turbulent kinetic energy shows variations throughout. The difficulty of maintaining the turbulent kinetic energy along the fetch has been noted by Richards & Hoxey especially on the first cell close to the ground where many CFD software show peak values.

Case 2 - Compatible wall roughness

When surface roughness conditions compatible with the inlet profiles are applied, both velocity and turbulence intensity profiles are maintained throughout the domain as shown in Fig.4.2. The sand grain roughness used for the simulation is determined according to the relation $K_s = 20z_0 = 0.2$ and $C_{ks} = 0.5$. However the calculated turbulent kinetic energy profile still shows variations from the expected constant vertical profile.

Case 3 - Fixed U, k and ϵ at the top

From the previous simulations, we observe that the flow quantities at the top show some variations due to the imposed symmetry boundary condition. Blocken et al. has suggested using Dirichlet boundary condition to make sure that the flow quantities remain the same at least at the top of the boundary. The result for this case is shown in Fig. 4.3. While velocity and turbulence dissipation show an almost perfect fit from start to finish of the fetch, the turbulent kinetic energy profile show a rather distorted profile compared to the previous cases. Other simulations have been carried out which confirm the same observation.

Case 4 - Uniform k and ϵ at the inlet

It is customary to specify constant values of k and ϵ at the inlet for convenience. The assumption is correct for k but not for ϵ . The simulation result for this case shows a developing ϵ profile along the fetch, before reaching more or less the same values at the outlet, as shown in Fig.4.4.

So far we have managed to get homogeneous velocity and turbulent dissipation profiles. To get a homogeneous turbulent kinetic energy profile, further modifications to wall functions are necessary. Most commercial CFD code do not usually offer wall functions that can maintain k profile this way, however we note that it is possible to implement modifications to wall functions to achieve horizontal homogeneity for k as described in Hargreeves & Wright (2007).

Figure 4.4: Profiles of horizontal velocity, turbulent kinetic energy and dissipation for case-4

4.2 Complexity 1: Homogeneous roughness evaluation

The next level of complexity concerns uniform (homogeneous) roughness due to array of obstacles. Simulations are carried out on regular and staggered array of blocks for wind coming from different angles. The arrangements of the roughness blocks considered are all symmetric, which allows for a reduction of computational domain to a much smaller section of one or two rows as shown in Fig.4.5. The test setups and results obtained are described in the following sections.

4.2.1 Test setup

The test setup used in this study is similar to that used by MacDonald et al. (1998). Regular or staggered arrays of cubes are exposed to wind coming from different directions, and velocity profiles are recorded at different sections behind the obstacles. Wind speed profiles show variations in the transverse direction because some of the locations are sheltered by the blocks while others lie in the gap between the blocks. Therefore multiple measurement points are considered in the transverse direction, and results are averaged to get a representative velocity profile for that section. This approximation is acceptable for regular arrays of cubes but it may be inaccurate for irregular array of obstacles. Close to the ground and right behind an obstacle, negative velocity profiles can develop due to re-circulation, while at locations close to center line of gap the velocity is positive. The averaging operation removes these variations and positive velocity values are observed also at heights where recirculation happens.

The area density ratio for the configurations considered can be approximated by the following formula.

$$\lambda = \frac{1}{\left(1 + \frac{S}{H}\right)^2} \quad (4.9)$$

For example, a spacing $S = 1.5H$ between blocks gives $\lambda = 0.16$. The Lettau (1969) model predicts a roughness length $z_0 = 0.5\lambda H = 0.08H$. The test is conducted for various configurations of obstacles with different spacing, regular and staggered arrangement, rectangular obstacle shapes, and different wind angle of attacks as shown in Figs.4.5-4.6. Symmetry of arrangement of obstacles is exploited to reduce computational domain. Then models are prepared for six area density ratios (0.05, 0.11, 0.16, 0.2, 0.33, and 0.5) for every configuration of obstacles considered. A series of 32 blocks of height 20 m are arranged in different ways, and a steady state solution of the flow problem is sought.

Figure 4.6: Plan of regular array of cubes with height H and spacing $1.5H$ also showing location of probes

4.2.2 Analysis

The objective is to calculate roughness length and displacement height from velocity and turbulence intensity profiles obtained from CFD simulations. For this purpose average of five velocity profiles measurements at locations shown in Fig.4.6 is considered instead of a single profile. First the displacement height is determined iteratively using Eq.(2.41) from Lo (1990). The value of d obtained using this method is usually satisfactory, however value of z_0 is very sensitive to the selected reference heights because it is based on measurements at two heights in the inner layer.

As the fetch length becomes larger, the internal boundary layer grows until it becomes equal or greater than the height of the computational domain. This stabilization of flow is usually achieved earlier than the last row of blocks. The average velocity within the viscous layer increases with fetch length, while the velocity in the inner and outer layers decrease. The roughness length and displacement height obtained from averaged velocity profile measured at the last row of a series of blocks is shown in Fig.4.8, along with predictions from different roughness models. The McDonald roughness model is tested in two ways in which the displacement height is calculated differently. The first method determines roughness length from displacement height calculated using Lo (1990)'s equation (*McDonald1*). The second method uses d calculated from Theurer (1993)'s equation (*McDonald2*). The results from the analysis are briefly summarized as follows. The *McDonald1* method gives the best fit to the CFD calculated result as shown in Fig. 4.9. The Theurer model also shows good fit up to area density ratio of 20%. Lettau's and Counihan's models hugely underestimate the roughness for area density below 20% and overestimate it for area density larger than 20%. The staggered obstacle arrays and regular arrays with 45 degree wind angle of attack resulted in higher roughness compared to the simple case of regular arrays as shown in Fig. 4.10. The staggered placement of obstacles increase roughness due to relatively larger exposure of faces of the cubes to on coming wind. A regular array of cubic obstacles exposed to a 45 degree on coming wind is equivalent to a staggered array of triangular obstacles as shown in Fig.4.5. We can also observe that the deviation of Lettau's and Counihan's models from CFD model is less pronounced on staggered array of blocks compared to the regular arrangement. This is a reasonable observation because of much less wake interference in staggered arrangement that has large spacing (small λ), in which case the flow becomes effectively isolated for each block. However Lettau's and Counihan's model still show significant deviations from the CFD model, which is partly explained by the larger drag imposed by the cubic obstacles ($C_D = 1.2$).

4.3 Complexity 2: Inhomogeneous roughness evaluation

Proper evaluation of wind speed and turbulence intensity profiles is important for correct determination of wind loads on buildings. Both profiles are sensitive to upwind roughness changes especially close to the building. In design of structures usually a level terrain is first assumed, and then departures from this caused by topographic changes and surface roughness inhomogeneities are assessed. The significance of the effect of inhomogeneous roughness within the pertinent fetch was overlooked in building codes and standards before the Engineering Science Data Unit (ESDU) model is introduced. The earliest investigation of this effect was carried out by Deaves (1981), Deaves & Harris (1978) using CFD simulations over single changes of roughness. The result of this work is incorporated in the ESDU model which is recommended methodology in many building codes and standards for the case of multiple roughness changes close to building.

Recently Wang & Stathopoulos (2007a) put forward wind speed and turbulence intensity models that improved upon the ESDU model. Their model, henceforth called Wang and Stathopoulos Model (WS), is validated with wind tunnel experiments and simplified 2D CFD simulations over multiple roughness changes. The motivation for this work is that the ESDU model can sometimes overestimate wind speed by as much as 20% , which means a 40% increase in wind load. In this work the performance of three dimensional CFD simulations for predicting wind speed and turbulence intensity profile will be compared with the above mentioned models.

Inhomogeneous roughness within the pertinent fetch length of the building site affects both wind speed and turbulence intensity profiles. The boundary layer for multiple roughness changes is stratified with an upper boundary layer up to the gradient height G and as many inner boundary layers as there are patches, with a possible transitional layer in between. The case of a single roughness change with a transition layer is shown in Fig. 4.11. Three distinct regions can be seen namely the outer layer, the transition layer and Internal Boundary Layer (IBL).

Deaves & Harris divide the flow horizontally in to three regions.

- $x < 0$: The upstream region where flow is characterized solely by roughness conditions there.
- $0 < x < F$: The region of influence of the roughness change where IBL is still growing on the new roughness z_0 . The friction velocity $U_*(x)$ is a function of distance from transition point.

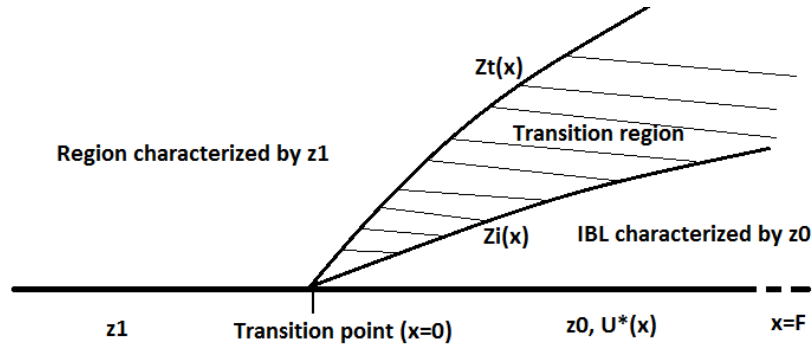

Figure 4.11: Schematics of the growth of internal boundary layer for single roughness change

- $x > F$: IBL has fully developed and is in equilibrium with new parameters U_* and z_0 .

Similarly at any position in $0 < x < F$, the flow can be divided vertically in to three regions.

- $0 < z < z_i(x)$: The flow is in equilibrium with the new surface so any of the homogeneous wind speed models can be used to determine using the new surface roughness parameters.
- $z_i(x) < z < z_t(x)$: The flow here is neither in equilibrium with the new roughness nor does it retain upstream character. Velocity profiles should be smoothly interpolated between $z < z_i$ and $z > z_t$.
- $z > z_t(x)$: The upstream flow is unmodified as the disturbance has not reached there yet.

In the following sections, a review of different models for both homogeneous and inhomogeneous terrain is given.

4.3.1 Homogeneous roughness wind speed models

4.3.1.1 Roughness estimation

An estimate for roughness length in a homogeneous terrain can be obtained from Davenport roughness classifications. If the obstacles are big with measurable dimensions e.g. buildings, a better estimate can be found using empirical formulas as discussed in 2.7.1. A brief overview of simple formulas to approximate roughness parameters follows. Given mean height of obstacles: buildings, bridges, crops, forests etc., roughness length is estimated as

$$\frac{z_0}{H} = c_1 \quad (4.10)$$

where $c_1 = 0.1$ gives good results in many situations, however it is established that z_0 is not constant. Similarly an approximation for the zero-plane displacement height is

$$\frac{d}{H} = c_2 \quad (4.11)$$

where $c_2=0.75$. Lettau (1969) provided an empirical formula to determine z_0 from frontal area density ratio of obstacles

$$\frac{z_0}{H} = 0.5\lambda_f \quad (4.12)$$

This simple approximation fails to give good results for moderately dense regions. MacDonald et al. (1998) suggested a model that tackles limitations of Lettaus and other similar empirical models. The MacDonald model improvements include a non-linear decrease of z_0 at high area density ratio , and different obstacle shapes and layouts.

4.3.1.2 Models

The log-law and power law wind speed models have been discussed in section 2.6.2.1 and 2.6.2.2, but we repeat the relevant equations here for convenience.

$$\frac{U(z)}{u_*} = \frac{1}{\kappa} \ln\left(\frac{z-d}{z_0}\right)$$

$$U = U_{ref} \left(\frac{z-d}{z_{ref}}\right)^\alpha \quad (4.13)$$

$$I_u(z) = c \left(\frac{z}{z_{ref}}\right)^{-d}$$

Homogeneous roughness wind speed models from ESDU 82026 ,that are based on the work of Deaves & Harris (1978), incorporate the effect of Coriolis force. The simplified homogeneous model (for $z \leq 300m$) has an additional term over the log-law model that relates with the gradient height G.

$$\frac{U(z)}{u_*} = \frac{1}{\kappa} \left(\ln\left(\frac{z}{z_0}\right) + \frac{34.5f_c z}{u_*} \right) \quad (4.14)$$

And the corresponding model for turbulence intensity is given as follows

$$I_u(z) = \frac{u(z)}{U(z)} = \frac{u(z)}{u_*} \frac{u_*}{U(z)} \quad (4.15)$$

$$\frac{u(z)}{u_*} = \frac{7.5\eta[0.538 + 0.09 \ln(\frac{z}{z_n})]\eta^{1.6}}{1 + 0.156 \ln(\frac{u_*}{f_c z_0})} \quad (4.16)$$

$$\eta = 1 - \frac{6f_c z_u}{u_*} \quad (4.17)$$

4.3.2 The ESDU model

The set of equations provided in ESDU-82026, ESDU-84030, for determining wind speed and turbulence intensity respectively for multiple roughness changes, are based on numerical work of Deaves (1981). A comparison of the Deaves model with the log-law and power-law for heterogeneous terrain can be found in Nicholas (1997). The ESDU model is now adopted in several building codes and standards such as American Society of Civil Engineers - 7 (ASCE7) and National Building Code of Canada (NBCC). Deaves conducted CFD simulations using simple eddy-viscosity (mixing length) models for turbulence closure. Contemporary CFD studies dropped the second horizontal derivatives rendering the Navier-stokes equations parabolic and solutions were carried out by ‘marching’. Deaves solved the full elliptic set of equations in which Coriolis force is also included using an approximation that allows the equations to remain two dimensional.

4.3.2.1 Wind speed model (ESDU 82026)

A set of equations for U and I_u are proposed for both homogeneous and inhomogeneous terrain. For inhomogeneous terrain with n roughness patches the following set of equations are provided, however ESDU recommends the use of the equations for up to a maximum of three patches. This is partially due to lack of sufficient experimental validation for four or more patches.

The velocity profile within each IBL , $g_n \leq z \leq g_{n-1}$, can be calculated using the following equation

$$U(z) = K_{x2}K_{x3}K_{x4} \cdots K_{xn}U_n(z) \quad (4.18)$$

The coefficient K is a terrain dependent coefficient calculated differently for smooth to rough (S-R) and rough to smooth transitions (R-S) as follows

$$K_{xi} = \begin{cases} 1 + 0.67R_i^{0.85} f_{S-R} \\ 1 - 0.41R_i f_{R-S} \end{cases} \quad (4.19)$$

$$R_i = \frac{[\ln(\frac{z_{0,i-1}}{z_{0,i}})]}{(\frac{u_*}{fu_*})_i^\beta} \quad (4.20)$$

$$\beta = \begin{cases} 0.23, & \text{for S-R} \\ 0.14, & \text{for R-S} \end{cases} \quad (4.21)$$

$$f_{S-R} = \begin{cases} 0.1143E^2 - 1.372E + 4.087 & \text{if } E \leq 5.5 \\ 0 & \text{if } E > 5.5 \end{cases} \quad (4.22)$$

$$f_{R-S} = \begin{cases} 0.0192E^2 - 0.550E + 2.477 & \text{if } E \leq 5.6 \\ 0 & \text{if } E > 5.6 \end{cases} \quad (4.23)$$

$$E = \log_{10} X, \text{ where } X = X_2 + X_3 + \cdots + X_i \quad (4.24)$$

Then the IBL depths $g_i(x)$ can be determined by continuity requirement at each transition. Two profiles can be combined into one continuous profile using the following equation

$$g_i(x) = \exp\left(\frac{K_{xi}\left(\frac{u_{*,i}}{u_{*,i-1}}\right) \ln(z_{0,i}) - \ln(z_{0,i-1})}{K_{xi}\left(\frac{u_{*,i}}{u_{*,i-1}}\right) - 1}\right) \quad (4.25)$$

4.3.2.2 Turbulence intensity model (ESDU 84030)

Here equations are provided for determining turbulence intensity profile for inhomogeneous roughness.

$$I_u(x) = \frac{u(x)}{u} \frac{u}{u_*} \frac{u_*}{U(z)} \frac{U(z)}{U(z, x)} \quad (4.26)$$

$$\frac{u - u(x)}{u - u'} = \begin{cases} \cos^2\left[\frac{\pi^2}{4}\left(\frac{\zeta - 0.25}{0.8}\right)\right], & \text{for } 0.25 \leq \zeta \leq 1.85, S - R \\ \cos^2\left[\frac{\pi^2}{4}\left(\frac{\zeta - 0.1}{0.8}\right)\right], & \text{for } 0.10 \leq \zeta \leq 1.70, R - S \end{cases} \quad (4.27)$$

where u' , u and $u(x)$ are the upwind, far-downwind and local values of fluctuating velocities respectively.

$$\zeta = \frac{\ln(x) - \ln(g')}{\ln(g) - \ln(g')} \quad (4.28)$$

$$\frac{g'}{z_{0,(n,n-1)}} = \left(\frac{z}{10z_{0,(n,n-1)}}\right)^{5/3} \quad (4.29)$$

Figure 4.12: Schematics of change in velocity profile for three roughness patches.(Wang & Stathopoulos 2007b)

$$\frac{g}{z_{0,n}} = \begin{cases} \left(\frac{z}{0.36z_{0,n}}\right)^{4/3}, & \text{for } S - R \\ \left(\frac{z_{0,n-1}}{z_{0,n}}\right)\left(\frac{z}{0.07z_{0,n}}\right), & \text{for } R - S \end{cases} \quad (4.30)$$

4.3.3 The WS model

4.3.3.1 Wind speed model

The WS model assumes the stratification of the IBL for each patch follows the power law model. Unlike the ESDU model, each segment of the wind profile has a wind speed curve dictated by the power law index of the corresponding patch as shown in Fig. 4.12. The IBL growth is assumed to follow a power law with coefficient 0.8.

$$\begin{aligned} g_0(x) &= G \\ g_n(x) &= 0.5z_{0,(n,n-1)}^{0.2}x_n^{0.8}, \text{ where } z_{0,(n,n-1)} = \max(z_{0,n}, z_{0,n-1}) \end{aligned} \quad (4.31)$$

The wind speed model for each segment of the profile is

$$U(z) = U(g_n(x))\left(\frac{z}{z_{g_n}}\right)^{\alpha_n}, \text{ where } g_{n+1} \leq z \leq g_n \quad (4.32)$$

4.3.3.2 Turbulence intensity model

The corresponding model for turbulence intensity requires that the IBL be subdivided into a transitional and equilibrium sublayer. The total IBL depth $g(x)$, including the transitional sublayer, is still to follow a 0.8 power law but the equilibrium sub-layer depth is assumed to follow a 0.72 and 0.4 power law for smooth-rough and rough-smooth transitions respectively.

$$g'_n(x) = \begin{cases} 0.5z_{0,(n,n-1)}^{0.2}x_n^{0.72}, & \text{for } S - R \\ 0.5z_{0,(n,n-1)}^{0.2}x_n^{0.40}, & \text{for } R - S \end{cases} \quad (4.33)$$

The turbulence intensity profiles are then obtained using the following equations based on inverse power law.

$$I_u(z) = \begin{cases} I_{un}(10)\left(\frac{z}{10}\right)^{-0.4}, & \text{for } g_{n+1} \leq Z \leq g_n \\ I_u(g_n)\left(\frac{z-g_n}{g'_n-g_n}\right)(I_u(g'_n) - I_u(g_n)), & \text{for } g_n \leq Z \leq g'_n \end{cases} \quad (4.34)$$

Letchford et al. (2001) noted that in general turbulence intensity requires shorter fetch length to forget the upwind patch influence than wind speed.

4.3.4 Comparison of WS and ESDU models

The WS model discussed in the previous section was verified using boundary layer wind tunnel tests on sixty-nine cases of multiple roughness patch detailed in Table 4.1. A roughness patch is characterized by three parameters namely length, distance to building site, and roughness length or (l, x, z_0) . The letters c, s and u represent open, sub-urban and urban roughness patches respectively. The number following the letters represent the length of the patch in meters. For the patch upstream of all other patches, a relatively long fetch length of 2km is assumed. The basic single patch roughness cases are case-1 for open terrain, case-8 for sub-urban and case-55 for urban. First a simple program is written to compare the performance of WS and ESDU models using the formulas discussed in the previous sections. Sample results for some of the cases is given in Fig. 4.13. For the open terrain patch there is a good agreement between the two models, but a significant difference is observed for the sub-urban and urban patches. The ESDU model gives conservative results which can overestimate the velocity by as much as 20% as is confirmed by Wang & Stathopoulos, which was one of the motivations for the development of their model.

4.3.5 Three dimensional CFD simulations

The conventional method of using wall functions for roughness model has problems when the surface is very rough. Blocken et al. (2007) discusses the problems and gives recommendations for very rough surfaces in which the requirement that the first cell's $Y_p > K_s$ can not be satisfied. There is a conflict with the requirement that a fine mesh need be used close to the wall to resolve the high gradients. In this case, Blocken et al. suggests explicit modeling of roughness elements. This has been done by Miles & Westbury (2003) and leads to a significant improvement of the computed results compared to the results obtained with an approach flow over a smooth flat wall. The roughness blocks used in CFD simulations correspond to those used in wind tunnel study, using only smooth wall boundary conditions. The disadvantage of this methodology is that computational resources are wasted on less important part of the computational domain rather than improving the model of the primary object of study.

Figure 4.14: A look inside of a 3D symmetrical computational domain for regular array of cubes. The 2D plan of the model is previously explained in Fig.4.5

4.3.5.1 Simulations on a row of roughness elements

The first step is to determine configurations of roughness elements that yield a desired profile at a target downstream location. This iterative process could sometimes be time consuming if data is not available from previous wind tunnel tests. If a regular array of blocks arranged in simple manner (aligned or staggered) is used to represent roughness explicitly, the inherent symmetry can be exploited to reduce the computational domain. A typical symmetrical computational domain is shown in Fig. 4.14. It is clear that simulating one row of obstacle arrays is sufficient if a time averaged turbulence model, such as the k-epsilon model, is used. A section passing through the center of the cubes and another one passing through the center of the open space between two rows gives same result as the one shown in the Fig. 4.15. A two dimensional simulation can be used, but it results in larger spacing of roughness blocks because the blocks are assumed to be continuous in the transverse direction.

An approximate formula to relate roughness length with average frontal and planar area of obstacles can be found in MacDonald et al. (1998). The spacing and height of blocks using the formula are usually good estimates for starting the iterative process. The first simulations conducted are for homogeneous roughness patches of open-country, sub-urban and urban roughness characteristics. Steady state simulations with k-epsilon turbulence model are conducted on a 2km long domain for each of the roughness patches. The result of this preliminary analysis are shown in Fig. 4.15.

We can observe the three possible flow regimes first predicted by Oke (1998). The first roughness configuration is representative of open terrain ($B/H \sim 24$) is in an isolated flow regime. The wake and the separation bubble behind each obstacle is fully developed with re-

Figure 4.15: Velocity contours for different roughness characteristics showing isolated (open-terrain), wake-interference (sub-urban) and skimming flow (urban).

attachment occurring before the next element. With increasing density, the roughness elements become close enough so that the wake behind an obstacle starts to interfere with that of the downstream obstacle. The suburban roughness configuration ($B/H \sim 5$) seems to be in this wake interference regime. If the density increases further to a very rough urban setting ($B/H \sim 1.7$), the flow begins to skim over the elements. Our simulations used a constant height of $H = 10m$ for the blocks, varying only the spacing B for different roughness. As a result the skimming flow effect is more pronounced than it would have been if variable height blocks were used.

In all cases the bulk of the flow is forcibly displaced up and over the obstacle, which causes acceleration or a jet, but once over it is able to expand again and decelerates accordingly. This flow region, disturbed because of the presence of the obstacle, is called the displacement zone. Jimenez (2004) emphasizes the importance of the blockage ratio σ/h to the development of a logarithmic profile. The ratio measures the direct effect of the roughness on the logarithmic layer. For our simulations the boundary layer height $\delta = 500m$ and height of blocks $H = 10m$, hence $\delta/h = 50$. Jimenez notes that the ratio should be larger than 40 before similarity laws can be expected, and experimental results suggest that it should be greater than 80. Flows with higher blockage fractions retain few of the mechanisms of normal wall turbulence, and can better be described as flow over obstacles. Hence it is important to make sure the blockage ratio is within the acceptable range.

4.3.5.2 Simulation of a BLWT with spires and barriers

Before we conduct a case by case study of multiple roughness patches, we simulate a virtual wind tunnel with and without raised roughness blocks. The flow in a wind tunnel is bounded by walls all around, unlike the case of ABL flow where symmetry boundary is usually assumed at the sides and top of the domain. It is appropriate to use a no-slip boundary condition on all walls since boundary layers develop on all four sides. The wind tunnel in University of Western Ontario has a length of 26m, a width of 2.4m and a variable height from the inlet (1.55m) to the exit (2.15m). The roughness features are spires, barrier and roughness blocks. We first simulate the case where none of these roughness features are used, and evaluate the change in velocity profile due to the expansion of the tunnel alone. This simulation is similar to that of a smooth pipe flow. A grid with about 2.6 million cells (480x40x40) is used which is found to be enough for a grid independent result.

Next we simulate with roughness blocks of 0.1m high placed in a staggered manner. As we can see from Fig. 4.16 and 4.18, the boundary layer thickness on the bottom surface increases

(a) Inside look of surface(left) and close-up of surface mesh(right)

(b) Cross-section of velocity contours: empty domain(left) and with roughness blocks (right)

(c) Planar section of velocity contours

Figure 4.16: V-BLWT simulation results with surface roughness blocks

due to addition of the blocks. This is associated with an increase in turbulent kinetic energy. A planar view at half of blocks height shows that each block develops a wake. The interference effect in staggered arrangement is not as pronounced as that of a regular arrangement where the sheltering effect is maximum. We can observe that the first couple of rows have the longest wakes where the wind adjusts to the new roughness conditions.

Next three spires and a barrier are added to help in development of boundary layer as soon as possible. If a uniform flow enters the tunnel, it is expected that a boundary layer will develop $6H$ downstream of the spires. Figure 4.17 shows the mesh and result of the analysis after the addition of these new roughness features. It can be observed that the boundary layer depth and turbulent kinetic energy has significantly increased compared to using roughness blocks alone. The dimension of spires and height of barrier have a significant effect over the profile at the turntable. The wake from spires is very elongated as shown in Fig. 4.17.

4.3.5.3 Simulation of multiple cases with a virtual Wind tunnel

First we consider an approach of simulating a whole boundary layer wind tunnel similar to that done in section 4.3.5.2 but without using spires and barrier as shown in Fig. 4.21. Also the V-BLWT used for this case is from Wang & Stathopoulos's study, Concordia University BLWT. Roughness blocks are used to model suburban and urban roughness, while carpet is used for open country roughness. Some of the V-BLWT setups for multiple roughness patches are shown in Appendix A. We do not incorporate spires, barriers or grids to the models to save on simulation time. Fully developed boundary layer velocity and turbulence intensity profiles are applied at the inlet of the V-BLWT instead. The wind tunnel has a length of 12.2m, width of 1.8m and height of 1.8m. Open country roughness is directly incorporated by the use of wall functions. This method has a limitation in that the nearest cell to the wall should be big enough, but since $z_0 = 0.024$ is small the requirement is satisfied. For the suburban and urban roughness blocks are used as shown in Fig. 4.19. The blocks used in Wang & Stathopoulos's study were 1in cubes for suburban (S), and 1.5in cubes for urban (U). This results in too many roughness elements for the simulation, so it is decided to double the size of the cubes to 2 in and 3 in respectively. The number of roughness blocks is as a result reduced by four times. This is in accordance with formulas that use area density ratios to determine average roughness characteristics. The modified block sizes result in the same planar and frontal area density ratios as the original, hence they are equivalent. For this simulations we consider blocks to be the only roughness features, and no spires, grids or barriers are used. Instead of a uniform wind profile as used at wind tunnel inlet, an ABL boundary layer profile is applied. The inlet velocity

(b) Contour of U at mid vertical section

(c) Contour of U at height of blocks

Figure 4.17: Virtual BLWT simulation with spires, barrier and roughness blocks

Figure 4.18: Comparison of U and Iu profiles for different roughness features

profile is logarithmic with the gradient height fixed at 600mm and $U_g = 12.5m/s$. The length scale of the BLWT simulations is 1:400 and time scale is 3:400. A preliminary simulation is

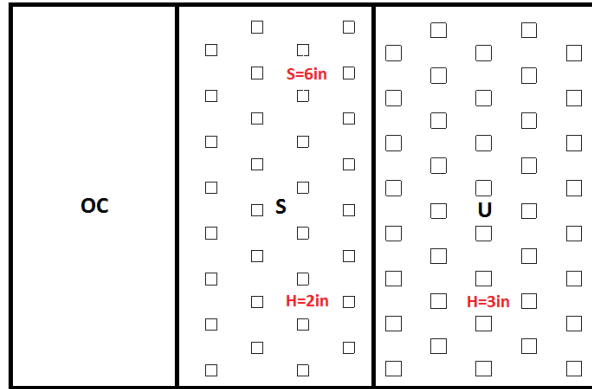

Figure 4.19: Open country(OC), Suburban(S) and Urban(U) roughness representation

carried out on an open country roughness. A sand grain roughness of $K_s = 20z_0 = 0.48$ is used for the wall function. The result is shown in Fig. 4.20. There are two problems with this simulation. First the first cell height $Y_p = 0.48$ is too high compared to the boundary layer thickness $\delta = 0.6m$. The problem of matching roughness in wind tunnel problems is a well known problem. For the simulation of the 69 cases of Wang & Stathopoulos a much lower roughness is assumed for the carpet so that the $Y_p > K_s$ condition is met. The first simulations we carried out with $K_s = 0.48$ for open carpet turned out to be bad where a bulge in the velocity profile is observed close to the ground. Using a lower roughness for OC corrected this problem much better fit are obtained except for the cases where open country roughness dominates the other patches. Second one should not expect horizontal homogeneity as the case of an empty domain because of the no-slip boundary conditions used at the top and side walls.

Figure 4.20: Inlet and outlet horizontal velocity profiles for open surface roughness

The results for the 69 cases are given in the following pages and Appendix A. We can observe that in most of the cases the V-BLWT fits the data much better than ESDU model. This is in contrast to the result found by Wang & Stathopoulos using numerical model with 2D simulations, which gave closer result to the ESDU model. The reason for this difference is not the simplified 2D model rather the difference in the shear stress modeling at the wall. Wang & Stathopoulos assumed a model of shear stress variation with fetch suggested by Bradley (1968).

$$u_*(x) \sim x^{-0.1} \quad (\text{for S-R}) \quad (4.35)$$

Garrat (1989) found that the shear stress initially increase to about twice its equilibrium value for S-R change, and decreases to about half its final value for R-S change.

$$\begin{aligned} u_*(x) &\sim 2x^{-0.1}u_* & (\text{for S-R}) \\ u_*(x) &\sim 0.4x^{-0.1}u_* & (\text{for R-S}) \end{aligned} \quad (4.36)$$

These equations were directly incorporated in Wang & Stathopoulos's numerical model. Our approach does not model shear stress but let it develop from the simulation. Also we should note that it is difficult to incorporate Wang's numerical approach into an existing CFD software due to the shear stress model. The other difference concerns turbulence models. Wang's numerical model uses linear eddy viscosity (mixing length) model for turbulence closure, while the current approach uses two equation Reynolds Averaged Navier-Stokes (RANS) model, namely standard $k - \epsilon$ model. We believe that these two differences, primarily the shear stress model, are the reasons for better result found from virtual wind tunnel simulations.

4.3.5.4 Simulation of WS cases using simplified 3D models

The results of the V-BLWT simulations suggest that computational effort can be reduced by taking advantage of symmetry of arrangement of the roughness elements. This is especially true for the rows in the middle that are farthest from the side walls. If the wind tunnel was infinitely wide, i.e. in the transverse direction, full symmetry can be achieved at all rows. Hence we can exploit the symmetry by considering only two rows with the sides of the domain cutting through the centerline of the rows. If the arrangement was a regular, one row of blocks would have sufficed as outlined in the preliminary investigations and shown in Fig. 4.5. The Symmetric Virtual Boundary Layer Wind Tunnel (S-BLWT) represents an infinitely wide BLWT where as the V-BLWT represents an actual BLWT with limited width in which the side walls retard the flow for a no-slip boundary condition. If the side walls of V-BLWT are also slip walls (symmetry), then the result of V-BLWT and S-BLWT should be exactly the same.

All the 69 cases of Wang are simulated again with this new setup , i.e. S-BLWT. The simulation time decreases tremendously since the width of the tunnel is decreased by almost 35 times. The results are shown along with the V-BLWT simulation results. We can observe that both wind speed and turbulence intensity results for the S-BLWT and V-BLWT are very close to one another. In some cases the V-BLWT wind speed result matches Wang's wind tunnel results better than the S-BLWT, hence V-BLWT is the better model for reproducing actual wind tunnel results. However the S-BLWT may actually be better in the grand scheme of things, because wind speed models over multiple roughness patches assume infinitely wide patches. Both Wang and ESDU model only take into consideration the length of patch (l) and not width of it(b).

4.4 Complexity 3: Semi-idealized built environment

So far the cases considered focused on determination of average roughness characteristics of highly idealized built environment models. This is acceptable in cases where detailed wind flow characteristics inside the built environment are not of high importance. For example, in BLWT testing, the building of interest and its surrounding within a short radius are modeled as best as possible, whilst the rest of the model is replaced with regular array of blocks that have similar roughness characteristics as the original model. The next higher level of complexity concerns flow in a semi-idealized urban canopy model. Wind tunnel test results are available, for the purpose of validation, from CEDVAL-LES (2011) for the urban model to be considered here. CEDVAL-LES is a compilation of wind-tunnel datasets intended to be used for validation of Large Eddy Simulation (LES)-based numerical flow and dispersion models. The database consists of both time series and time-averaged statistics against which LES and RANS models can be validated. This study uses RANS turbulence models thus only the time-averaged statistics is used.

The semi-idealized urban model is shown in Fig. 4.25. Hertwig et al. (2012) mentions that the model is so chosen to be heterogeneous and morphologically consistent with a typical central European city characteristics. It has sharp building corners, open courtyards, plazas and complex intersections etc. The on-line database has two cases, one where all roofs are flat and the other where some of the buildings have slanted roofs. The flat roofs case is chosen for this study.

4.4.1 Computational domain setup and grid generation

The computational domain is setup similar to Hertwig et al. (2012), who conducted numerical simulations using various CFD software and compared the results with the CEDVAL-LES database. The model tested in the boundary layer wind tunnel has a scale of 1:225, with the full scale size representing an area of about 1320m X 820m X 24m. The size of the computational domain is 1672m X 1140m X 144m. First a background mesh of 191 X 118 X 41 is applied which is then transferred to snappyHexMesh for molding the urban model from the STL file of the building surfaces. All the three stages of snappyHexMesh are used but there were still some visible problems at the edges of inclined walls as shown in Figs. 4.26-4.27. The total number of cells generated by snappyHexMesh is about 4 million.

4.4.2 Boundary conditions

At the inlet a logarithmic profile with $U_{ref} = 6.537m/s$ at a height of $H_{ref} = 144m$ is applied. A homogeneous roughness of $z_0 = 0.06m$ is used for the ground, and hence the friction velocity is $U_* = 0.346m/s$. At the sides of the computational domain a symmetry boundary condition is used, and at the top the values of U , k and ϵ are fixed to the same value used for the inlet at the same height: $U = 6.537m/s, k = 1.057m^2/s^2, \epsilon = 0.0049m^2/s^3$. The profiles of k and ϵ are determined according to Richards & Hoxey (1993) formulas. At the outlet an outflow boundary condition is used.

4.4.3 Results and discussion

Plots of velocity contours at different heights within the urban canopy of height 24m is shown in Fig. 4.28. We can observe that wind flow inside the built environment is complex due to the sharp corners, open yards, intersections and other features. The wind speed decreases and flow becomes more chaotic close to the ground thus grid refinement in the lower portions helps to capture the complex flow behaviour better. As mentioned before, the purpose of this simulation is to assess performance of CFD for prediction of detailed wind flow characteristics inside a built environment. For this reason, mean wind speed profiles at many locations inside the core are compared with measurements in wind tunnel of the same model.

The wind field is sampled at 40 locations distributed uniformly across the area in an 5 rows X 8 columns. Densely spaced measurements are also available at the core of the model to characterize street canyon flow, but this work compared only normalized vertical velocity profiles at the 40 locations. A comparison between wind tunnel and CFD results are shown in Fig. 4.30. We can observe that there is in general a good agreement between the current CFD results using RANS model and the BLWT measurement. At some of the probe locations, some deviations are observed especially close to the ground where surface roughness effects have pronounced effect. Also use of additional layers of grid that are aligned with the surface can improve the accuracy of results, but as is the case in many CFD simulations there is a trade-off between accuracy and simulation time. The good agreement obtained here also serves as a verification of the current CFD code's RANS model, k-epsilon in this particular case, for built environment studies. The LES model can be verified using this model in the future using the instantaneous measurements in the database for which it is primarily intended for.

4.5 Complexity 4: Built environment

CFD simulations in urban environment can be grouped in to two categories (Blocken & Carmeliet 2004) : (a) fundamental studies on simple and generic building configurations (b) applied studies on complex case studies. Fundamental studies on isolated cases help to understand flow behavior in and around a building, and also to validate CFD codes against wind tunnel or field measurements. Applied studies on specific urban setting have been conducted by many researchers despite the lack of extensive validation. Blocken et al. (2009) have reviewed the status of CFD in building performance studies of outdoor environment. The four main applications areas are summarized as follows.

- Pedestrian level wind comfort is an important consideration for high rise buildings. Usually wind tunnel studies are done to take point measurements of wind velocity at pedestrian height 1.8m. Area measurement techniques such as sand erosion can be used to spot the problematic points where hot wires are to be placed. CFD can be used to avoid at least this preliminary stage of the investigation. A case study of CFD simulation for pedestrian comfort in a University campus is described in Blocken et al. (2011).
- Air pollutant dispersion around buildings have been carried out using CFD on micro-scale level of about 5km horizontal length. Due to complexity of the phenomenon, studies are usually focused on two simplified models : urban street canyon and isolated building. Although studies have been carried out on complex urban environments, there is a lack of extensive validation which is usually the case for complex models.
- Wind driven rain (WDR) studies on buildings also benefit from CFD simulations albeit not as much as wind comfort studies do. The physical modeling of WDR requires expensive CFD techniques such as Lagrangian particle tracking of raindrops and LES turbulence model for accurate simulation, however RANS turbulence model are commonly used in practice.
- Convective heat and mass transfer studies on buildings using CFD requires accurate modeling of the boundary layer. Using wall functions as is used for other CFD simulations can overestimate heat transfer coefficients significantly. High Reynolds number simulation without wall function require very fine grids. Therefore the simulations are usually limited to simple cubic models.

The previous section focused on validation of CFD on semi-idealized built environment. The next higher level of complexity is a real built environment that is classified as Complexity

5 by CEDVAL-LES dataset. For this study, validation data is not available hence its purpose is for demonstration of the procedures to be followed. The built environment is an area in downtown Miami which has some high rise buildings. The computational domain has dimensions 4.3km X 4.3km X 2km. Micro-scale simulations of this magnitude need to consider the effect of Coriolis force since some buildings penetrate well into the Ekman layer. However this is ignored for the current simulations. The boundary layer height is chosen to be 2km to reduce blockage effect due to high rise buildings with heights $\geq 200m$ as shown in Fig. 4.34.

4.5.1 Computational domain setup and grid generation

First a background mesh of 120 X 120 X 60 cells is generated, which is then transferred to snappyHexMesh for refinement close to the ground. The final grid consisted of 2.3 million cells. The meshing process involves three stages : clipping, snapping to surface, and layer additions for better boundary layer simulations. The layer addition was problematic for this particular case, producing cells of high skewness and similar low quality cells, so the result after the snapping stage is retained. Snapshot of the background STL surface edges of building and the corresponding mesh is shown in 4.32.

4.5.2 Boundary conditions

At the inlet a logarithmic velocity profile for a rough surface condition is assumed mainly because no field observation data is available and the upstream terrain resembles a mildly rough environment from visual inspection. If field observation data was available for the inlet profile, the correct procedure is to make logarithmic fitting of inlet velocity profile followed by modification of the k-epsilon model constants (Blocken et al. 2011, Martinez 2011). Symmetry boundary conditions are assumed for the sides and top of the computational domain, and a no-slip ground surface with roughness of $z_0 = 0.1$ is assumed.

4.5.3 Results and discussion

Velocity contour plots at pedestrian level and higher are shown in figures 4.34. The simulations are re-run with different grid sizes to check grid independence of results. The number of cells in the vertical direction is changed to 30 and 90 cells for a total of 1.2 million cells and 3.2 million cells respectively. The smaller case result shows some qualitative differences with the current case of 2.3 million cells obtained using 60 cells in the vertical direction, however the larger case did not show much difference with the current result. Therefore it can be said

Figure 4.31: Surface model of a region in downtown Miami

Figure 4.32: Building edges and corresponding mesh generated by snappyHexMesh

that grid independence has been reached with the current grid size of 60 cells in the vertical direction. The fact that a detailed information can be retrieved from CFD analysis, compared to just point probes in wind tunnel or full scale investigations, is what makes them attractive for many engineering applications. However the lack of validation data, as is the case in this simulation as well, and expertise in CFD modeling leave something to be desired.

The velocity contour at different elevations show that wind speed increases with height. Also only few of the buildings reach the height of 200m, hence the planar density area ratio of obstacles, a parameter that affects roughness, also decreases with height. Micro-scale simulations of built environment of this size, that do not cover the whole area, pose a problem with regard to the boundary conditions. Here we can see that at the sides of the domain there are many buildings thus assuming symmetry boundary condition is not appropriate.

Figure 4.33: Velocity contours at 5m height for different grid sizes in the vertical direction

Figure 4.34: Velocity contours at different heights

4.6 Prediction with artificial neural networks

It is clear the V-BLWT methodology presented in this research is costly in terms of computational resources, though less expensive than conducting actual BLWT experiments. An approach followed by Bitsuamlak et al. (2004) to reduce the number of simulations is use of neural networks. From a database of simulation results, a reduced model can be built using artificial neural network that can capture non-linear relationships among different parameters. For a quick estimation, the reduced model can be used to get expected outcomes of simulation. The current work did not produce enough V-BLWT data to be used for this purpose, hence a similar study using actual BLWT data is carried out to investigate the relation between roughness elements and wind profiles using a reduced model. From the developed model, roughness element configuration can be predicted from the observed wind velocity and turbulence intensity measurements and vice versa. The details of the procedures followed are briefly described in the following sections and in more detail in Abdi et al. (2009).

4.6.1 Data acquisition

The neural network model is first trained with velocity and turbulence intensity measurements, and then the resulting model is used for prediction of configuration of roughness elements. Wind profile data was collected in a recently commissioned BLWT at RWDI USA LLC in Miramar, Florida. The unique characteristic of BLWTs is an extended working section downwind of the contraction over which an appropriate wind profile is developed. This particular wind tunnel is a closed-circuit tunnel with a 40 ft long and 8 ft wide working section upwind of the wind tunnel model, which is mounted on a turntable at the end of the working section. The ceiling height varies from 6 ft to 7ft above the turntable. This wind tunnel employs the spire-roughness technique to develop the wind profile, as described by Irwin (1979).

Figure 4.35 shows the working section of the BLWT. Three trapezoidal spires extending from the wind tunnel floor to ceiling are situated at the entrance to the working section. The floor is covered with triangular roughness elements in 40 staggered rows 1 ft apart. Spires of various dimensions can be interchanged manually as necessary, while the roughness elements are raised lowered by means of mechanical actuators controlled from the wind tunnel control room in order to save testing time. Massing models of the test building, present and future surrounding buildings are mounted on the turntable at the end of the working section, which can rotate 360 degrees to simulate wind from any direction. In the use of the spire-roughness technique for boundary layer wind flow simulation, the fundamental question to be answered

Figure 4.35: RWDI wind tunnel working Section, spire and roughness blocks

is the following: ‘What size, shape, location and number of spires, and what floor roughness height is needed to recreate a particular target atmospheric boundary layer wind profile in the wind tunnel?’ While there are a multitude of combinations of spire sizes, shapes, locations and floor roughness heights, the problem was reduced to a manageable size through previous experience. Three trapezoidal spires spaced on the centerline and 18in from the tunnel wall, and uniform floor roughness were kept constant. Thus, the remaining design variables were the top and bottom spire widths, and the uniform floor roughness height. These design variables are summarized in Table 4.2, along with the variable ranges that were used. It was desired to collect data for various combinations of these variables in order to train and test the artificial neural network model. Pressure data were collected with a ‘pitot rake’ positioned at the centerline of

Table 4.2: Roughness features dimensions

Variables	Range
Spire top width	5in-8in
Spire bottom width	10in-19.5in
Block height	0in-3in in increment of 0.5in

the working section, at the upwind edge of the turntable. The rake consisted of 53 pitot tubes. The pitot tubes were spaced at 0.5in intervals up to 5in above the tunnel floor, at 1in intervals up to 30in, and at 2in intervals from 30in to 66in above the tunnel floor. At a typical model scale of 1:400, the uppermost measurement location equates to a full-scale height of 2200 ft. The pressure data were sampled at 512 Hz for 36 seconds. From these time series of pressure, longitudinal velocities and longitudinal turbulence intensities were determined. The velocity ratio was defined as the ratio of the mean velocity at a particular pitot to the mean velocity of the pitot at a reference height of 60in above the tunnel floor. The turbulence intensity was defined

Figure 4.36: Neural network model with CCNN architecture for roughness estimation: 3 input, 20 hidden and 2 output neurons

as the ratio of the r.m.s to the mean velocity at a particular pitot. Thus, for each combination of design variable values, profiles of velocity ratio and turbulence intensity from 1in to 66in above the wind tunnel floor were determined.

4.6.2 Artificial neural network model

The most practical design considerations to build and train a neural network include the selection of an appropriate internal error criterion, efficiency of learning algorithm as well as choice of network topology and optimum stopping criterion for maximum performance. In the present work the neural network tool for prediction of wind profiles or estimation of roughness height and spire dimensions required to generate a specific target profiles is developed based on the cascade correlation algorithm using object-oriented methodology following the methodology described in Bitsuamlak et al. (2006). The architecture of a Cascade Correlation Neural Network (CCNN) is shown in Fig. 4.36. In this algorithm new hidden neurons are installed one at time during run-time as required from a pool of candidate hidden neurons, which are initialized to different weights and trained separately in the background. Note that the candidate neurons are not connected to the rest of CCNN during training. Thus, for each new hidden neuron, the present algorithm tries to maximize the magnitude of the correlation between the new neurons output and the residual error signal of the CCNN. Installation of new hidden neurons is automatically stopped when the network meets the error criteria or exceeds the maximum number of hidden neurons set by the user. For validation and comparison purposes a second flavor of Neural networks is also tested. The Multilayer Perceptron Neural Network (MPNN) uses a

supervised learning technique called back propagation. The major difference with the CCNN method is that the CCNN method works by installing new neurons while MPNN continually adjusts weights of neural network until a desired level of accuracy is reached. The C++ code for the MPNN method is given in Appendix B.

4.6.3 Results and discussion

4.6.3.1 Wind profile prediction

The neural network is trained with the database and then used to predict mean longitudinal velocity and turbulence intensity profiles from four input parameters, namely, height above which velocity measurements are taken, roughness length, top and bottom spire widths. Samples are taken randomly from the available data to train the ANN and then predictions are made on the remaining data. Some of the inputs are normalized with respect to the maximum values for better efficiency. Comparison of the predicted velocity profile and turbulence intensity with observed values showed a very good match, as is shown in the figures 4.37.

4.6.3.2 Estimation of tunnel surface roughness and spire dimensions

The inverse problem of determining roughness length and width of spire is done in the same way as the forward problem but by switching the inputs and outputs. Thus for the inverse ANN modeling the following three inputs are used: Target mean longitudinal velocity profile, target turbulence intensity, and height above which velocity measurements are taken. The outputs include the roughness length (of the wind tunnel floor), and the ratio of width of spire at height z divided by the bottom spire width. The inverse modeling is noticed to require more iteration to converge to the solution for a given tolerance (mean square error). For one test setup, the spire widths and roughness length are kept the same while measurements of velocity are conducted at different height. Hence, it is expected that the inverse ANN model to predict a single value of roughness length and Top and Bottom width of a Spire. Table 4.3 shows the comparison of the measured and ANN predicted values. These values can be used as starting values for further wind tunnel verification thus reducing cycle in the trial and error process.

4.6.4 Conclusions

Artificial neural networks are used to predict wind velocity and turbulence intensity profiles in a wind tunnel for a given floor roughness and spire dimensions with the objective of assisting

Figure 4.37: Measured versus predicted velocity and turbulence intensity profiles

Table 4.3: Measured and ANN predicted roughness length bottom spire width difference

Test set 1	Actual value	Predicted value
Spire width difference	12in	10.2in
Floor roughness	2in	2.2in
Test set 2		
Spire width difference	5in	6.2in
Floor roughness	1in	1.1in

the flow management process. The neural network model is trained with part of the wind tunnel data collected for various roughness length and spire dimensions. The results predicted by the neural network model have shown excellent agreement with the observed data for both mean longitudinal velocity and turbulence intensity profiles considered in this study. The inverse problem of determining roughness length and spire dimensions has also shown good agreement despite the relatively difficult nature of the problem due to discrete-valued parameters. In future other family error optimization techniques appropriate step functions can be used to improve learning efficiency and performance the inverse ANN models for discrete outputs. The CCNN network is found to be more efficient than MPNN because relatively fewer number of iterations are required for a given tolerance level.

Chapter 5

Numerical evaluation of orographic effects

This chapter focus on evaluating the effect of topographic features such as hills, valleys and escarpments on wind speed and turbulence using Computational Fluid Dynamics (CFD). Wind loading standards provide guidelines to determine wind speed up over hills as a function of the hill slope. The provision is usually for an isolated and symmetrical hill that is a highly idealized scenario (Miller & Davenport 1998). Real topography contains three dimensional topographic features and thus not symmetrical, and also are surrounded by other topographic features and thus not isolated. Design made on complex terrain without considering these deficiencies may be overly conservative in some cases and unsafe in other cases.

First we consider wind speed alone and calculate speed up ratios over many topographic features . We start from simulation on a flat terrain similar to what is done in the previous chapter, and then progressively add topographical features in both 2D and 3D domain. The effect of orography on wind speed is compared by calculating fractional speed up ratios. Multiple topographic features placed one after the other are also investigated to gain insight on sheltering effects. For all the 2D test cases considered, corresponding 3D simulations are carried out using axi-symmetric version of the 2D topographic features and results are compared against each other.

The second part of this chapter discusses turbulence structure over topographic features. Different turbulence models such as mixing-length model, two-equation Reynolds Averaged Navier-Stokes (RANS), and Large Eddy Simulation (LES) models are compared with one another with regard to their ability to predict recirculation zones. Also qualitative comparisons are made with results available in literature. The effect of roughness on wind speed ups and root mean square (RMS) fluctuations is assessed using equivalent sand grain roughness approach. In general roughness impacts RMS fluctuation estimations more than it does wind

Figure 5.1: Transmission line with multiple towers crossing a hill

speed. Therefore careful consideration of all simulation parameters is mandatory for characterization of the turbulence structure behind topographic features.

5.1 Wind speed up over topography

5.1.1 Building codes and standards

Several building codes and standards incorporate the effect of topography on wind speed using simplified models of isolated two dimensional hills, escarpments and valleys. Design of structures for wind loads requires accurate estimation of wind speed and turbulence intensity at different heights of the site. For infrastructures that span a large length, such as transmission lines, wind speed information is required at many locations. The structure crosses different speed-up regions as shown in Fig.5.1. If the site consists of outstanding orography such as hills and escarpments, the fractional speed up ratio can be high depending on the slope of the orography. Even on hills with gentle slope the speed up can be large enough to cause structural damages if not properly accounted for. Thus many national codes such as National Building Code of Canada (NBCC), American Society of Civil Engineers - 7 (ASCE7), Australian/New Zealand Standard (AS/NZS 1170-2), and European Standard (Eurocode I), provide general guidelines to estimate topography multiplication factors for wind speed over hills and escarpments. As discussed in section 2.2, these codes give recommendations only for simple topographic features. Experimental methods is recommended for a complex terrain that is not covered well in building codes. Methods that can be used to estimate wind speed up factors include : field measurements, boundary-layer wind tunnel testing, analytical methods and numerical methods. This work focuses on a numerical CFD approach to asses the effect of orography features on wind speed.

The Fractional Speed Up Ratio (FSUR), Eq.(5.1), quantifies the effect of orography on the horizontal component of velocity at a given height relative to its value on a flat terrain at the

same height. If there are no topographic features, FSUR should be 1 at every location. At the top and upstream side of hills and ridges, $FSUR > 1$ indicating a speed up, while $FSUR < 1$ on the leeward side where back flow occurs. Maximum values of FSUR are reached at crest of hills or a little upstream of it.

$$FSUR = \frac{U(z)}{U_o(z)} \quad (5.1)$$

NBCC defines a relative speed up ratio ($\Delta S = 1 - FSUR$) as follows

$$\Delta S = \Delta S_{max} \left(1 - \frac{|x|}{\kappa_1 L}\right) e^{-\beta z/L} \quad (5.2)$$

where the values of the parameters are taken from the Table 5.1. To show application example

Table 5.1: NBCC parameters for speed up ratio

			κ_1	
Hill shape	ΔS_{max}	β	$x < 0$	$x > 0$
2D ridges(or valleys with $H < 0$)	2.2H/L	3	1.5	1.5
2D escarpments	1.3H/L	2.5	1.5	4
3D axi-symmetrical hills	1.6H/L	4	1.5	1.5

of the above mentioned national codes, wind speed-up ratio ΔS over isolated hills of dimensions $L=800$, $H=200$ (steep hill) and $L=1600$, $H=200$ (shallow hill) under open country (C) exposure are considered. The formulas provided in the national codes are complicated, thus a program is written to plot speed up factors at different locations within the lowest 200m of the Atmospheric Boundary Layer (ABL) as shown in Figs. 5.2 - 5.3. We can immediately observe that NBCC and ASCE7 codes give FSUR estimates that are higher than that of AS/NZS 1170-2 and Eurocode I. This is most likely due to the underlying approaches used to generate the codal provisions. Some may have used Boundary Layer Wind Tunnel (BLWT) based methods while others use analytical/numerical approaches.

5.1.2 Numerical studies

A number of numerical studies over complex terrain have been conducted since Jackson & Hunt (1975) first analyzed flow over isolated hills of low slope using linearized forms of fluid flow equations by analytical means. Their approach is still in use for large scale wind mapping where a quick estimation is required for micro-siting or other purposes. One such program developed at Risø-DTU is the Wind Atlas Analysis Application Program (WASP), that includes complex terrain flow model with roughness change, and a separate wake model. On complex

Figure 5.2: Speed up factors at $x=0$ (crest), $x = L/2$ and $x = L$ of a 2D steep hill using various building codes.

Figure 5.3: Speed up factors at $x=0$ (crest), $x = L/2$ and $x = L$ of a 2D shallow hill using various building codes.

terrain with high hills and mountains, linear models fail to predict flow separation behind obstacles. Therefore such programs should not be used without modification when flow separation is expected. Castro et al. (2003), Maurizi et al. (1998) conclude that even non-linear steady state numerical models (CFD) have problems in recirculation regions, because orography can induce unsteadiness. The early studies using linear models (Deaves & Harris 1978, Jackson & Hunt 1975, Miller & Davenport 1998) are motivated by limitations in computational resources, but the problem is still present in case of micro-scale wind simulations conducted for micro-siting of turbines. This work investigates the simplest turbulence model, Prandtl mixing length model, besides more complex RANS and LES models. Complex turbulence models such as LES should be used when accurate information is required about turbulent structure and its effects. Some examples of use of LES in literature: pollutant dispersion studies (Lee et al. 2002), complex terrain studies (Dupont et al. 2008, Feng & Fernando 2011, Iizuka & Kondo 2006, Tamura et al. 2007, Tsang et al. 2009), wind loading (Dagnev & Bitsuamlak 2013). There are many studies carried out using RANS turbulence modes: isolated hills (Chung & Bienkiewicz 2004, Takeshi & Hibi 2002), multiple hills in succession (Bitsuamlak et al. 2004, Carpenter & Locke 1999, Lee et al. 2002), real complex topography such as Askervein hill (Rasoulli & Hangan 2013, Stangroom 2004).

5.1.3 Analytical study of flow over low hills

Guidelines for estimation of wind speed up over crest of 2D hills in neutrally stratified flows started with the seminal work of Jackson & Hunt (1975). They derived formulas for estimating fractional speed up ratio (ΔS) for a low hill of arbitrary shape defined by $z = hf(x/L)$ where h and L are the characteristic height and length of the hill as shown in Fig.5.4. L is defined as the upstream length where the height of the hill is half the maximum. A theory is developed for the boundary layer flow over such a hill with surface roughness of z_0 subjected to the following conditions

$$\frac{L}{z_0} \rightarrow \infty$$

$$\frac{h}{L} = \frac{1}{8} \left(\frac{z_0}{L} \right)^{0.1}$$

$$\frac{\delta}{L} \gg \frac{2\kappa^2}{\ln\left(\frac{\delta}{z_0}\right)}$$

where δ is the boundary layer height. The incident profile is defined with logarithmic law in the boundary layer

$$U_0(z) = (u_*/\kappa) \ln(z/z_0)$$

and a constant value outside the boundary layer

$$U_0(z) = (u_*/\kappa) \ln(\delta/z_0)$$

Also the boundary layer region is divided in to two regions, namely inner and outer region, in which the velocities are calculated differently via 'perturbation' approach.

1. In the inner region of height l , the velocity above the surface of the hill henceforth termed as displacement $\Delta z = z - hf(x/L)$ is calculated from the upstream velocity at same displacement above level ground, and a perturbation of $\Delta \hat{u}$.

$$u = u_0(\Delta z) + \Delta \hat{u}$$

2. In the outer region, the velocity is assumed to be a perturbation of the incident velocity at the same height z , not displacement height Δz .

$$u = u_0(z) + \Delta u$$

In this region the flow is assumed to be essentially inviscid and thus governed by potential flow theory.

The vertical velocity v can be determined from continuity relations. The boundary conditions in the boundary layer are such that as $z \rightarrow \infty$ both Δu and v go to zero, and at $z = l$ the velocities match with that of the inner layer. Then the two dimensional navier stokes equation is linearized by omitting the non-linear terms, followed by substitution of appropriate order scales for the inner and outer region to arrive at the velocity perturbations from which FSUR is determined. Detail mathematical analysis of the solution can be found in the paper. This seminal work has been extended to 3D hills by Mason & Sykes (1979) and used in wind mapping software such as WAsP. The major disadvantage of this method is that it can not be used for steep hill where non-linear models are more appropriate to capture recirculation behind hills. But the fact that solutions can be obtained very quickly makes them still attractive at least for preliminary investigations of micro-siting or similar purposes. Improvements to the model can be obtained by using a better turbulence model than the mixing-length model used by Jackson

& Hunt, avoiding linear approximations of equations and solving the equations numerically instead etc. The current work investigates non-linear models (CFD) for the calculation of speed up ratios and turbulence intensity using different turbulence models.

Figure 5.4: Flow regimes for flow over a low hill. Adapted from Jackson & Hunt (1975)

5.1.4 BLWT studies

Miller & Davenport (1998) provided guidelines for the wind speed-up evaluation over complex two dimensional surfaces based on a wind tunnel study. Ishihara et al. (1999) presented the results of measurements of wind speed over a circular hill with a maximum slope of about 62.5%. Cao & Tamura (2007) studied the roughness blocks effect on the atmospheric boundary layer flow over a two dimensional low hill with and without a sudden roughness change. The effects of the roughness blocks were clarified by comparing the flow characteristics over hill models, with emphasis on wind speed-up and turbulence structure. Adding or removing roughness blocks on the hill surface or inflow area changes the velocity deficit and creates a completely different turbulence structure in the wake. Lubitz & White (2007) presented a wind tunnel and field investigation of the effect of local wind direction on speed-up over hills. Other wind tunnel investigations include: Arya et al. (1987), Ayotte & Hughes (2004), Carpenter & Locke (1999), Castro et al. (2003), Ferreira et al. (1995), Finnigan et al. (1990), Gong & Ibbetson (1989), Snyder & Britter (1987).

5.1.5 Description of test cases of the current study

The first case considered is that of flat terrain with no topographic features. While this sounds rather pointless, Richards & Hoxey (1993) and others have demonstrated the difficulty of sim-

ulating wind flow over a featureless terrain. If the inlet wind speed and turbulence intensity profiles are incompatible with wall functions used at the ground, horizontal gradients may develop. Therefore this benchmark case should result in an FSUR of one through out the domain when proper boundary conditions are applied. Any other value indicate artificial speed ups due to inconsistent boundary conditions.

The second set of cases considered are single hills of two dimensions classified as shallow and steep from here on. Both hills have the same height but the shallow hill has twice the length. This geometric configuration has been used by Bitsuamlak et al. (2004), Carpenter & Locke (1999). The expected speed up over a 2D hill is depicted in Figure 5.5. The simulations are carried out at full scale dimensions where the height of the hills $H = 200$ giving rise to a high Reynolds number (Re_h). This is not a problem when RANS models are used for the simulation, but for LES simulations either the dimension of the hills or the viscosity has to be reduced by the order of 1:1000 to make simulations feasible on current desktop computers.

Figure 5.5: Wind speed up over a single hill (NBCC)

Many equations are available to define shapes of hills that may have significantly different effects on the FSUR obtained (Bitsuamlak et al. 2004). This study uses cosine hills with curves defined below. Both hills have the same height(H), and the half length (L) of the hills are $L = 4H$ and $L = 2H$ for the shallow and steep hills respectively. The maximum slope angles are 38° and 21° for the steep and shallow hill respectively, hence according to Finnigan (1988) flow separation is expected for both cases because the maximum slopes are above critical angle of $\theta_{cr} = 16^\circ$.

$$z = H\left(\cos\left(\frac{\pi x}{L}\right)\right)^2 \quad (5.3)$$

Some national codes also provide recommendations for 3D hills, hence we consider axisymmetric version of most topographic features considered in this study. It is expected that the wind speed over the hill will decrease on the 3D hill because of more freedom in the span

wise direction, while in the 2D hill case all the fluid has to go over the top of the hill. Depending on the actual shape of the orography, a 2D or 3D model may be appropriate. However the simplicity and conservative FSUR estimate of 2D hills usually makes them preferable in practice.

The third case is that of an escarpment with a constant slope as shown in Figure 5.6. A three dimensional version of this case, a frustum, may be possible but only the 2D case is considered in the present study. The slope of the escarpment is chosen to be 1:2, which is the same setup used by Glanville & Kwok (1997).

Figure 5.6: An escarpment

The fourth set of cases considered are double and triple hills. Multiple topographic features are not covered in national codes but it is implied that the wind speed up factors applicable for the first hill are to be applied for the following hills as well. The flow characteristics for the second and third hills are fundamentally different from that of an isolated hill, because of flow separation on the upstream hills. As already discussed before, there is a reduction in wind speed associated with more turbulence on the leeward side of the upstream hills. FSUR for the second hill are typically reduced by 20-30%. National codes such as NBCC use an overly conservative approach that may have severe economical consequences in the design of structures for wind loads (Horsfield et al. 2002).

Figure 5.7: Double hills

The last set of cases concerns wind flow over valleys where a slow down is expected unlike the hill cases. A recirculation zone forms inside the valley, therefore wind speed reduces associated with an increase in turbulence similar to what happens on the leeward side of a hill.

Figure 5.8: An isolated valley

5.1.6 Ground surface representation and mesh generation

The first step in ABL simulation is to prepare a model of the actual terrain as best as possible. While most of the cases considered here are simplistic, the procedure that is followed is applicable to complex geometry cases. It is assumed that geometric information is available in (x,y,z) point-cloud format, from which surface of the terrain can be produced by triangulation methods. The data maybe collected by field surveying and depending on the resolution accurate reproduction of the orography features maybe possible. For large areas that span kilometers ,high resolution LiDAR (light detection and ranging) data can be used if available.

Once the model of the surface is generated usually in STL (Stereo Lithography) format, the computational domain can be meshed with emphasis (refinement) on orographic features. There are many tools available to generate tetrahedral meshes that are suitable for finite element methods, but such non-orthogonal meshes are not suitable for finite volume CFD calculations. Hexahedral (or polyhedral) elements are preferred whenever possible. In most cases purely Hexahedral mesh for arbitrary surface is not possible. Therefore tetrahedral elements with a layer of elements parallel to the surface close to the wall , and Hexahedrons away from the surface are used. The meshing component of OpenFOAM cfd software known as snappyHexMesh is used to mesh an arbitrary terrain.This tool saves the user time by avoiding a lot of manual work, and it is worth explaining the process of meshing using snappyHexMesh. There are four stages in the meshing process. First a background mesh is generated as shown in Figure 5.10, with refinement regions around the hills. Then cells outside of the computational domain are removed. After this stage, the surface boundary is roughly established but it is not smooth enough. Thus a third stage of snapping to the surface is applied by moving vertices. Some of the cells near the surface may be of deformed shapes (tetrahedrals etc). It is crucial to have a body-fitted gridded closer to the wall for convergence and better accuracy, thus a final stage of adding layers of cells parallel to the surface is done.

While it is very difficult to generate a good mesh for an arbitrary 3D terrain, let alone one that satisfies orthogonality requirement, it is possible to produce high quality mesh for the 2D cases as described in Bitsuamlak et al. (2004). The method of meshing used in the present study generates non-orthogonal but body fitted grid. A correction for non-orthogonality is added as

a source term using an approach known as deferred correction for non-orthogonality (Jasak 1996). In both the 2D and 3D grids the grid is stretched in the vertical direction so that the first cell height is roughly equal to $2K_s$.

5.1.7 Computational domain setup

The computational domain is setup following recommendations for the use of CFD in wind engineering (Franke & Hirsch 2004). The domain may be broken down into three regions: upstream, central and downstream regions. The length of the upstream region is fixed at $5H$ from the center of the first orography. It is recommended to use short distances for the upstream region to avoid horizontal gradients that may develop with inconsistent wall and inlet boundary conditions. In the upstream and downstream regions no obstacles are placed and effect of roughness is taken care of through wall function modifications. The mesh in the central region may be refined to capture the change in wind flow characteristics that occur there. The outlet of the domain is placed far away at $12H$ from the last orography so that zero gradient boundary condition can be assumed for all flow quantities: $\partial\phi/\partial x = 0$. The distance between hills is fixed at $8H-4L$ which is zero for the shallow hill case and $4L$ for the steep hill case. This separation is selected to compare with results available in literature. The sides and top of the computational domain are placed $6H$ from the center of the hill to reduce blockage effect. The

Figure 5.9: Computational domain for double 2D hills

boundary conditions to be applied are as follows. At the inlet the Richard and Hoxey equations for an open terrain roughness of $z_0 = 0.024$ are used. At the outlet zero gradient is assumed for all flow quantities. At the top of the boundary a Dirichlet boundary condition is assumed in which the horizontal component of velocity is fixed to gradient velocity U_g . If the top of the domain is not placed at sufficient distance from the hill top, symmetry boundary condition should be used. The fact that the gradient velocity is known and that a driving shear stress is required to avoid horizontal gradients makes Dirichlet boundary condition appropriate. At the

sides a symmetry boundary conditions is still used.

5.1.8 Grid independence study

Grid independence study for a single 2D hill case is carried out as a benchmark for selection of grid sizes for the other cases. The number of cells in the vertical and horizontal directions are changed to estimate their effect on speedup at the hill top. The speed up values obtained for the different cases are more or less the same. In all the cases stretching in the vertical direction is done in such a way that the first cell size is the same for all cases. The result for the coarsest mesh is not far away from the result for fine mesh confirming grid independence. A zoomed in plot of velocity at the top of the hill is shown in Figure 5.11 that indicates coarser meshes tend to slightly underestimate speed up. Using extra cells in the vertical direction gives better results than using them to resolve along wind flow. This is due to the fact that resolving near wall flow with high velocity gradient in the vertical direction requires finer grids. For example a coarser 117 X 72 grid shows better performance than a finer 294 X 36 grid because the latter though finer, applied fineness in the wrong direction. However, it is not possible to refine indefinitely in the vertical direction because of limits imposed by the wall function treatment, compatibility of wall roughness with inlet profiles, aspect ratio of cells close to wall etc. In general using more number of cells improves solution, but computation time becomes a constraint. It is possible to solve the 2D cases considered in this work with the finest grid considered, however simulations over 3D topography and/or complex turbulence models such as LES will require major grid optimization to get results within a reasonable time frame.

5.1.9 Results and discussion

First the benchmark case of an empty fetch of $17H \times 7H = 3400m \times 1400m$ is analyzed with inlet boundary conditions as specified in 4.1-4.3. The velocity profile is more or less sustained throughout the domain as shown in Figure 5.20. The FSUR is 1 in most of the domain except towards the ground where it is difficult to sustain the inlet profile. The inlet velocity profile used for this case follows the log-law equation through out the height of the domain which is rather unrealistic for a height of 1400m. The only reason for this choice is to be consistent with Richards & Hoxey (1993) rough wall functions that have a log-law format. For the other cases to be considered, a gradient height of 270m above the ground is assumed above which the velocity is assumed constant. A disadvantage of the later is that the discontinuity in the velocity gradient at 270m is felt downstream, as will be clear in forthcoming plots of velocity

Figure 5.10: Mesh refinement around hills: Background mesh (top-left), box refinement around hill (bottom-left), Planar view of refinement for triple hills (top-right), and close up view of layers towards the ground (bottom-left).

Figure 5.11: Grid independence study on single 2D hill: wind profiles at crest (left) and close-up view of maximum speed up region(right)

profiles.

The second 2D orography considered is an escarpment with a slope of 1:2. Flow separation and recirculation are observed at the top and foot of the escarpment as shown in Figure 5.21. Speed up factors of 2 and 1.8 are observed at 10m and 30m above the crest of the escarpment. Larger values of FSUR may be found at lower depths but those are not to be trusted. In general the values obtained in the present study match with published literature such as CFD solutions of Carpenter & Locke (1999), and analytical solutions of Weng et al. (2000).

From here on, the cases are analyzed using both 2D and 3D orography model. As discussed previously, it is expected that the FSUR values for the 3D cases will be lower than the 2D hills and this is exactly what is obtained for all cases. Plots of FSUR along the center line of the hills at 30m from the ground are shown in Figures 5.12-5.19. A difference of about 20% is observed at the extreme points of hills and valleys where the difference is the largest.

Results for isolated shallow and deep hills are given in Figures 5.12-5.13. A gradual increase of wind speed up the hill followed by a slow down and recirculation on the leeward side are observed. The color plots for the 3D case also show that FSUR reaches peak values on the sides of the hill as well. The recirculation zone behind the steep hill is larger than behind the shallow hills. Also the 3D cases simulations show a much smaller recirculation zone than their 2D counterparts. After a drop due to recirculation, the FSUR gradually increases to 1 on the downstream. At the outlet, which is 12H away from the lee of the hill, FSUR reaches values of greater than 0.9 for all the cases. The peak FSUR at 10m above the crest are 1.6 and 1.8 for the shallow and steep 2D hills respectively. The 3D cases show lower values, by about 15%, of FSUR at the top of the hill as expected.

The next set of simulation results is that of double hills Figures 5.14-5.15. The purpose of this simulation is to determine by how much the FSUR drops from the first hill to the second. For the 2D simulations a drop of about 20% is observed, slightly larger for the steep hill case. This is in accordance with the result of Bitsuamlak (2004). However the 3D simulations do not show that big of a drop which can be explained by reduced sheltering in the lateral direction. For the shallow hill cases where the second hill starts off where the first one stopped, there is a continuity in the FSUR from the first to the second hill. But in between the steep hills there is a long recirculation zone where the FSUR remains roughly constant.

The case of triple hills is investigated further to see if there is further drop in FSUR. The results, Figures 5.16-5.17, show that there is not a significant drop in FSUR from the second to the third hill. This is again in accordance with results from literature. Therefore this shows that the approach taken by NBCC to design structures on sheltered hills for the same wind load as

the those on the first hill is an overly conservative approach.

The last set of cases analyzed are single valleys with big recirculation zones. Analysis of separated flow requires a better turbulence model as is done in Bitsuamlak (2004) but the standard $k - \epsilon$ model is used for the present study. The wind speed first decreases reaching negative values in the case of steep valley, and then the wind is sped up the second slope reaching or exceeding $FSUR = 1$ at the ridge. The 3D valleys show less recirculation similar to the case with hills.

5.1.10 Conclusions

A numerical procedure for computing speed up factors for different orography have been described, starting from meshing a complex terrain to post-processing the results. The results obtained using CFD procedure are generally in agreement with those found in literature. Three dimensional orography show reduced FSUR and also reduced recirculation in the lee compared to their 2D counterparts. Steeper slope leads to higher speed up factors over the crest and larger re-circulation zones. The reduction in wind speed up due to sheltering effects from hills in succession has also been investigated. While there is a significant drop in FSUR from the first to the second hill, not much drop is observed from the third hill onwards.

The result obtained from 3D simulation is significantly different from that obtained from 2D simulations to justify the associated cost of simulation. In general the speed up on 3D topographic features are found to be less than those obtained from corresponding 2D simulation. This is attributed to the fact that the flow has more freedom in the lateral direction in a 3D simulation.

5.2 Turbulence structure

5.2.1 Background

A fact that is usually overlooked in design codes is that turbulence intensity profiles are also significantly increased over crests of hills as much as wind speed. Some codes either ignore this fact or make suggestions for the overall turbulence intensity to be reduced. Miller & Davenport (1998) argue no allowance for reduction of turbulence intensity should be made at the very least, given the significant increase in local turbulence intensity at crest of hills as shown in Figure 5.22. The horizontal turbulence intensity increases significantly from the first to the second hill, and also the same phenomenon is observed for the vertical turbulence intensity as well. Miller & Davenport (1998) also used computational approach to evaluate speed ups using

Figure 5.22: Horizontal velocity fluctuation on upstream (dotted) and crest (solid) of sinusoidal hills (Miller & Davenport 1998)

a Mixed Spectral Finite Difference (MSFD) method. The method is computationally economic and can give good predictions on speed ups but it is limited to hills with slope not more than 30%. The current work also investigates accuracy and economy of different turbulence models for general computation of turbulence intensity over complex terrain. Carpenter & Locke (1999) have also investigated flow over multiple hills using wind tunnel and CFD approaches. They concluded that CFD shows good agreement with experimental data for the mean flow quantities but the agreement for RMS fluctuation was poor. Takeshi et al. (1999) have conducted wind tunnel studies to evaluate the turbulence structure over a steep cosine-squared hill with a slope of 32° . They observed pronounced wind speed up at the midway slope besides the one that occurs at the crest. Then the flow separates at the crest and re-attaches at the lee foot.

The variation of turbulence structure over the hill is better described from the plots of normal Reynolds stress components as shown in Fig. 5.23. This work also produces similar plots for Reynolds stress components for multiple topographic features from CFD analysis. Roughness

Figure 5.23: Horizontal normal stress σ_h/U_∞ profiles(Takeshi et al. 1999)

has a more severe effect on the turbulence structure than on the wind speed. Shuyang & Teturo (2006, 2007) have investigated this effect of roughness on wind flow over hills using wind tunnel experiments. Roughness is modeled by placing blocks over the hills. In analytical and numerical methods roughness is usually modeled using Nikurdase's approach where the roughness is assumed to be continuous and dense. Real hills are usually covered by isolated and relatively larger roughness blocks, and also roughness changes in the wind direction are common. Thus experimental investigation gives more accurate results against which analytical and numerical methods could be compared. They concluded that for low hills of up to a slope of 0.21, the roughness conditions greatly influence the turbulence structure.

Atmospheric boundary layer simulations are usually carried out using RANS or other more economical turbulence models. Some work on the use of large eddy simulations (LES) to study turbulence structure over hills can be found in Dupont et al. (2008), Feng & Fernando (2011). In general the accuracy of LES technique and sub-grid scale models is not well studied. Feng & Fernando (2011) have tested Smagorinsky and Lagrangian dynamic SGS models against experimental results. They have found that the Smagorinsky model grossly over-predicts the size of the re-circulation bubble behind hills. Also the Smagorinsky model under-predicts the speed up at the crest. The dynamic models improved the latter problem but some of the dynamic models also under-predicted the size of the recirculation bubble. The simulations are usually carried out on a model scale that reduces the Reynolds number by orders of magnitude.

5.2.2 Turbulence models

The choice of turbulence model is important for the simulation of the separated flow behind hills. When considering ABL flows, RANS models have the most appeal due to their low computational cost while still providing reasonable results close to experimentally observed results. The most commonly used RANS model is the standard k-epsilon model, which is known to have problems in adverse pressure gradient conditions. Modifications to the model to improve its performance in that regard resulted in RNG k-epsilon and Realizable k-epsilon models among others. The wall functions used can also be modified to consider effect of pressure gradient on velocity profile. Advanced turbulence models such as LES and DNS can be used to resolve the flow all the way to viscous layer. This usually requires too much computational cells to be feasible for practical flows with high Reynolds numbers. Hybrid models of RANS and LES have been proposed to get the best of the two approaches. Wall functions or RANS models can be used to model near wall flow, while the more accurate LES model is used away from the wall to resolve large scale eddies.

In both RANS and LES approaches, the flow equations are solved for averaged quantities (temporal, ensemble or spatial), while the effect of turbulence or sub-grid scales is modeled. The RANS models approximate the unknown Reynolds stress terms using turbulence viscosity hypothesis. The turbulence viscosity ν_t is determined from representative velocity and length scales of the largest energy carrying eddies.

$$\nu_t = u_* l_* \quad (5.4)$$

$$R = \nu_t |S| = \nu_t \sqrt{2\bar{S}_{ij}\bar{S}_{ij}} \quad (5.5)$$

On the other hand subgrid scale stress models of LES model the smallest unresolved scales hence the length and velocity scales are chosen to represent those smaller scales instead. Therefore selection of turbulence model in RANS is relatively more important than that for LES. Different turbulence models used in this study are briefly discussed in the following sections.

5.2.2.1 Mixing length model

The mixing length model is the simplest turbulence model that is known to give good results for simple two dimensional flows such as wakes, jets, mixing layers and boundary layers. The length scale is dependent on the type of flow. For boundary layer type flows with high Re and zero-pressure gradient, Prandtl's mixing length $l_m = \kappa y$ gives a good approximation. However

in adverse pressure gradient conditions such as the wake behind the hill, a stable boundary layer assumption is incorrect thus mixing length models do not work well.

$$l_* = l_m \quad (5.6)$$

$$u_* = l_m |S| \quad (5.7)$$

$$\nu_t = l_m^2 |S| \quad (5.8)$$

The mixing length for a boundary layer can be modified to incorporate the viscous and buffer layers as well. For ABL flows with high Reynolds number the boundary layer is very thin thus the linear approximation for mixing length is acceptable. The distance from the ground surface y can be obtained by solving the following differential equations proposed by Spalding (1994).

$$\nabla \cdot \nabla \phi = -V \quad (5.9)$$

$$y = \sqrt{\nabla \phi \cdot \nabla \phi + 2\phi} - |\nabla \phi| \quad (5.10)$$

The boundary conditions for ϕ are Dirichlet at ground surface and Neumann elsewhere. This partial differential equation is solved only once at start up, similar to orthogonal grid generation, hence it is not as costly as solving an additional set of turbulence equations for instance.

5.2.2.2 K-epsilon models

The first improvement to the mixing length model is to calculate the velocity scale from the turbulent kinetic energy k . One equation turbulence models solve a transport energy equation for k from which velocity scale is determined.

$$u_* = ck^{1/2} l_m \quad (5.11)$$

To make the model complete, i.e. one that does not require flow dependent specification, the length scale has to be calculated from the flow as well. Two equation models such as k-epsilon and k-omega solve one additional transport equation for turbulence dissipation or similar quantity to determine time/length scales. The most commonly used two equation model in practice i.e. standard k-epsilon model is known to give very good results in many engineering

applications. However it is known to give inaccurate results in regions of high acceleration / deceleration such as flow separation points and wake regions, where turbulence production is over predicted. To address this problem many modifications to the standard model have been proposed. The simplest of which is an ad hoc modification suggested by Kato and Launder to replace one of the S 's in equation 5.5 by vorticity ω .

$$R = \nu_t \sqrt{2\bar{S}_{ij}\bar{\omega}_{ij}} \quad (5.12)$$

More formal approaches to the problem have lead to different RANS models with moderate degrees of success. Renormalization group k-epsilon and Realizable k-epsilon models have been tested in this study to evaluate the re-attachment length of flow behind a single two dimensional hill.

5.2.2.3 LES models

In LES the effect of the larger eddies is explicitly solved while that of smaller scales is modeled using an eddy-viscosity approach similar to that used in RANS models. The major difference with RANS is that LES models the smallest scales that are below a certain filter width. In finite volume calculation the grid itself is usually taken as a filter for convenience. The simplest subgrid scale stress models (SGS) is that of Smagorinsky first developed for meteorological applications. The model is similar to mixing length model where the length scale is substituted by a new dimension calculated from the grid itself as shown in formulas below.

$$l_m = C_s \Delta \quad (5.13)$$

$$\Delta = \sqrt[3]{V} \quad (5.14)$$

The Smagorinsky coefficient C_s is determined experimentally to be usually between 0.1 and 0.2. The length scale at the surface of walls should be zero but the above equation for l_m gives non-zero values. A damping function can be used to reduce the length scale towards zero close to the wall. This can be achieved by integrating Prandtl mixing length to the model as follows.

$$l_m = \min(C_s \Delta, \kappa y) \quad (5.15)$$

For low Reynolds number flows with thick viscous and buffer zones, Van Driest damping can be applied as follows.

$$l_m = \min(C_s \Delta [1 - \exp(-y^+/A^+)], \kappa y) \quad (5.16)$$

For high Reynolds number flows, LES with near wall resolution is very costly. The number of grids required is estimated to be about $Re^{1.76}$ (Pope 2000). Wall models can be used to reduce this cost. Unlike wall damping modifications that are applied to all control volumes, wall functions are applied only to the cell closest to the wall. If wall functions are used, the length scale and hence the filter width become in order of flow length scale. As a result, the number of grids becomes independent of the Reynolds number.

5.2.3 Wall models

High Reynolds number flows have thin viscous layers that necessitates use of very fine grids to resolve all near wall behavior. To reduce computational resources, wall model are usually used in practical high-Re flows. Flow quantities at the first cell nearest to the wall are directly specified to satisfy the universal log-law equation, instead of being solved. There are two approaches of wall function implementation. In the first approach, named the standard wall function, the first cell close to the wall is placed in the logarithmic region ($y^+ \geq 30$). The friction velocity u_* is then calculated iteratively from the log law equation using U_p and y_p of the first cell. Then the wall shear stress $\tau_w = \rho u_*^2$ can be directly specified as a source term in the momentum equation, or equivalently in the form of modified effective viscosity.

$$\frac{U}{u_*} = \frac{1}{\kappa} \ln\left(\frac{E u_* y_p}{\nu}\right) \quad (5.17)$$

$$\tau_w = \rho u_* u_w = \frac{\rho u_* U_p \kappa}{\ln(E y^+)} \quad (5.18)$$

The turbulence kinetic energy k and dissipation ϵ are also specified at the first cell closest to the wall.

$$k = \frac{u_*^2}{\sqrt{C_\mu}} \quad (5.19)$$

$$\epsilon = \frac{u_*^3}{\kappa y} \quad (5.20)$$

The above approach has problems in re-circulating flows where the friction velocity is zero, by definition, at separation and re-attachment points. To solve this problem Launder & Spalding

(1974) proposed to calculate the friction velocity from k instead of using the log-law.

$$u_* = C_\mu^{1/4} \sqrt{k} \quad (5.21)$$

The transport equation for turbulent kinetic energy is solved with a modified production term that incorporates velocity gradient term that satisfies the log law. Then turbulence dissipation ϵ is fixed at the first cell close to wall. While this method can only be used with models that have equation for turbulent kinetic energy k , the standard wall function method can be used also in LES models with no k equation. Both wall functions discussed above are not applicable in flows with adverse pressure gradient such as wake behind a hill. Advanced wall functions suitable for LES simulations are described in Eugene (2006).

5.2.4 Simulation results and discussions

5.2.4.1 Effect of turbulence models

The selection of turbulence model is important for the prediction of turbulence structure in the wake region. Comparison between the mixing length, standard k-epsilon and RNG k-epsilon and LES turbulence models is shown in Fig. 5.24. The RNG k-epsilon and standard k-epsilon models give close results in most part of the hill except in the wake where the former predicts more recirculation (lower velocity) and longer re-attachment length. On the other hand, the mixing length model and in some cases LES, under-predict the presence of recirculation zone behind the hill in most cases. It is known the mixing length model is not reliable for studying the wake structure, however its prediction of wind speed up at the crest is acceptable. The LES simulation was carried out with a wall function and Prandtl damping function, hence it can hardly be called a large eddy simulation as is commonly done. The wall models dominate all other flow behavior, and the larger eddies in the outer region does not have much influence on the recirculation zone. Resolving the flow down to the viscous layer, as in a typical LES simulation, requires a lot of computational cells. For the current simulation that has Reynolds number of $Re_h \sim O(10^8)$ based on hill height of 200m, about $O(10^{14})$ cells are required. The usual remedy for this problem is to simulate a model scale, e.g at 1:1000, that violates the Reynolds number by orders of magnitude, similar to the case in wind tunnel testing. This has been done by many researchers (Dupont et al. 2008, Feng & Fernando 2011, Iizuka & Kondo 2006, Tamura et al. 2007, Tsang et al. 2009) at a Reynolds number of about $O(10^4)$ without using wall models. The purpose of those LES simulations was to validate wind tunnel results of a scaled model, and LES has shown good agreement with the experimental results. Typically

large recirculation zones are observed at lower Reynolds number compared to the current full scale simulations that displayed smaller recirculation zones.

It was then decided to conduct LES simulations without using wall functions at model scale of about 1:10000 with $H=40\text{mm}$. The Reynolds number is about $Re = 12000$ similar to the case studied in Tamura et al. (2007). For the LES simulations a longer computational domain is used so that the inflow at the inlet can be specified by recycling result from a location downstream of hill. Inflow turbulence is usually generated using ‘precursor’ simulations for as many time steps as the actual simulation. Recycling avoids the need to store results and usually gives good results if the source plane for turbulence is placed far from the inlet. Another method is to artificially synthesize turbulence that has required spatial and temporal correlation, i.e. from inverse Fourier transform of von Karman spectrum. Simply applying random and uncorrelated correlations is not appropriate for wind engineering applications. The simulation results show large recirculation zones with long re-attachment length of about $6H$ as shown in Fig. 5.34. This is in agreement with the result of Tamura et al. who found it to be about $5.8H$ using numerical LES simulations and about $5.4H$ experimentally in wind tunnels. The RNG k-epsilon model show much shorter re-attachment length of about $4H$ but it is still significantly larger than the re-circulation zones observed at high-Re flow with full scale dimensions.

5.2.4.1.1 Model scale LES and RANS simulations In the previous section, the effect of Reynolds number on the results of LES simulations, in particular the recirculation behind hills, is demonstrated over a test case obtained from (Tamura et al. 2007). Next all the cases of the current study are simulated at model scale of 1:10000 so that the LES simulations are feasible without the use of wall functions. The Reynolds number calculated based on the height of the hill is about $Re_h = 30000$. A RANS simulation is done in parallel using the best performing model so far, namely the RNG k-epsilon model. The computational domain is extended in the longitudinal direction so that the ‘recycling method’ can be used for inlet turbulence generation as discussed before. The results of these simulations are shown in Figs. 5.35-5.38.

We can immediately see that both the LES and RANS simulations show larger recirculation zone for the steep hill cases at this relatively low Reynolds number of 30000. This is in accordance with the results of Tamura et al. (2007) that used a hill which has more or less the same slope as the current study’s steep hills. However differences are observed between LES and RANS for the case of shallow hills in which LES shows much bigger recirculation than that of RANS simulations. The wall functions used for the RANS simulations play an important role in the accuracy of results. It is known that wall functions work well at high Reynolds numbers

(d) RNG k-epsilon mean velocity

Figure 5.34: Horizontal velocity contour plots for model scale simulations ($Re=12000$) using LES and RANS models

and non-separated flows, however their accuracy decreases with Reynolds number, which in the current case is a drop by a factor of 10^4 compared to the previous full scale simulations. Griffiths & Middleton (2010) stresses the influence of the wall function on accuracy, while comparing two CFD software (RAMS and FLUENT) with regard to modeling separated flow behind hills. They also observed that better agreements are found for the steepest hill cases, similar to the findings of the current study.

Figure 5.35: Instantaneous velocity contours of LES simulations for all the 2D hills: single shallow hill, single steep hill, double shallow hill, double steep hill, triple shallow hill, triple steep hill

5.2.4.1.2 Extracting fluctuations from simulations For LES turbulence models, the RMS fluctuations can be directly obtained, however RANS turbulence models keep only mean flow

Figure 5.36: Mean velocity contours of LES simulations for all the 2D hills: single shallow hill, single steep hill, double shallow hill, double steep hill, triple shallow hill, triple steep hill

quantities so it has to be inferred from Reynolds stresses. A simple method is to assume isotropic turbulence ($u' = v' = w'$), and calculate it from TKE as $u' = \sqrt{2/3k}$. A better method is to extract it from normal Reynolds stress components ($\langle u'u' \rangle$). The linear eddy viscosity assumption used in RANS models gives RMS fluctuations that are proportional to the mean straining field components. On the other hand, if the six Reynolds stress components were directly solved, as is done in Reynolds stress models (RSM), better estimates of RMS fluctuations can be obtained. The result using the RNG k-epsilon model and second approach of calculating RMS fluctuations are shown in Figs. 5.25-5.33. For a succession of multiple hills, we can observe that TKE at the crest increases significantly from the first hill to the

Figure 5.37: Mean velocity contours of RANS simulations for all the 2D hills: single shallow hill, single steep hill, double shallow hill, double steep hill, triple shallow hill, triple steep hill

second. The increase in TKE from the second to the third hill is not significant. The variation of Reynolds normal and shear stress components shows similar pattern to those found in literature for isolated and multiple hills.

5.2.4.2 Roughness effects

The effect of roughness on simulation results is briefly assessed. Both wind speed and turbulence structure are affected by roughness of the terrain surface (Shuyang & Tetsuro 2006, 2007). For CFD simulations, Nikurdase type equivalent sand-grain roughness (K_s) is commonly used. As noted in literature review, this method is not realistic but it is simple to im-

Figure 5.38: Mean horizontal velocity for shallow and steep a) isolated hill b) double hills c) triple hills d) isolated valley at 20m height from model scale simulations

plement in CFD codes. The standard wall function is modified with an additional term that is dependent on K_s to incorporate the effect of roughness. Blocken et al. (2007) discusses different issues concerning use of wall functions. The inlet velocity and turbulence intensity profiles should be compatible with the wall function used at the ground surface to avoid development of stream-wise gradients. For this study four roughness classes are considered: smooth terrain ($Z_0=0.005$), open ($Z_0=0.024$), roughly open ($Z_0=0.1$) and very rough ($Z_0=0.42$). The results for mean velocity and turbulence kinetic energy at $z=10\text{m}$ are shown in Fig. 5.39. It can be observed that roughness affects turbulent kinetic energy more than it does wind speed. Significant TKE increases are observed on the crest and wake of the hill with each increase in roughness class.

Figure 5.39: Mean velocity and TKE for different roughness lengths

5.2.4.3 Scheme sensitivity

The sensitivity of results, especially the turbulence structure behind hills, to the selected discretization schemes is briefly assessed. Simulations are carried out with different convection discretization schemes. The commonly used upwind scheme (UDS), while being very stable, is very dissipative and may perform very poorly in the re-circulation bubble. For equal number of control volumes, second order and other higher order schemes can give much better results. Higher order schemes can have higher dispersive errors and give unrealistic results with wiggles. To avoid this problem while maintaining second order, the higher order schemes are flux limited to satisfy a Total Variation Diminishing (TVD) criteria. The isolated hill problem is again analyzed for four different convection schemes applied to all terms: upwind (UDS), unbounded central difference (CDS), bounded QUICK and SUPERBEE. We can observe that the result for wind speed does not show much difference. However the TKE plot shows that the

higher order schemes show significant differences at the crest and wake. The CDS scheme, being unbounded, seem to overshoot TKE at the crest and lee foot. Therefore the use of bounded schemes is important. Martinez (2011) have done similar work but it is not clear if the significantly different result observed at the lee foot is due to the schemes being unbounded.

Figure 5.40: Mean velocity and TKE comparison for different convection discretization schemes

5.2.5 Conclusions

The study of turbulence structure in the wake of hills using CFD requires more effort than estimating speed up factors at the crest of hills. Significant increase in local turbulence intensity is observed at crest of hills. Also if a second hill is in the wake of another hill, the second hill shows significantly larger RMS fluctuations at its crest. From the third hill onwards, the increase in TKE is not as large. The current CFD result reinforces the statement made by Miller & Davenport (1998) that no reduction in turbulence intensity should be made at sheltered hills.

The turbulence model used for simulation play a significant role in the accuracy and economy of the simulation. The simplest model considered in this study, the mixing length model, under-predicts the size of the recirculation zone. RNG k-epsilon model gives better estimates than the standard k-epsilon model for prediction in the wake region. The LES results showed reduced recirculation zone but this is mostly due to the use of wall functions used for the current high-Re of $O(10^8)$ simulations. To have confidence in this observation, a model scale LES simulation without wall functions is carried out at Re of 10^4 . The result show large re-circulation bubble with long re-attachment lengths that are in line with result from literature.

The effect of surface roughness is briefly investigated by changing sand grain roughness K_s . It is found that roughness affect both wind speed ups over the crest and RMS fluctuations

in the wake, but its effect on the RMS fluctuations is more pronounced.

5.3 Wind flow simulations on real complex terrain

So far we have considered only idealized topographic features with a smooth shape. In a real complex environment, this kind of ideal topography is rarely found. In this section we conduct simulations over a real topography and validate our results with field observations. The Askervein hill is the standard benchmark for validation of CFD code for complex terrain simulations, hence we begin the study by conducting wind flow simulations over this hill and then validate the results using field observation data of Taylor & Teunisson (1986). Then we proceed simulating an even more complex terrain to highlight the associated difficulties. The chosen complex hill has sharp edges and steep slope. Data is not available to validate the results for this case, because it was chosen randomly from USGS database for demonstration. In general lack of field observation data is a problem that plagues complex terrain studies.

The slopes of topographic features and roughness of the terrain are important factors that affect wind speed up over hills. A terrain is classified as complex when it has a steep slope leading to significant flow separation and other complex phenomenon on the leeward side. Wind codes incorporate these effects using simplified terrain models that are not representative of a real complex terrain. Besides the slope, the terrain roughness also plays a role to retard the wind near the ground.

CFD codes incorporate the effect of roughness usually through equivalent sand grain roughness (K_s) after Nikurdase who first proposed the idea. A continuous and dense roughness is assumed, and a corresponding shear stress is applied as a body force to the nearest cell to the wall. If the ground surface model consists of distinct patches with variable roughness characteristics such as grass, buildings, parking lots etc., then averaged roughness parameters K_s and C_s over the patch are specified for each patch. On the other hand, if roughness data is available in a contour format, K_s and C_s are applied to each boundary face after the computational domain is discretized. In any case the variance of surface roughness should either be explicitly modeled (for bigger obstacles) as done in the previous section or implicitly modeled through rough wall functions. An implementation for OpenFOAM for the second approach is discussed in Xabier (2009).

5.3.1 Askervein hill case study

CFD codes for micro-scale model simulations are usually validated against a well known case of wind flow over the Askervein hill. The hill has been subjected to extensive field measurements in the 1980s, making it ideal for CFD benchmarking studies in literature (Castro et al. 2003, Crasto 2007, Martinez 2011, Stangroom 2004). However it is hardly complex by the definition we gave before : nearly two dimensional, isolated ellipsoidal hill with a gentle slope varying from 12% to 25%. Contour map of the hill is shown in 5.42. Other hills may pose a challenge in meshing and modeling of variable roughness characteristics, though automatic meshing for complex terrain is a difficult task anyway.

The TU03-B data set from Taylor & Teunisson (1986) is used to validate our CFD results. The data set was acquired while the wind was blowing at 210 degree clockwise for more than three hours. The wind direction is almost perpendicular to the hill for this particular case. The hill is 116m high and has elliptical shape as shown in the contour plot of Fig. 5.42. It is located in an area where there are no major buildings or other obstacles, hence a constant roughness is assumed thereby simplifying the analysis. The value of the roughness length z_0 was also measured during the field investigation and found to range from 0.01m to 0.05m. This study used $z_0 = 0.03m$.

The surrounding is flat on the upwind side of the hill and is hilly on the down side. A reference site is located 3km south west of the hill. The wind flow is relatively un-perturbed by the surrounding at the location hence the inlet of the computational domain is placed there. The instrument towers for the field observations are located along a line passing through HT and inclined at 220^0 .

5.3.1.1 Computational domain setup and grid generation

The dimension of the computational domain is set at 10km X10km X 2km around the hill center similar to that used by Stangroom (2004). A smaller height of 1km is also tested and found to be satisfactory. The hill is 116m high hence a 1km computational domain has a gap of about 9H between the hill top and the top of the domain. This is more than enough to satisfy the recommendations of Franke & Hirsch (2004) with regard to blockage effects. The blockage ratio is about 2% for a 1km boundary layer. The terrain data for the hill is available in triangulated STL file format which is in ready to use format for many commercial CFD software. Usually the problem lies in generating a grid from such complex surface model. Automatically generating a good mesh consisting of mostly hexahedral elements is still an active research area. One such meshing tool that significantly reduces involvement of the user

Figure 5.41: Contour map of Askervein hill showing Line-A and the hill top (HT)

Figure 5.42: Elevation map of Askervein hill including surrounding

is snappyHexMesh (Weller et al. 1998). The meshing for Askervein hill and all other complex surfaces in this study are done by this tool. It is able to generate an unstructured mesh of mostly

hexahedral elements from a given digital surface model. A description of the steps involved and meshing refinements close to the hill is found in Martinez (2011). Mesh refinement is done around the hill in two boxes similar to the idealized isolated hill case considered in Fig. 5.10, and also seven boundary layers are added on top of the ground surface to avoid convergence problems due to skewed and other low quality cells. The main difficulty with snappyHexMesh is that it requires a background mesh with an aspect ratio of one. This requirement leads to excessively high number of cells, most of them being placed where they are not much required. It is important to place as many cells as possible in places where flow variables change very rapidly i.e. have the highest gradient.

5.3.1.2 Grid independence study

Simulations are carried out for different grid sizes to check the sensitivity of the results with the grid size. The grids used are generated in a two step manner. First a relatively coarse background meshes of $30 \times 30 \times 8$, $50 \times 50 \times 13$, $100 \times 100 \times 24$, and $120 \times 120 \times 32$ are generated, and then refinements are applied close to the hills and the ground surface to capture the boundary layer flow better. The number of cells that snappyHexMesh produced after application of boundary layers and other refinements are 150k, 520k, 2.5million and 4million cells respectively. These numbers are significantly larger than those of corresponding background meshes, thereby highlighting the importance of mesh refinement in important regions for efficient simulation. The TU03-B data set, which was recorded along line A and while the wind was blowing at 210 degrees from north, is used for the simulations. The result of this grid independence study is shown in Fig. 5.44. Along most of the uphill slope the speed up remains the same for all grids, but starting from the crest through the wake zone significant differences are observed. This is especially true for the coarsest grid considered i.e 30×30 . For the purpose of determining maximum wind speed up at the crest, the 50×50 grid gives acceptable results. However it shows some differences with 100×100 and 120×120 grids for the flow in the leeward side of the hill. Therefore we can conclude that the 100×100 case gives grid independent results for the flow over the whole length of the hill.

5.3.1.3 Different turbulence models

Another factor that has similar consequences as the grid resolution is the turbulence model. The standard k-epsilon turbulence model is commonly used for wind engineering applications, however it is known that steady RANS models give good predictions only on the upwind side. The unsteady effects on the lee side are not captured by RANS models, and it may be important

Figure 5.43: Coarse and fine meshes of Askervein hill with surrounding hills

Figure 5.44: Normalized horizontal velocity for different size of grids

to use unsteady models for better understanding of re-circulation zones behind hills according to Castro et al. (2003). This study tests only RANS models even though LES simulations were attempted without success due to convergence problems. Three turbulence models namely mixing length, k-epsilon and RNG k-epsilon model are used. The results are shown in Fig. 5.45. The k-epsilon model does not show significant differences with RNG k-epsilon model in most part of the hill except at the strongest areas of re-circulation towards the bottom of the lee. The mixing length model shows differences with the above models both at the crest and the lee but in general it is not very much off as one might expect from the simplicity of the model. The reason for this observation could be that Askervein hill has a relatively gentle slope, that is favorable for linear models such as mixing length model. Nonetheless the results highlight the importance of the turbulence model to resolve the flow in the wake region. The

Figure 5.45: Normalized horizontal velocity for different turbulence models

grid independence study conducted in the previous section has also stressed the importance of this region.

5.3.1.4 Comparison with field measurements

The TU03-B data set along line A is used for validation of the best performing RANS model. The velocity data from the field observations is shown in Table 5.2. As we can see from Fig. 5.46, there is generally a good agreement on the upwind side of the hill, but significant differences are observed on the leeward side of the hill. This is mainly due to flow separation and unsteady flow characteristics that can not be captured with time-averaged turbulence models (Castro et al. 2003). Hence large eddy simulations may give better results. This has been investigated by many researchers including Castro et al. (2003), Crasto (2007) who concluded the superiority of LES if enough small scales are resolved and appropriate boundary conditions are used. However LES is rarely used in practice for simulation over complex terrain solely due to excessive cost of computation. In any case, our simulation results using RANS models were able to predict presence of recirculation zones to a certain extent, with the best results coming from the RNG k-epsilon turbulence model using the finest grid.

Figure 5.46: Normalized horizontal velocity comparison with field measurements

Table 5.2: Wind speed data at 10m height

Distance from HT	Wind speed (m/s)
RS	8.6
-850	7.8
-500	6.7
-350	7.2
-200	10.5
-100	13.2
HT	16.2
100	12.0
200	5.6
400	3.0

5.3.2 A second complex hill simulation

The primary reason for choosing Askervein hill is availability of field observation data for validation, but the hill can hardly be considered complex compared to other hills found elsewhere. In this section simulations are carried out on a steep and complex hill downloaded from freely available United States Geological Survey (USGS) database. Another source of terrain/built environment data, usually in point cloud format, is the International Hurricane Research Center (IHRC) that provides LiDAR data for parts of Florida. One can download terrain and roughness data for a square grid of about 5000ft X 5000ft. The point cloud data can be converted to

digital surface data (STL format) using triangulation techniques (e.g. Delaunay), after which a grid can be generated with the surface used as the base of the computational domain. The grid generation procedure is already described in the previous section of meshing idealized 3D hills, namely using snappyHexMesh, thus no additional effort is required. This is an important advantage in automatic meshing and analysis of random complex topography that would otherwise have required a lot of manual work to generate grid of acceptable quality.

The purpose of this work is not validation but to assess and demonstrate problems that may be encountered for a randomly chosen complex topography. The first difficulty arises from choosing a hill that is not surrounded too much by other topographic features. It is to be recalled that the previous case of Askervein hill is ideally placed on a flat terrain which has uniform roughness. It is not common to find such an ideally placed hill in a complex topography, therefore the boundary conditions used for a more realistic topography are usually complicated than that of Askervein's. The hill chosen for this exercise did not have such perfect conditions, but we assumed it is surrounded by a flat terrain anyway. The ground surface is cut by a horizontal plane at 1m height (shown in Fig. 5.47) to get a smooth surface and establish a zero-plane where logarithmic profiles are applied. The second problem concerns roughness that was assumed to be constant for the Askervein hill case. The current hill is in an area where vegetation and small ponds exist hence the assumption of constant roughness, as in the case of Askervein hill, is not accurate. Nonetheless, here again we make a simplifying assumption of constant roughness of $z_0 = 0.01$.

Figure 5.47: A randomly selected complex hill with sharp edges and its mesh (top), elevation contour (bottom)

The computational domain and boundary conditions are set up following Franke & Hirsch's recommendations. Velocity and turbulence quantities are assumed at the inlet since field data is not available for comparison. Then simulations are carried out with the standard k-epsilon turbulence model. A planar section of velocity and turbulent kinetic energy contours are shown in Fig. 5.48. The flow is complex due to multiple sharp ridges, but a distinct recirculation zone, though small in size, is observed behind one of the hills. If the area is to be used for micro-siting wind turbines it is crucial that such locations with high turbulence intensity and recirculating flow are avoided.

Chapter 6

Conclusions and future work

This section gives brief summary of the conclusions and findings of the current research work. The theme of the research has been numerical simulations on complex terrain and urban environment for various wind engineering purposes. The large scale nature of the project makes numerical simulations and wind tunnel testing as the most feasible investigation techniques. While field observations can potentially provide better quality data, the associated cost and the time required to carry out the investigations limit their use, except in very few cases where field observation data is required for validation purposes. The relative ease with which many numerical simulations (parametric study) can be carried out makes them suitable at least in the preliminary stage of investigations of micro-siting studies and similar purposes. Atmospheric boundary layer flow is affected by presence of topographic features such as hills, escarpments and valleys as well as surface roughness characteristics. This research has investigated these two factors separately in Chapter 4 and Chapter 5 using Computational Fluid Dynamics (CFD) methodology.

The current research has three main themes pursued in Chapter 3 to Chapter 5. The findings, conclusions and unique contributions in each chapter are briefly summarized in the following sections.

6.1 High performance CFD code

This research work started from development of an in-house CFD software tailored for Atmospheric Boundary Layer (ABL) simulations, through which the author has gained expertise on the components of CFD software. The final outcome is a 7300 lines of CFD code that has all the necessary features for ABL simulation over a complex topography. The program is a three

dimensional finite volume code and uses polyhedral elements as building blocks. The program is parallelized using Message Passing Interface (MPI) to run on a cluster of processors such as the Shared Hierarchical Academic Research Computing Network (SHARCNET) cluster at Western. It can also utilize the latest technology in high performance computing such as Graphic Processing Units (GPUs). Different turbulence models suitable for ABL simulation are implemented and tested for suitability of complex simulations. The turbulence models implemented include linear mixing-length model, many Reynolds Averaged Navier-Stokes (RANS) models including k-epsilon and RNG k-epsilon, and the Smagorinsky Large Eddy Simulation (LES) model. The code is validated against well known benchmark cases including problems specific to wind engineering.

Contribution:

A common problem regarding large scale simulations is scaling of algorithms on supercomputers. CFD is usually parallelized using domain decomposition strategies in which a processor is responsible for a part of the terrain and information (pressure and velocity) is exchanged at the interfaces. Usually the parallelization scheme is done with blocking calls, where every processor is forced to synchronize at the end of each iteration. As far as the author's knowledge goes, industry standard CFD software such as Fluent and OpenFOAM suffer from scaling issues related to synchronized communication. This work has investigated a unique approach of asynchronous communication where processors can be at different stages of solution, and exchange of pressure and velocity is not necessarily forced. This has the potential to avoid bottlenecks incurred by synchronization calls, and allow for scaling on larger cluster of computers.

6.2 Effect of roughness

Chapter 4 have investigated the effect of roughness alone on wind characteristics. First simplified models with roughness blocks of different arrangement, similar to the case in a boundary layer wind tunnel, are simulated using the developed software. The simulation results are compared against empirical formulas that use average frontal and planar area density ratios. Then the problem of multiple roughness patches on the upstream side of a building is investigated. This work has investigated 3D explicit modeling of roughness elements. First a Virtual Boundary Layer Wind Tunnel (V-BLWT) is simulated by replicating all the roughness features such as spires, barrier and roughness blocks to examine the effect of each element. Then spires and

barrier are dropped in the latter simulations with the blocks as the only roughness features and a boundary layer profile applied at the inlet. This setup is used to evaluate the effect of multiple roughness features on wind profile using many test setups found in literature. The results are compared with Boundary Layer Wind Tunnel (BLWT) data and existing wind speed models. Furthermore for roughness elements that are arranged in a regular manner, the inherent symmetry is exploited to reduce the computational domain significantly. The results obtained are almost the same as that of the full virtual wind tunnel simulation. Finally a semi idealized urban environment is simulated and results validated against existing BLWT tests of the model, with which good agreements are obtained. Finally a complex models that is representative of real built environment is simulated.

Contribution:

Surface roughness is usually incorporated into CFD codes using an equivalent sand grain roughness concept. However this approach can not be used when the roughness elements are large due to conflicting requirements as outlined in Blocken et al. (2007). This work has investigated one of the approaches suggested in that work, namely explicit modeling of roughness elements for sub-urban and urban surfaces. The effect of multiple roughness patches is investigated using this approach and the results obtained are found to be in good agreement with existing wind speed models. A second contribution is an extensive use of virtual boundary layer wind tunnel to conduct simulations on multiple array of blocks. Even though it is found later that a simplified model with a single row of obstacles is enough for the purpose at hand, the virtual wind tunnel approach can be used for more complex cases. The progressive approach taken to investigate roughness effects starting from the simplest case of empty domain to a real built environment is unique.

6.3 Effect of topographic features

Topographic features such as hills, valleys and escarpments significantly modify ABL flow. While recommendations for idealized models (isolated and symmetrical) can be found in building codes and standards, complex cases are not covered well. This work extends original work done by Bitsuamlak et al. (2004) using 2D simulations on multiple topographic features to a more elaborate 3D CFD simulations. Many turbulence models, ranging from the simplest mixing-length to LES models, have been investigated. In general, the 2D simulation overestimate the speed up over crests of the hill and also has larger recirculation bubbles compared to

their 3D counterparts. Fractional Speed Up Ratio (FSUR) comparisons with results available in literature show good agreement. The next phase of the work involved conducting simulation on a real complex topography with field measurements that are used to validate simulation results. The Askervein hill is selected for this study because of availability of validation data and a relatively simple digital surface model. Parametric studies are conducted for different resolutions of grid, different turbulence models and dimension of the computational domain. The results obtained show good agreement with field measurements concerning wind speed up over the upstream side, but distinct differences are observed in the wake of the hill. This is attributed to weakness of RANS turbulence models that are not able to capture the unsteady effects in recirculation zones. On upstream side of the hill, the simplest turbulence model gives comparable results with the more complex RANS models. This is mainly because of the gentle slope of the Askervein hill where linear models have the potential to perform as well as more complex turbulence models.

Contribution:

Effect of 3D orography on wind flow has been investigated using CFD simulations over idealized and real complex terrain models. Jackson (1981) first analyzed flow over an isolated hill analytically using linearized forms of the governing equations. Their model is applicable only to low hills where recirculation zones are absent. In light of this original work, the current work has investigated the simplest turbulence model for non-linear CFD, i.e. mixing length model, along with more complex RANS and LES turbulence models. The mixing length model has been found to give good predictions of speed up over the crest and upstream side of hills. The simulations carried out in this study are done at full scale dimensions where the hill height is $H = 200m$. In literature, model scale simulations at 1:100 to 1:10000 are usually carried out. This is mainly because these simulations are meant for validating corresponding wind tunnel tests at the same scale. This work has shown that there can be a significant Reynolds number effect for the LES simulations. LES simulations on an isolated hill carried out at Reynolds number $(Re) = O(10^4)$ show significantly larger recirculation bubble compared to one carried out at full scale dimensions with wall functions and also to results obtained from RANS models as well.

6.4 Future work

Potential improvements and possible extensions of the present study are:

1. The current software can be run on homogeneous cluster of CPUs or a single GPU. Its capability can be extended to heterogeneous accelerator based many-core architecture. This will allow simulations of ever bigger atmospheric problems with better accuracy on current/future generation High Performance Computing (HPC) clusters.
2. A neutrally stratified atmospheric boundary layer (dry atmosphere) is assumed for all the micro-scale simulations conducted in this study. For domain sizes of $\sim 10km$, hydrostatic assumptions does not hold anymore. Therefore future research which considers stability of the atmosphere can be conducted to include non-hydrostatic effects due to density (temperature) variations.
3. The effect of Coriolis force has also been neglected but it is known that flow in the Ekman layer ($> 100m$) and above is significantly affected by it depending on the location of orographic features (via Rosby number) and altitude above which FSUR is computed. Thus investigation of Coriolis effects on ABL flows over topography is a potential extension of the current study.
4. While the Askervein hill is used to validate the case of flow over a real complex terrain, validation data for the corresponding real built environment case, namely the Downtown Miami case, was not available. This is a problem that plagues such studies in general, thus in the future simulations over a built environment of which field measurements are available can be conducted for validation.

Appendix C

CFD program

C.1 Brief information on usage

The CFD code is compiled into three separate programs for the following purposes

1. Grid generation: **mesh** Grid can be imported from FIUENT ascii format (.msh)

```
1 ./mesh -i test.msh -o test
```

This will import the grid file *test.msh* and save the result in the file *test*. The second option, useful for simple hexahedral grid generation, is to use the built-in grid generator

```
1 ./mesh block.txt >grid
```

This will generate grid according to specification in *block.txt* and save the result in the file *grid*. The specification file basically consists of the *vertices*, *faces* and *control volumes* of the computational domain.

2. Solvers: **solver** There are currently five solvers implemented as described in Chapter 3
 - (a) PISO - for Navier-Stokes equations
 - (b) Walldist - Wall distance solver
 - (c) Diffusion - Heat diffusion solver
 - (d) Transport - Transport equation solver
 - (e) Potential - Potential flow solver

The type of solver and settings for the solvers can be specified in a separate file *controls.txt* and passed to the solver program

```
1 ./solver controls.txt
```

The contents of *controls.txt* look like the following

```
1 general
2 {
3 #####
4 # mesh file name and solver type
5 #####
6     solver                piso

66 }
67 turbulence
68 {
69     k_UR                  0.5
70     x_UR                  0.5
71 }

```

3. Pre/Post processing; **prepare** This tool is used for pre and post processing results such as generating VTK file of results for viewing with paraview or similar tool, taking samples at specified probe points, preparing to run program in parallel via static domain decomposition, merging decomposed results in to one etc...

```
1 ./prepare prepare.txt -vtk -start 0 -end 5
```

This converts the results into VTK file format for time steps between 0 and 5. The contents of *prepare.txt* look like

```
1 general
2 {
3 mesh grid
4 decompose 3 {2 1 1}
5 fields 5 { U p k e emu}

5808 Navier stokes solver using PISO algorithm
5809 ~~~~~
5810 References:
5811 Hrvoje Jasak, "Error analysis and estimation of FVM with
5812 applications to fluid flow".
5813 Description:
5814     The PISO algorithm is used to solve NS equations on collocated grids
5815     using Rhie-Chow interpolation to avoid wiggles in pressure field.
5816
5817 Prediction
5818 ~~~~~
5819 Discretize and solve the momentum equation with current values of pressure.
5820 The velocities obtained will not satisfy continuity unless exact pressure
5821 happened to be specified.
5822
5823 Correction
5824 ~~~~~
5825 Step 1)
5826     Determine velocity with all terms included except pressure gradient source
5827         contribution.
5828          $ap * Up = H(U) - grad(p)$ 
5829          $Up = H(U) / ap - grad(p) / ap$ 
5830     Dropping  $grad(p)$  term:
5831          $Ua = H(U) / ap$ 
5832     One jacobi sweep is done to find  $Ua$ .
5833 Step 2)
5834     Solve poisson pressure equation to satisfy continuity with fluxes calculated
5835     from interpolated  $Ua$ .
5836      $div(Up) = 0$ 
5837      $div(1/ap * grad(p)) = div(H(U)/ap)$ 
5838      $lap(p,1/ap) = div(Ua)$ 
5839 Step 3)
5840     Correct the velocity with gradient of newly found pressure
5841          $U -= grad(p)$ 
5842     These steps are repeated two or more times for transient solutions.
5843     For steady state problems once is enough.
5844 \endverbatim

6073 /**
6074     \verbatim
6075     Potential flow solver
6076     ~~~~~
6077     In potential flow the velocity field is irrotational (vorticity = curl(U) = 0).
6078     This assumption fails for boundary layers and wakes that exhibit strong vorticity,
6079     but it can still be used to initialize the flow field for further simulations.
6080
6081     For incompressible flow
6082         div(U) = 0
6083         Velocity is the gradient of velocity potential phi
6084         U = grad(phi)
6085         div(grad(phi)) = 0
6086         lap(phi) = 0
6087         phi is pressure for this solver. The initial flow field will inevitably not
6088         satisfy
6089         continuity due to imposed boundary conditons. Therefore we solve a pressure poisson
6089         equation and then correct the velocity with the gradient of p.
6090         lap(p) = div(U)

6542     d(rho*u)/dt + div(rho*uu) = -grad(p) + div(mu*gu)
6543 RANS:
6544     d(rho*U)/dt + div(rho*UU) + div(rho*u'u') = -grad(P) + div(mu*gU)
6545     d(rho*U)/dt + div(rho*UU) = -grad(P) + div(mu*gU) - div(rho*u'u')
6546     d(rho*U)/dt + div(rho*UU) = -grad(P) + div(V + R)
6547 where Viscous (V) and Reynolds (R) stress tensors are
6548     V = mu*gU
6549     R = -rho*u'u'
6550 Boussinesq model for R:
6551     Traceless(R) = 2 * emu * Traceless(S)
6552 where S = (gU + gUt) / 2
6553     R - R_ii/3 = 2 * emu * (S - S_ii/3)
6554     R = 2 * emu * (S - S_ii/3) + R_ii/3
6555     = 2 * emu * ((gU + gUt)/2 - gU_ii/3) + R_ii/3
6556     = emu * gU + emu * (gUt - 2/3*gUt_ii) + R_ii/3
6557     = emu * gU + emu * dev(gUt,2) - 2/3*rho*k*I
6558 Viscous and Reynolds stress together:
6559     V + R = {mu * gU} + {emu * gU + emu * dev(gUt,2) - 2/3*rho*k*I}
6560     = (mu + emu) * gU + emu * dev(gUt,2) - 2/3*rho*k*I
6561     = ( eff_mu ) * gU + emu * dev(gUt,2) - 2/3*rho*k*I
6562 Volume integrated V+R i.e force:
6563     div(V + R) = div(emu * gU) + div(emu * dev(gUt,2)) - div(2/3*rho*k*I)
6564                 Implicit      Explicit      Absorbed in pressure
6565                 p_m = p + 2/3*k*rho
6566 Final RANS equation after substituting div(V+R):
6567     d(rho*U)/dt + div(rho*UU) = -grad(P) + div(V + R)
6568     d(rho*U)/dt + div(rho*UU) = -grad(P_m) + div(emu * gU) + div(emu * dev(gUt,2))
6569 Since the k term is absorbed into the pressure gradient, we only need models for
6570 turbulent diffusivity emu.
6571
6572 Base turbulence model:
6573     This default class has no turbulence model so it is a laminar solver.
6574     Only the viscous stress V is added to the NS equations. Turbulence models
6575     derived from this class add a model for Reynold's stress R usually by solving
6576     some turbulence transport equations.

6850 \verbatim
6851 References:
6852     Book by Pope pg. 369
6853 Description:
6854 Velocity and time scales are modelled as:
6855      $l^* = lm$ 
6856      $u^* = lm * |S|$ 
6857      $eddy\_nu = u^*l^*$ 
6858             =  $(lm^2) * |S|$ 
6859     Generalization of the mixing length model for 3D flows:
6860     by Smagorinsky (1963).
6861      $eddy\_nu = (lm^2) * \sqrt{2 * (S \& S)}$ 
6862     by Baldwin & Lomax (1978)
6863      $eddy\_nu = (lm^2) * \sqrt{2 * (O \& O)}$ 
6864 The turbulent kinetic energy k can be approximated by equating turbulent
6865 viscosity eddy_nu with the one from Prandtl/Smagorinsky one equation models.

```

```

6866     u* = C * k^1/2
6867     eddy_nu = C * k^1/2 * lm
6868     Equating with the above eqn yields
6869     k = (lm / C)^2 * (2 * (S & S))
6870
6871     For high-Re flows, the mixing length close to the wall is set :
6872     lm = kappa * y_wall
6873     Thus for Smagorsky LES model
6874     lm = min(Cs * Delta, kappa * y_wall)

Curriculum Vitae

Name: Daniel Abdi

Post-Secondary Education and Degrees: Addis Ababa University, Addis Ababa, Ethiopia
1998 - 2003 B.Sc

Indian Institute of Technology, India, Roorkee
2004 - 2006 M.Tech.

Florida International University, Miami , FL
2009 - 2012

University of Western Ontario, London, ON
2012 - 2013 Ph.D.

Honours and Awards: Chi Epsilon
2010-2012

Related Work Experience: Research Assistant at Florida International University
2009 - 2012

Reasearch Assistant at The University of Western Ontario
2012 - 2013

Publications:
