

# Increased Incidence of Vestibular Disorders in Patients With SARS-CoV-2

Lawrance Lee,<sup>1</sup> Evan French,<sup>2</sup> Daniel H. Coelho,<sup>1</sup> and Nauman F. Manzoor,<sup>1</sup> on behalf of the N3C consortium.

**Objective:** Determine the incidence of vestibular disorders in patients with SARS-CoV-2 compared to the control population.

**Study Design:** Retrospective.

**Setting:** Clinical data in the National COVID Cohort Collaborative database (N3C).

**Methods:** Deidentified patient data from the National COVID Cohort Collaborative database (N3C) were queried based on variant peak prevalence (untyped, alpha, delta, omicron 21K, and omicron 23A) from covariants.org to retrospectively analyze the incidence of vestibular disorders in patients with SARS-CoV-2 compared to control population, consisting of patients without documented evidence of COVID infection during the same period.

**Results:** Patients testing positive for COVID-19 were significantly more likely to have a vestibular disorder compared to the control population. Compared to control patients, the odds ratio of vestibular disorders was significantly elevated in patients with untyped (odds ratio [OR], 2.39; confidence intervals [CI], 2.29–2.50;  $P < 0.001$ ), alpha (OR, 3.63; CI, 3.48–3.78;  $P < 0.001$ ), delta (OR, 3.03; CI, 2.94–3.12;  $P < 0.001$ ), omicron 21K variant (OR, 2.97; CI, 2.90–3.04;  $P < 0.001$ ), and omicron 23A variant (OR, 8.80; CI, 8.35–9.27;  $P < 0.001$ ).

**Conclusions:** The incidence of vestibular disorders differed between COVID-19 variants and was significantly elevated in COVID-19-positive patients compared to the control population. These findings have implications for patient counseling and further research is needed to discern the long-term effects of these findings.

**Key Words:** COVID-19—Dizziness—SARS-CoV-2—Vestibular disorder.

SARS-CoV-2 is a novel betacoronavirus that causes the clinical syndrome termed COVID-19, which caused a global pandemic leading to 7 million deaths worldwide. Many of the disease's effects and complications have now been extensively studied and documented in the literature (1–3).

Within the field of otolaryngology, the most common sequelae associated with COVID-19 are chemosensory deficits (ie, smell and taste), with prevalence as high as 47.4% (4). Contributing authors to our current study have also investigated the prevalence of chemosensory deficits associated with COVID-19, demonstrating differences in the rate of chemosensory dysfunction between COVID-19 variants (5).

However, other head and neck symptoms related to COVID-19, particularly of the cochleovestibular system, also necessitate our attention, as up to 58% of patients affected by COVID-19

reported vestibular symptoms and 9% reported auditory symptoms upon initial diagnosis (6). These symptoms have also been found to affect women disproportionately (7). Jeong et al have demonstrated a mechanism of viral entry into the cells of the cochleovestibular end organs via the angiotensin-converting enzyme 2 receptor pathway, providing further insight into the impact it has on hearing loss, tinnitus, and vertigo (8–10).

In this study, we investigated the incidence of vestibular and balance disorders associated with COVID-19 variants and compared it to the general population within the same timeframe using data from a large multi-institutional database.

## MATERIALS AND METHODS

Data from the National Center for Advancing Translational Sciences National COVID Cohort Collaborative (N3C) (11) were utilized for analysis of this study. To compare the impact that variants have on vestibular symptoms, the “peak period” for each variant was determined using covariants.org (12). The “peak period” for each variant (initial/untyped, alpha, delta, omicron 21K, omicron 23A) was defined as the 12 weeks with the highest prevalence of that particular variant in the United States. The peak period date ranges for initial/untyped variant ranged from July 6, 2020 to September 28, 2020, alpha variant from March 22, 2021 to June 14, 2021, delta variant from August 9, 2021 to November 1, 2021, omicron 21K variant from December 27, 2021 to March 21, 2022, and omicron 23A variant from February 3, 2023 to March 28, 2023. The N3C database was queried for patients with positive COVID-19 tests within each variant peak and a vestibular disorder diagnosis occurring within 2 weeks of the test date. Patients with no documented history of COVID-19 were used as the control population for each wave. Because this group represents the general population, each control patient is included in the control population for every wave where their corresponding institution had contributed data at least through the

end of the outcomes period. The diagnosis of a vestibular disorder diagnosis was defined by SNOMED code 271789005, which is equivalent to R42 dizziness and giddiness diagnosis code (ICD-10). Relative rates of vestibular disorders were calculated using patients without a recorded COVID diagnosis by querying for unique patients with vestibular disorder diagnosis codes during a 4-week period in the middle of each 12-week variant period. Statistical analysis between groups was performed by odds ratio (OR) calculations (95% confidence interval [CI]) and log odds significance testing using MedCalc (13). This study was conducted under data use request RP-64CD77 and approved by VCU IRB HM20022747. Authorship was determined using ICMJE recommendations.

## RESULTS

Demographic data is displayed in Table 1. The total number of patients with COVID-19 and those with COVID-19 and vestibular disorders by variant are presented in Table 2.

### Combined Data

At the time of our analysis, 12,419,287 patients met the inclusion criteria for the time intervals of interest. Of these patients, 1,849,257 patients, or 14.89%, tested positive for COVID-19, and 19,610 of 1,849,257 patients, or 1.06%, tested positive for COVID-19 with our diagnosis of interest. The remaining 10,570,030 patients, or 85.11%, had no documented history of COVID-19 infection.

### Variant Specific Data

There were 10,828,713 patients within the initial/untyped peak period. 37,480 of 10,570,030 patients, or 0.35%, of control patients had a diagnosis of vestibular disorder, compared to 2182 of 258,683, or 0.84%, testing positive for COVID-19 with this diagnosis (OR, 2.39; CI, 2.29–2.50;  $P < 0.001$ ).

A total of 10,740,764 patients were included within the peak period of the alpha variant. 39,883 of 10,570,030 patients, or

0.38%, of control patients had a diagnosis of vestibular disorder, compared to 2314 of 170,734, or 1.36%, testing positive for COVID-19 with this diagnosis (OR, 3.63; CI, 3.48–3.78;  $P < 0.001$ ).

Within the peak period of the delta variant, there were 10,195,690 patients. 35,443 of 9,768,954 patients, or 0.36%, of control patients had a diagnosis of vestibular disorder, compared to 4656 of 426,736, or 1.09%, testing positive for COVID-19 with this diagnosis (OR, 3.03; CI, 2.94–3.12;  $P < 0.001$ ).

A total of 10,619,977 patients were included within the peak period of the omicron 21K variant. 31,269 of 9,683,469 patients, or 0.32%, of control patients had a diagnosis of vestibular disorder, compared to 8928 of 936,508, or 0.95%, testing positive for COVID-19 with this diagnosis (OR, 2.97; CI, 2.90–3.04;  $P < 0.001$ ).

Lastly, 8,674,093 patients were included within the peak period of the omicron 23A variant. 27,127 of 8,617,497 patients, or 0.31%, of control patients had a diagnosis of vestibular disorder, compared to 1530 of 56,596, or 2.70%, testing positive for COVID-19 with this diagnosis (OR, 8.80; CI, 8.35–9.27;  $P < 0.001$ ).

### Intervariant Risk Comparison

As demonstrated previously, patients testing positive for COVID-19 are often 2 to 3 times more likely to develop symptoms of vestibular dysfunction. However, the incidence of vestibular disorders between variants can vary significantly as well. Table 3 illustrates the likelihood of developing vestibular disorders between each variant wave, with the data suggesting that individuals testing positive for the omicron 23A variant are at highest likelihood of vestibular disorder, being 8.80 times greater than the general population, as previously noted, but also being 2.02–3.27 times more likely compared to other variants. On the other hand, patients with the untyped variant appear to be at the lowest risk of developing vestibular symptoms, being 2.39 times more likely than the general population, but at 0.31 the rate compared to individuals affected by the omicron 23A variant.

**TABLE 1.**

**Demographics of patients with COVID-19 and vestibular disorder, by variant**

	Initial/untyped	Alpha	Delta	Omicron 21K	Omicron 23A
Age (SD)	51.7 (18.9)	51.9 (17.8)	52.2 (18.7)	53 (19.3)	61.5 (19.3)

**DISCUSSION**

The data we present demonstrate that individuals testing positive for COVID-19 are over twice as likely to develop vestibular symptoms compared to the general population. Although our data estimates the overall prevalence of vestibular disorder amongst these patients at between 1% and 3%, other studies have estimated the self-reported numbers to reach as high as over 40% (7,14,15). One must also consider individuals whose vestibular symptoms remain undiagnosed, those who did not seek medical attention for their vestibular symptoms during our observation window, and those who were never tested and diagnosed with COVID-19.

Vestibular neuritis as an inflammatory process of the vestibular nerve due to acute viral infection or secondary to reactivation of latent neurotropic viruses (eg, herpes simplex virus type 1 or varicella zoster virus) are the second most common cause of vestibular dysfunction, after benign paroxysmal positioning vertigo, with an estimated incidence of 3.5 in 100,000 (16–18). Despite this, our understanding of its pathophysiology remains limited and treatment is mostly centered around symptom management and long-term therapy. Within the context of the COVID-19 pandemic, nearly 700 million individuals were infected with the virus globally with around 100 million of those individuals within the United States at the time of writing. This constitutes over 3 million people with vestibular disorder likely related to COVID-19, with at least 500,000 of those individuals residing in the United States, thus significantly increasing the incidence of vestibular dysfunction secondary to viral etiologies.

A prior study by Almishaal of 939 patients showed a statistically significant increase in subjective, self-reported incidence of audiovestibular symptoms in patients with COVID-19, but did not demonstrate significant differences between viral variants (15). However, it is difficult to assess the clinical significance of subjective, self-reported findings. We aimed to better understand the significance of vestibular symptoms by assessing patients whose symptom severity required medical evaluation. Based on our data, different variants of COVID-19 have differing impacts on the development of vestibular symptoms, with individuals affected by the omicron 23A variant being at highest risk of developing vestibular symptoms, while individuals affected by the initial untyped variant demonstrated a lower risk. It is also important to note that patients with COVID-19-related vestibular symptoms have also demonstrated a different clinical course than the general population, compensating slower compared to the general population (19). Recognizing this phenomenon and intervariant risks may raise clinicians’ suspicions of COVID-19-related vestibular disorder and better guide patient education and treatment options.

As a retrospective cross-sectional study, the biggest limitation of this study is determining the long-term implications and sequelae of vestibular disorder in patients testing positive for COVID-19. Prior studies have suggested that dizziness was one of the most common symptoms lasting greater than 4 weeks in children (20). However, the long-term manifestation and impact of vestibular dysfunction amongst adults is not well-documented in the current literature and would facilitate

physicians in understanding the clinical course of COVID-19-associated vestibular disorders and in providing appropriate patient counseling and therapies. Additionally, the diagnosis code queried for “dizziness and giddiness” is general and not specific to otolaryngologists, which may introduce differences in interpretation or misdiagnoses spanning various medical specialties. Similarly, due to the nonspecific nature of the diagnosis code, inferences regarding the vestibular dysfunction such as symptomatology, duration, or severity cannot be deduced. A final limitation is that N3C is sourced from many institutions with multiple source data models that have all been harmonized into the observational medical outcomes partnership common data model. This harmonization process can potentially introduce errors in the data.

**CONCLUSION**

Individuals afflicted with COVID-19 are more than twice as likely to develop symptoms of vestibular dysfunction compared to the general population, and the risk of developing vestibular symptoms can vary widely depending upon the variant an individual is impacted by. Continuing to follow trends of how the disease affects patients, further research on the mechanisms causing vestibular symptoms, as well as a better understanding of the long-term impacts these symptoms have on patients will provide a more robust framework for physicians to manage COVID-19-associated vestibular disorder.
