Abstract

Neoplasm history increases morbidity and mortality after solid organ transplantation and has disqualified patients from transplantation. Studies are needed to identify factors to be considered when deciding on the suitability of a patient with previous tumor for heart transplantation. A retrospective epidemiological study was conducted in heart transplant (HT) recipients (Spanish Post-Heart Transplant Tumor Registry) comparing the epidemiological data, immuno-suppressive treatments and incidence of post-HT tumors between patients with previous malignant noncardiac tumor and with no previous tumor (NPT). The impact of previous tumor (PT) on overall survival (OS) was also assessed. A total of 4561 patients, 77 PT and 4484 NPT, were evaluated. The NPT group had a higher proportion of men than the PT group ($p < 0.001$). The incidence of post-HT tumors was 1.8 times greater in the PT group (95% confidence interval [CI] 1.2–2.6; $p < 0.001$), mainly due to the increased risk in patients with a previous hematologic tumor (rate ratio 2.3, 95% CI 1.3–4.0, $p < 0.004$). OS during the 10-year posttransplant period was significantly lower in the PT than the NPT group ($p = 0.048$) but similar when the analysis was conducted after a first post-HT tumor was diagnosed. In conclusion, a history of PT increases the incidence of post-HT tumors and should be taken into account when considering a patient for HT.

Abbreviations: ATG, antithymocyte globulin; AZA, azathioprine; CIC, chemotherapy-induced cardiomyopathy; CI, confidence interval; CsA, cyclosporine A; HR, hazard ratio; HT, heart transplant; MMF, mycophenolate mofetyl; MPS, mycophenolate sodium; mTOR, mammalian target of rapamycin; NPT, no previous tumor; OKT3, Orthoclone OKT3; OS, overall survival; PT, previous tumor; RR, rate ratio; SPHTTR, Spanish Post-Heart Transplant Tumor Registry; TAC, tacrolimus

Introduction

Neoplasm history classically has been considered a condition that increases posttransplant morbidity and mortality because of recurrence of the pretransplant malignancy or occurrence of a new one and has disqualified patients from transplantation. The frequent occurrence of neoplasm in these patients is probably favored by the effect of the immunosuppressive treatment used [1, 2] as well as the individual predisposition of the patient that contributed to the original neoplasm.

Organ transplant recipients are at increased risk of malignancies, especially certain types, compared with the general population [3-5]. In the case of heart transplant (HT), the incidence of post-HT neoplasm is higher than among recipients of other organs and is a strong limitation of long-term survival [3, 6]. Previous neoplasms seem to increase the already high risk of post-HT tumors; however, successful cases of HT in patients with previous malignancies have been reported since the 1990s [7].

In liver transplantation for hepatoblastoma, several tumor-related variables have been identified that have an impact on recurrence of the tumor in the transplanted organ [8], and the success of liver transplantation for hepatocellular carcinoma has been shown to depend on careful patient selection on the basis of the Milan criteria (patients with a single tumor ≤ 5 cm or no more than three tumors, each no larger than 3 cm) [9-11]. The consideration of certain cancer-associated factors in patients with previous tumors have also been recommended for the indication of renal transplantation [12]. In a similar fashion, recommendations for the selection of HT candidates have been stated with regard to cancer [13]. The transplant recipient is assessed to rule out any current neoplasm, and when a history of neoplasm exists,

transplantation is considered only once the cancer-free interval meets the length of time for the cancer to be considered cured, usually 5 years [13-15].

Further studies are needed to determine other putative factors that may influence the post-HT recurrence of a previous tumor and the occurrence of new tumors after HT in patients with pre-HT history of malignancy. A comparison of the aforementioned patients with HT patients who had no previous tumor (NPT) might help identify these factors as well as characterize the patients. To know more about these patients to make more precise informed decisions when indicating HT, a study in patients from the Spanish Post-Heart Transplant Tumor Registry (SPHTTR) was conducted to compare HT recipients who had a previous history of neoplasm with those who had no previous history.

Materials and Methods

A historical cohort study was conducted in HT recipients included in the SPHTTR from 1984 to December 31, 2010. The SPHTTR continually updates data on tumors for every patient undergoing HT at age ≥ 16 years in Spain since 1984, when HT was initiated in that country. The SPHTTR is a standardized database that includes 175 clinical variables with data on recipients, donors, surgery, immunosuppression and follow-up [16]. The use of a similar database by all Spanish transplant teams confers high reliability for the results [16]. This registry is one of the largest national heart transplant registries and contributes to other larger international registries, such as the International Registry for Heart and Lung Transplantation [17]. In addition, it probably has one of the largest samples of HT patients with previous tumors.

The main objective of the study was to describe the profile of the HT recipients with a history of previous neoplasia and to compare their epidemiological data (age and sex), baseline and subsequent immunosuppression, and the incidence of post-HT tumors with the rest of the HT population in Spain with NPT. In addition, the possible impact of previous tumor (PT) history on overall survival (OS) compared with the OS of patients with NPT was evaluated.

Patients included in the study should have survived >3 mo after transplantation. For the PT group, patients with previous nonmalignant tumors were excluded from the analysis, as were those with cardiac angiosarcoma because patients with this type of tumor are no longer transplanted due to the high recurrence rate [18]. In addition, retransplanted patients were excluded because retransplantation is a significant risk factor for cancer [19].

The types of pre-HT tumors were described for the PT group, and the types of post-HT tumors were described for both groups. Localization and histology were considered for the classification of tumor types: solid tumor (e.g. breast, prostate, colon, stomach, kidney, bladder, and lung carcinoma), melanoma, hematologic tumor (multiple myeloma, Hodgkin lymphoma, non-Hodgkin lymphoma, leukemia), nonmelanocytic skin tumor (e.g. epidermoid and basocellular carcinoma) and Kaposi sarcoma.

The research protocol was approved by the institutional review board of the University 12 de Octubre Hospital (Madrid, Spain; number 13/267), and the study was conducted according to Spanish regulations.

The retrospective design of the study made it difficult to locate patients (some of them already dead), and because the patients were codified in the registry (maintaining their anonymity), informed consents were not required to conduct the study. Patients gave their consent to have their data included in the registry database.

Statistical analysis

Categorical variables were described by means of absolute and relative frequency tables, whereas continuous variables were described by central and dispersion measurements. The Pearson Chi-square test was used to compare the distribution of the categorical variables between the PT and NPT groups.

The incidence rate of post-HT tumor and the mortality rate per 1000 person-years were assessed for each group as well as the ratios between rates (rate ratio [RR]). OS during the first 10 years after transplant was estimated by Kaplan-Meier curves for the PT and NPT groups, and the two curves were compared with the log-rank test. December 31, 2010, was considered the end of follow-up. All statistical calculations were performed using Stata version 10.1 for Windows (StataCorp, College Station, TX).

Results

At the time of the study, the SPHTTR contained records for 5672 patients who had undergone HT in Spain at age ≥ 16 years between 1984 and the end of 2010. Of these, 1025 died within 3 mo of HT, and 86 met other exclusion criteria (Figure 1). Consequently, 4561 patients, 77 (1.7%) with PT (malignant noncardiac neoplasia) and 4484 (98.3%) with NPT, were included in this analysis.

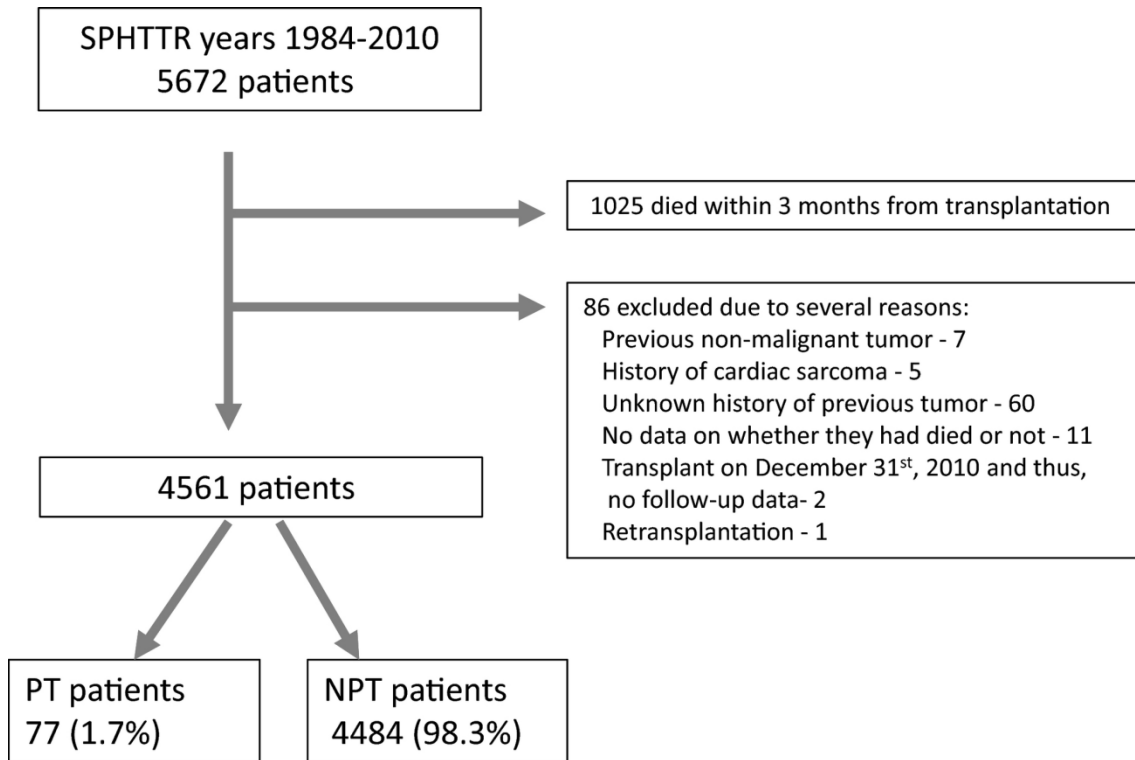

Figure 1. Patient disposition flow chart. NPT, no previous tumor; PT, previous tumor; SPHTTR, Spanish Post-Heart Transplant Tumor Registry.

The sociodemographic and clinical characteristics of the patients are shown in Table 1. There were significantly more men in the NPT group than in the PT group (84% vs. 62%; $p < 0.001$), but age distribution was similar in both groups ($p = 0.459$). Every patient with a previous tumor had been considered cured by the multidisciplinary transplantation medical team, with a mean time since cancer diagnosis to the transplant of 8.3 years. In the PT group, 64% of previous tumors were solid tumors, 31% were hematologic and 5% were melanomas. Regarding tumor stage, 84.4% were localized tumors, and cancer spread in 12 patients (7 hematologic neoplasia and 5 solid tumors with local extension but no further dissemination).

Immunosuppressive treatment

The most frequent immunosuppressive drugs used in both groups were prednisone (in almost every patient) and cyclosporine A (CsA; $\geq 74\%$) (Figure 2), which were administered mainly during the first 3 mo after HT and decreased gradually thereafter. Azathioprine (AZA) also decreased with time but seemed to be used in a larger proportion of NPT than PT patients. Mycophenolate mofetyl (MMF) decreased with time only in the PT group; use stayed at similar proportions in the NPT group. Tacrolimus (TAC) stayed in similar levels up to 2 years and seemed to be used in a higher proportion of PT than NPT patients. Muromonab CD3 (Orthoclone OKT3 [OKT3]; Janssen Biotech, Horsham, PA), antithymocyte globulin (ATG), thymoglobulin and IL-2R blockers (basiliximab and daclizumab) were typically used only during the first 3 mo after HT because they are used mostly as induction therapy. A significantly ($p \leq 0.0001$) larger proportion of PT patients received induction compared with NPT patients (80.5% vs. 71.8%, respectively) (Table 1). In contrast, sirolimus and everolimus were typically used after 3 mo, even more after 2 years, with everolimus used in higher proportions of PT than NPT patients. Globally, a higher percentage of PT than NPT patients seemed to use TAC, MMF, everolimus, basiliximab and daclizumab, whereas a higher percentage of NPT than PT patients seemed to use AZA, OKT3 and thymoglobulin (Figure 2).

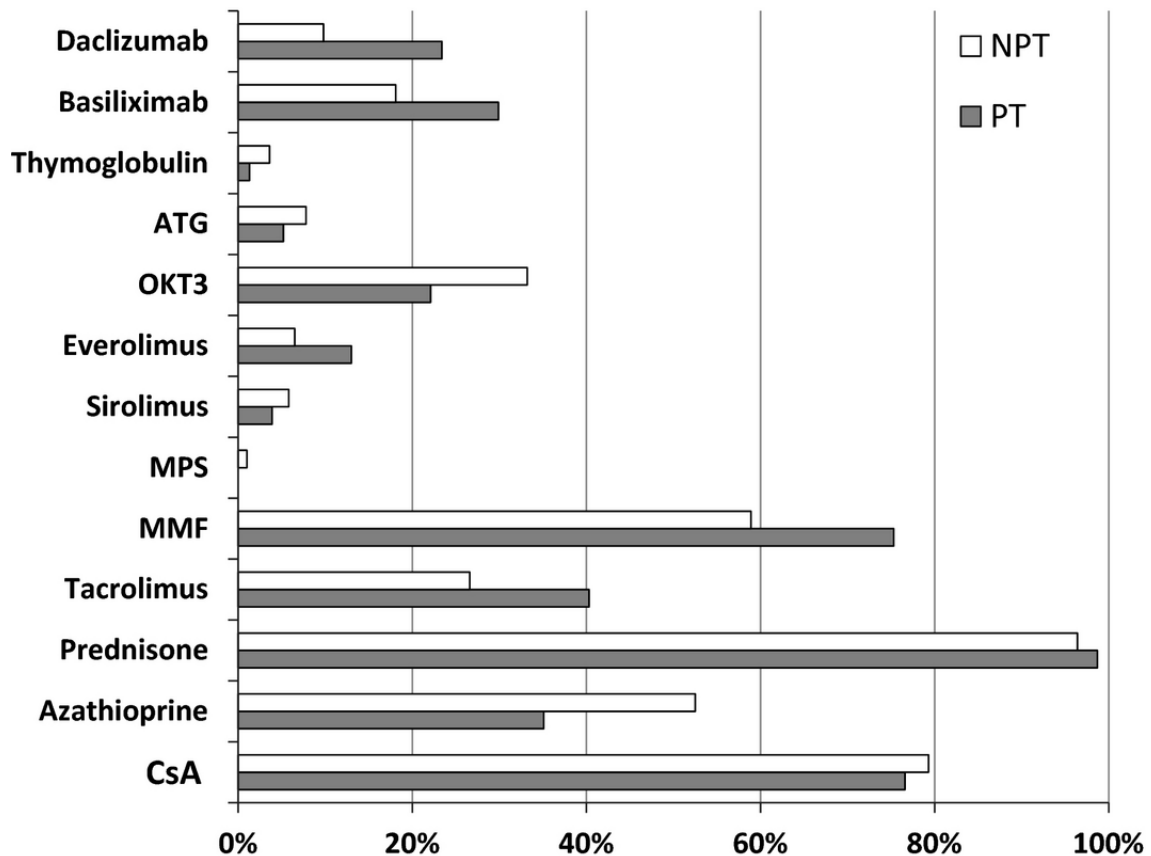

Figure 2. Immunosuppressive treatments. ATG, antithymocyte globulin; CsA, cyclosporine A; MMF, mycophenolate mofetil; MPS, mycophenolate sodium; NPT, no previous tumor; OKT3, Orthoclone OKT3; PT, previous tumor.

Incidence of posttransplant tumors

In the post-HT period, 1281 tumors developed in 914 patients (30 tumors in 25 PT patients and 1251 tumors in 889 NPT patients). The different types of tumors developed are shown in Table 2. The incidence of post-HT tumors was greater in the PT group than in the NPT group (RR 1.8, 95% confidence interval [CI] 1.2–2.6, $p < 0.001$) because of an excess risk among patients with a pre-HT hematologic tumor (RR 2.3, 95% CI 1.3–4.0, $p = 0.04$) (Table 3). When excluding the four cases considered as relapsing malignancies (one hematologic neoplasia and three solid tumors), the incidence of post-HT tumors was still greater in the PT than the NPT group (RR 1.6, 95% CI 1.1–2.4, $p = 0.016$) (Table 3).

^d NPT versus PT adjusted by time period.

^e The p-value is from the chi-square test; p-values in bold are significant.

^f Adjusted RRs are calculated with the Mantel-Haenszel method.

Chemotherapy-associated cardiomyopathy and posttransplant tumors

Overall, 18 of the 77 patients with PT required HT because of chemotherapy-induced cardiomyopathy (CIC). No significant differences in the incidence rate or in the types of post-HT tumors were shown between those patients with CIC and those requiring HT due to other cardiopathies (RR 1.53, 95% CI 0.62–3.74, $p = 0.348$) (Table 1).

Induction therapy and posttransplant tumors

Patients receiving induction had greater incidence of post-HT tumors than those not receiving induction (RR 1.98, 95% CI 1.71–2.28, $p \leq 0.0001$) because of excess risk in patients receiving classic induction (OKT3, ATG and thymoglobulin; RR 2.20, 95% CI 1.91–2.55, $p \leq 0.0001$) (Table 4). This finding was the same when looking exclusively at patients with NPT. In the PT group, it seemed there was no difference in the incidence of post-HT tumors whether or not patients received induction, but this is probably due to the small sample size.

Table 4. Incidence rates of post-HT tumors in patients submitted or not to induction treatment

ATG, antithymocyte globulin; CI, confidence interval; HT, heart transplant; OKT3, Orthoclone OKT3; RR, rate ratio.

^a Incidence rate per 1000 person-years.

^b RR with respect to no induction.

^c The p-value is from the chi-square test.

When the incidence rates of post-HT tumors were adjusted by induction, PT patients receiving induction showed an RR of 1.9 more risk of post-HT tumors than NPT patients receiving induction (95% CI 1.3–2.7, $p < 0.01$) (Table 3).

Time period and posttransplant tumors

The incidence rate of post-HT tumors was 32.77% (95% CI 29.09–36.90) when transplantation was performed between 1984 and 1992, 39.52% (95% CI 36.93–42.30) between 1993 and 2001, and 22.99% (95% CI 19.84–26.65) between during 2002 and 2010.

When post-HT tumor incidence rates were adjusted by time period, PT patients had a risk of post-HT tumors that was 1.8 times greater than that of NPT patients (95% CI 1.3–2.6; $p = 0.001$) (Table 3).

Posttransplant mortality and OS

No significant differences were observed in post-HT mortality incidence rates or hazard ratios (HRs) between the groups (Tables 3 and 5). Women had significantly lower mortality risk than men, and mortality decreased significantly in more recent periods (Table 5). Mortality HRs were adjusted by sex and time period, but again, no significant differences were observed between the PT and NPT groups (Table 5).

Table 5. Mortality by Cox regression analysis

	HR	95% CI	p-value
Pre-HT tumor			
No	1

CI, confidence interval; HR, hazard ratio; HT, heart transplant.

^a Adjusted by sex and period year.

OS during the 10-year posttransplant period was significantly greater in the NPT than the PT group ($p = 0.048$) (Figure 3A), showing the following survival data for NPT and PT groups, respectively: 93% and 95% at 1 year, 79% and 74% at 5 years, and 65% and 51% at 10 years. When the survival analysis was performed after the diagnosis of the first post-HT tumor (Figure 3B), no significant survival differences were observed between the groups.

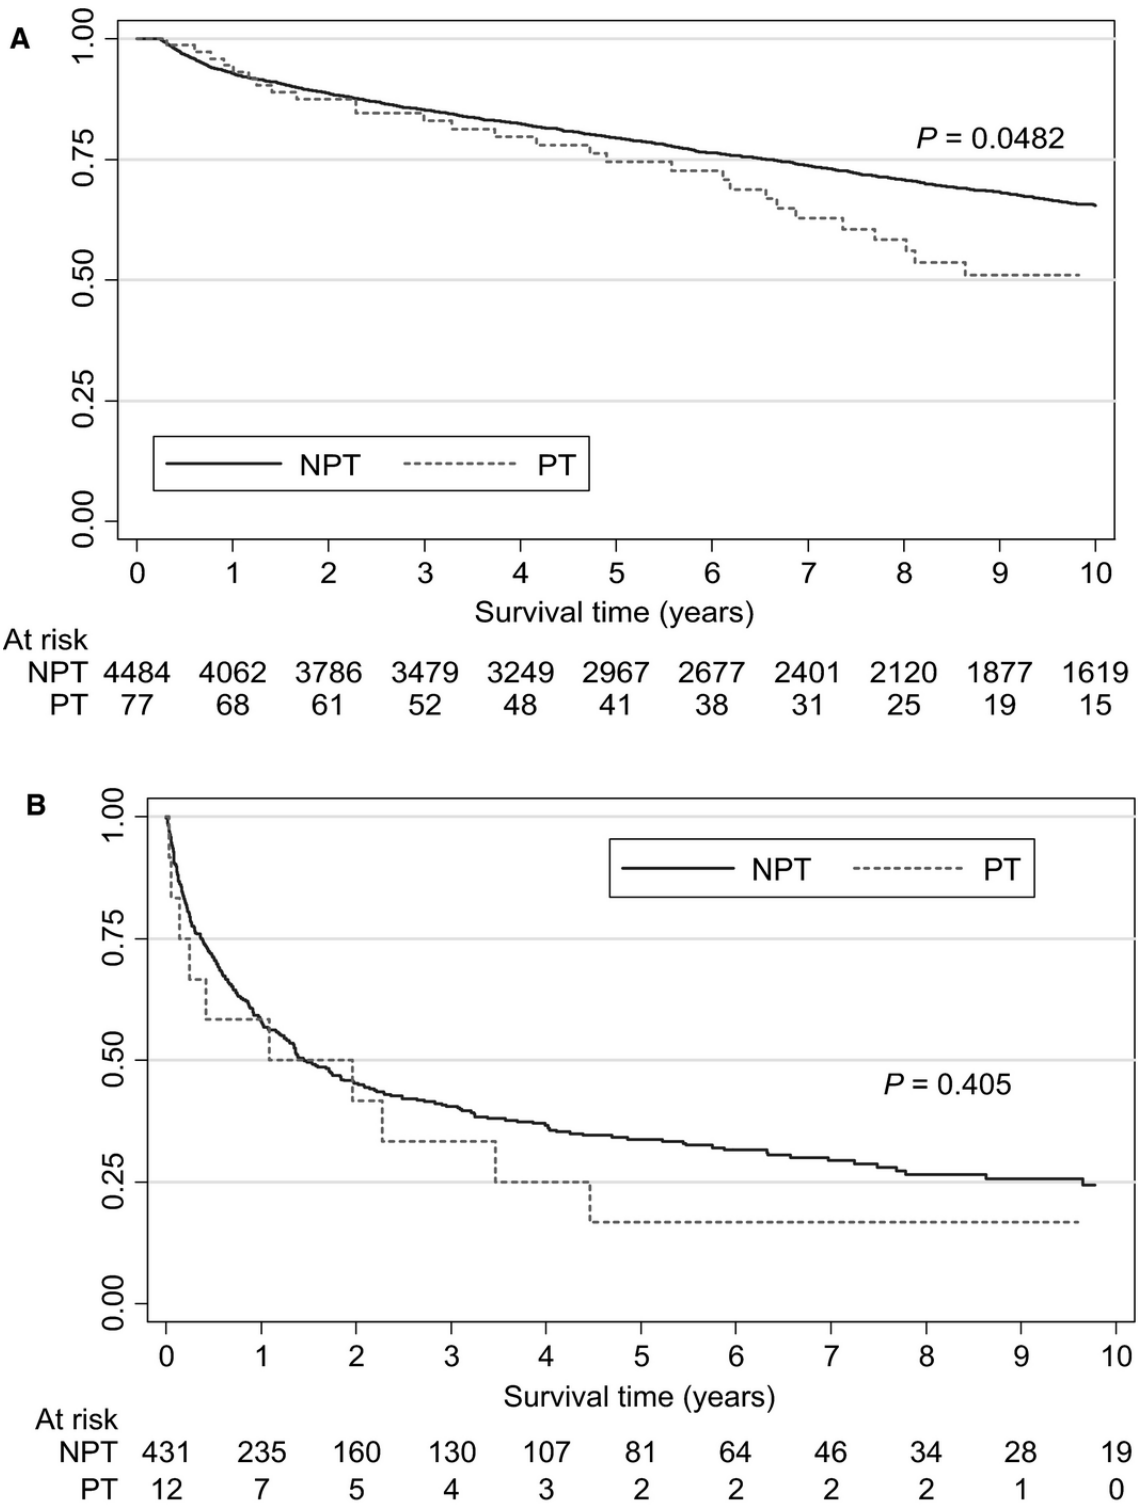

Figure 3. Kaplan-Meier survival curves for patients with PT and NPT. (A) Starting right after transplantation. (B) Starting at the time of first post-heart transplant diagnosed tumor. NPT, no previous tumor; PT, previous tumor.

Table 6 shows the causes of mortality in both groups. Cancer-related death was 21.3% and 32.2% in the NPT and PT groups, respectively.

NPT, no previous tumor; PT, previous tumor.

Discussion

The current study shows that the tumor incidence rate in post-HT patients with PT history was almost double that of post-HT patients with NPT history (RR 1.8, $p \leq 0.001$), in agreement with previous studies showing higher incidence of *de novo* tumors in posttransplant patients with PT history [20, 21]. In the study by Higgins et al conducted in 6211 U.S. HT recipients, of whom 283 had pretransplant malignancies, a multivariate analysis showed that previous history of cancer had a relative risk of 1.6 ($p = 0.02$) for posttransplant tumors, although older age and earlier date of transplant were the two most significant risk factors. In agreement with these data, our study showed that post-HT tumor incidence rates were higher at earlier dates of transplant compared with more recent dates.

It is important to note that in the current study, the tumor incidence rates in the group with previous solid tumors and in the NPT group were similar, and it was only that of the group with previous hematologic tumors that was significantly larger compared with the rate in the NPT group (RR 2.3, $p \leq 0.004$). Some tumors, including hematologic tumors, are prone to genomic instability, namely, an increased tendency of tumor cells to acquire new mutations with each cell division [22, 23]. In addition, leukemia cells have been shown to release fragmented DNA derived from their genome, which may enter the nuclei of other cells and induce double-strand breaks or integrate into the chromosomal DNA, promoting genome instability of these cells [24]. All of these aspects might help explain the greater incidence of post-HT tumors in patients with such a history of cancer. In agreement with this theory, Brattstrom et al showed that the type of previous malignancy had a great impact on cancer recurrence and mortality, with hematologic cancer showing the greater overall and cancer-specific mortality among the different pretransplant cancer types [25].

The incidence rates of tumors in the NPT group (34.2 per 1000 person-years) and the PT group (61.2 per 1000 person-years) were much higher than the rate estimated by Globocan 2008 for the overall

Spanish population (4.4 per 1000 person-years for all cancers, excluding nonmelanoma skin cancer) [26], as expected for patients submitted to transplantation. Skin cancer, especially nonmelanoma skin cancer, represented a major proportion of the post-HT tumors, in agreement with previous data, showing this cancer type as the most common to develop *de novo* in recipients of organ transplant overall and in recipients of HT specifically [5, 27-29]. Eleven *de novo* nonmelanocytic skin cancers arose in 77 patients with previous cancer history (14.3%), and the frequency of skin cancer in patients without a cancer history was similar at 14.9% (668 *de novo* tumors in 4484 patients). Noncutaneous solid tumors arose in 14.3% of patients with PT (three considered relapsing malignancies [two colon carcinomas, one bladder carcinoma]) and 9.3% of patients with NPT. Lung cancer was the most common one, in agreement with data from a study assessing post-HT lung cancer incidence [30] and other studies showing lung cancer as one of the most frequently developing solid tumors in HT recipients [19, 21, 31, 32]. Hematologic tumors developed in 3.9% (three of 77) of PT patients (one tumor was multiple myeloma, considered a relapsing malignancy) and 2.4% (108 of 4484) of NPT patients. One-third of the PT patients had a history of hematologic tumors, and such tumors are likely to recur [25]. Still, the frequency of recurrence was low (5.2% or 4% in 77 patients), as observed by Higgins et al [21]. The proportion of post-HT multiple myeloma was higher in the PT than the NPT group (2.6% vs. 0.1%, respectively), although the latter group had a higher proportion of men, and multiple myeloma is known to be more common in men than in women [33].

Immunosuppressive treatments affect the cancer risk of transplanted patients [29]. Drugs used for induction, other than IL-2R blockers, have been shown to increase the risk of neoplasia [34-36]. The mammalian target of rapamycin (mTOR) inhibitors sirolimus and everolimus are known to show anticancer effects in HT recipients and other solid organ recipients [37-39]. The use of induction therapy has increased in recent years, and the drugs used have changed from mainly OKT3 and ATG to daclizumab and, especially, basiliximab [16]. In addition, mTOR inhibitors have been available only recently [37-39]. The immunosuppressive regimen used in HT in Spain has evolved from OKT3 induction and maintenance with CsA, AZA and steroids to basiliximab induction and maintenance with CsA/TAC, MMF and steroids [40]. According to the changes in immunosuppressive drugs used, patients transplanted more recently showed significantly lower posttransplant tumor rates. In addition, patients receiving induction therapy showed increased post-HT tumor rates over those with no induction, due to the increased rate in the group induced by classic induction drugs (OKT3, ATG, and thymoglobulin). No such effect was observed when induction was performed with the IL-2R blockers basiliximab or daclizumab. Because most patients with previous tumors were transplanted recently (this type of patient has been considered for HT only recently), immunosuppressive treatments differed between them and patients with NPT. When incidence rates were adjusted by time period or by induction, the PT group still showed a post-HT tumor rate almost twofold greater than the NPT group. The use of antineoplastic treatments in PT patients prior to HT might also influence the incidence of post-HT treatment; however, when patients who were transplanted due to chemotherapy-induced cardiomyopathy were compared with those transplanted for other indications, no significant differences in post-HT tumor incidence rates were observed.

OS was significantly better in the NPT than the PT group during the first 10-year posttransplant period, a difference that started being noticeable only by the fifth or sixth year. The similar survival data between the groups during the first 4–5 years after transplant seem to agree with a previous study conducted in Spain that showed similar actuarial survival at 1, 3, and 5 years in the PT and NPT groups [41]. In the study by Higgins et al [21], the percentage of patients free from malignancy, which was significantly lower in the PT group compared with the NPT group in the 15-year posttransplant period, did not start to show noticeable differences between groups until the fifth or sixth year. Consequently, the appearance of a survival difference between our two groups of patients only 5 years after transplant might reflect the different timing of occurrence of the first posttransplant tumors, which seem to occur earlier in the PT than the NPT group. In fact, when OS was estimated after the first tumors were diagnosed, no differences in survival were observed between the PT and NPT groups, further suggesting that the differences observed in survival from the fifth to the 10th year after transplant reflect an earlier appearance of tumors in the patients with a history of cancer.

The mortality HR or instantaneous risk of dying was not significantly different between the PT and NPT groups (adjusted for sex and time period, HR 1.41 [95% CI 0.98-2.04, $p = 0.068$, Table 5). The study by Brattstrom et al [25] conducted in a Swedish population-based cohort of 10 448 solid organ recipients, of whom 416 (4%) had a prior malignancy, showed an 80% increase in overall mortality (adjusted for sex, age and time period, HR 1.8 [95% CI 1.3–2.5]) among nonkidney recipients (including HT recipients) with cancer history, compared with those without such history, driven by cancer-specific death. Brattstrom et al showed that the type of previous malignancy and the waiting time between cancer remission and transplantation had a great impact on relapses and mortality. Every PT patient in our study

had been considered cured at the time of transplantation, with a mean interval of 8.3 years from diagnosis to transplant, and in fact, relapses were very uncommon. When HT started to be performed in patients with a history of tumors, the average cancer-free interval before transplantation was almost 10 years [42]; however, the current arbitrary threshold value for considering cancer cured is 5 years, although it depends on the cancer type [13, 43]. In the study by Bratstrom et al, 45% of patients had a waiting time ≤ 5 years, and those patients, as well as those with a waiting time >10 years (29%), had significantly higher cancer-related mortality than patients with a waiting time of 5–10 years [25]. This high percentage of patients with <5 years of waiting time might explain the increased mortality observed in the PT patients from the study by Bratstrom et al; this did not show in our PT patients.

A limitation of the current study might be the different sizes of the PT and NPT groups; however, the analyses were initially performed simply, with no adjustments, minimizing the possible problems that this difference might represent. Another limitation of the study is that although both groups were homogeneous in age, they differed in proportions of men and women, time period of transplantation and use of induction; however, the analyses were adjusted by sex, time period and induction, and results similar to the initial analyses were obtained.

In conclusion, after adjusting the analyses by different variables, HT patients with previous malignant noncardiac tumors, specifically those with previous hematologic tumors, showed higher post-HT tumor incidence than those with NPT and worse OS over a 10-year period, most likely due to earlier occurrence of posttransplant tumors in patients with PT. Consequently, patients with a history of previous noncardiac tumor should be carefully considered for HT. In addition, when transplantation is carried out in such patients, they should be followed more carefully, with increasing surveillance for arising tumors during at least the first 5 years after transplant.

Acknowledgments

We are grateful to the researchers and staff of all the Spanish heart transplant centers that contributed data to this study and Odds for helping with study coordination. This study was partially supported by an unrestricted grant from Novartis and by the Spanish cardiovascular networks RIC (Instituto de Salud Carlos III, Ministerio de Economía y Competitividad). Other investigators involved in maintaining the Spanish Post-Heart Transplant Tumour Registry are as follows: Manuel Gómez Bueno, Javier Segovia Cubero, and Inés Sayago Silva (Hospital Universitario Puerta de Hierro, Madrid); Vicens Brossa, Eulàlia Roig, and Laura López (Hospital Santa Creu i Sant Pau, Barcelona); Luis Martínez, Ignacio Sánchez-Lázaro, Mónica Cebrián, and Elena Marqués (Hospital Universitari i Politècnic La Fe, Valencia); María Ángeles Castel (Hospital Clínic i Provincial de Barcelona); María Jesús Paniagua Martín, Raquel Marzoa Rivas, and Eduardo Barge Caballero (Hospital Universitario A Coruña, La Coruña); José Antonio Vázquez de Prada (Hospital Universitario Marqués de Valdecilla, Santander); Iago Sousa, Adolfo Villa Arranz, and Juan Fernández-Yáñez (Hospital General Universitario Gregorio Marañón, Madrid); Marisa Sanz Julve and Ana Portoles Ocampo (Hospital Universitario Miguel Servet, Zaragoza); Miguel Angel Gómez, Pilar Escribano, and María José Ruiz Cano (Hospital Universitario 12 de Octubre, Madrid); Nicolás Manito Lorite and Josep Roca (Hospital Universitari de Bellvitge, Barcelona); Amada Recio Platero (Hospital Clínico Universitario de Valladolid); Montserrat Lorente (Clínica Universidad de Navarra, Pamplona); J. Manuel Sobrino Márquez and Diego Rangel Sousa (Hospital Universitario Virgen del Rocío, Sevilla); Iris Garrido Bravo (Hospital Universitario Virgen de la Arrixaca, Murcia); José Luis Lambert Rodríguez (Hospital Universitario Central de Asturias); Amador López Granados, Carmen Segura Saint-Gerons, and Juan Carlos Castillo Domínguez (Hospital Universitario Reina Sofía, Córdoba).
