Objective Several recent intraventricular hemorrhage prevention bundles include midline head positioning to prevent potential disturbances in cerebral hemodynamics. We aimed to study the impact of head position change on regional cerebral saturations SctO₂ in preterm infants (< 30 weeks gestational age) during the first 3 days of life.

Study Design Bilateral SctO₂ was measured by near-infrared spectroscopy. The infant's head was turned sequentially to each side from midline (baseline) in 30-minute intervals while keeping the body supine. Bilateral SctO₂ before and after each position change were compared using paired *t*-test.

Results In relatively stable preterm infants (gestational age 26.5 ± 1.7 weeks, birth weight 930 ± 220 g; *n* = 20), bilateral SctO₂ remained within normal range (71.1–75.3%) when the head was turned from midline position to either side.

Conclusion Stable preterm infants tolerated brief changes in head position from midline without significant alternation in bilateral SctO₂; the impact on critically ill infants needs further evaluation.

Intraventricular hemorrhages (IVH) remain common in very preterm infants and contribute significantly to poor outcomes later in childhood.¹ A significant proportion of IVH (~50%) occurs in the first 4 days of life.² During this critical transition period, preterm infants have limited ability to autoregulate cerebral blood flow (CBF) and are at high risk for brain injury due to systemic hemodynamic instability.^{3–5} Recent evidence suggests that abnormal cardiac function and cerebral hemodynamics during early postnatal days are associated with peri- and intraventricular hemorrhages.⁵ Clinical interventions (e.g., ventilation strategies, transfusions, and pharmacological management of hypotension) profoundly affect cerebral hemodynamics (e.g., CBF, cerebral oxygenation, etc.), which further elevate the risk of brain injury in preterm infants.^{3,6–9} Recently, routine head position changes have

been postulated to affect cerebral hemodynamics. Adult patients at risk for elevated cerebral pressure due to traumatic brain injury are routinely placed in head-neutral position to facilitate venous drainage.¹⁰ Doppler studies in term infants have shown that turning the head toward one side functionally occluded jugular venous drainage on the ipsilateral side.¹¹ This is of concern in preterm infants, for whom there are currently no official guidelines or recommendations with regard to head positioning during early days of life. In particular, an intubated preterm infant's head may be turned toward one side (facing the ventilator, e.g., high-frequency oscillator) for prolonged periods of time. As impaired venous drainage and decreased cerebral tissue oxygenation are factors implicated in the pathogenesis of IVH,^{5,12,13} midline head positioning during early transitional period has been

included in recent IVH prevention bundles in many institutions, albeit without strong data to support the practice.^{14–16}

The ability to noninvasively monitor cerebral hemodynamics at the bedside can be valuable in optimizing neonatal care. Near-infrared spectroscopy (NIRS) technology noninvasively measures relative changes in oxygenated (HbO₂) and deoxygenated hemoglobin (HbR) levels within brain tissues.^{17–19} The cerebral tissue oxygen saturations (SctO₂) can then be calculated as a ratio of HbO₂ to total hemoglobin (total hemoglobin = HbO₂ + HbR). The normal reference range of SctO₂ for preterm infants varies between 55 and 85% depending on multiple factors such as instrumentation design, clinical status, postnatal age as well as the precision of the instrument.^{18,20–22} Unlike pulse-oximetry (also based on light spectroscopy) that approximates arterial oxygen saturation, NIRS measurements are heavily weighted (70–80%) toward the venous component¹⁸; therefore, NIRS is uniquely suited for detecting any potential venous drainage impairment associated with head turning. Previous studies involving preterm infants at varying postnatal ages have shown conflicting outcomes regarding the effect of head positioning on cerebral hemodynamics.^{23–26} In addition, in light of evidence showing unilateral obstruction of venous drainage in response to head turning,^{11,21} potential bilateral regional differences in cerebral SctO₂ in response to head turning have not been investigated.²¹ Therefore, the aim of this study was to investigate regional SctO₂ measures with the head in midline and the acute effect of changing head positioning on bilateral regional SctO₂ in a cohort of preterm infants during the first 3 days of life, using noninvasive NIRS.

Materials and Methods

This is a prospective observational study designed to investigate the short-term effect of head position change on bilateral SctO₂ in a cohort of preterm infants.

Study Population

After obtaining parental consent, preterm infants (< 30 weeks estimated gestational age [EGA]) were prospectively recruited within the first 12 hours of life (► **Table 1**) in the neonatal intensive care unit (NICU) at St. Louis Children's Hospital. Infants were not prescreened based on initial head ultrasound findings since the timing of the clinical ultrasounds at the study site was not consistent in the first 3 days of life. Exclusion criteria included infants: (1) whose parent(s) could not be reached for consent prior to 24 hours of age; (2) who were suspected to have chromosomal abnormalities or severe congenital abnormalities; or (3) who were clinically moribund and unlikely to survive as determined by the primary medical care team. The study was approved by the local institutional human research protection office (HRPO).

Cerebral Tissue Oxygen Saturation (SctO₂)

Regional SctO₂ was measured by a commercially available NIRS device (ForeSight, CAS Medical Systems, Branford, CT) which can simultaneously measure regional SctO₂ from two separate channels.²⁷ This is a continuous wave, 4 wave-

lengths, device that has been FDA approved for neonatal applications. Data sampling rate is 0.5 Hz. Detailed specifications of this device have been previously published.²⁷

Head Positioning

Regional SctO₂ measurements were performed at the bedside. NIRS probes were placed over each frontoparietal region of the head. At the start of the study, the infant was placed

supine with head in midline. The head of the bed was elevated at $\sim 30^\circ$ which is a standard practice at the study site. Simultaneous SctO₂ from each side of the head were then recorded continuously in four consecutive head positions changed at 30-minute intervals:

1. Head in the midline position (baseline)
2. Head turned (45–60 degrees) from midline toward the left side with the body remaining supine
3. Head returned to the midline position
4. Head turned (45–60 degrees) from midline toward the right side with the body remaining supine.

We chose not to forcefully turn the head past 60 degrees to either side. The chosen range of rotation represents typical head placement by nursing staff within the study NICU if the head is turned to either side. During the NIRS measurements, the heart rate, pulse-oximetry, and mean arterial blood pressure (via umbilical catheter when available) were continuously recorded and synchronized with the SctO₂ measurements. A member of the research team stayed at the bedside during the study to note changes in physiologic parameters and clinical stability, and to ensure proper head positioning. If an infant required changes in FiO₂ after head turning and failed to wean back down to reference baseline FiO₂ within 5 minutes, the bedside team member was instructed to reset the current head position measurements and a new reference baseline (head back in midline position) was then obtained with the current FiO₂.

Statistical Analysis

All data were collected using a customized data acquisition software (CAS Medical Systems, Branford, CT), which provided output in an Excel-compatible format. The statistical package IBM SPSS (version 20) was used to analyze the data. Time traces of bilateral SctO₂, heart rate, blood pressure (when available), respiratory rate, and systemic saturation (SpO₂) were plotted to identify periods of instability. First, 10 minutes of data immediately before each positioning change were averaged to reflect a baseline value for subsequent comparison. After the head was turned toward the side, the time traces were re-examined for clinical stability (e.g., without apnea, bradycardia, and desaturation). Once the infant was determined to be stable from observing the time traces, the first 10 minutes of data (after clinical stability) and the subsequent second 10 minutes of data were separately averaged to reflect progressive changes in SctO₂ in response to the head positioning change. Two-tailed paired *t*-tests were used to compare the changes in averaged SctO₂ within the same side of the head. Comparisons of averages were made between the same channels (measuring the same side of the head) due to inherent within-subject and inter-subject variabilities.

Results

We recruited a total of 26 infants, of whom complete head turning datasets were available in 22 infants. In the remaining four infants, data were available only with head in the midline

position because the primary care teams preferred the heads of these infants to remain in the head midline position for the first 3 days of life; hence, these infants were excluded from further analyses. Two additional infants with severe IVH (24 and 26 weeks of gestation at birth, respectively, **Table 1**) were first excluded from analyses to present data on a cohort of infants with no apparent or mild (grade I) IVH. Severe grade IVH is defined as grades III and/or IV on either side, based on clinical ultrasounds during the first 7 days of life. Only one infant developed IVH (grade I) in the remaining cohort. Out of those four infants without complete head turning dataset mentioned above, one was found to have a grade IV IVH shortly upon admission and prior to the NIRS study. The clinical characteristics of the recruited subjects are summarized in **Table 1**. The final cohort ($n = 20$) had a mean (SD) gestational age of 26.5 ± 1.7 weeks and birth weight of 930 ± 220 g. Eighteen infants were studied on the second day of life, with a range of 1 to 3 days. The average clinical risk index for babies score was 3.6 ± 3.1 . Most infants ($n = 13$, 65%) did not require mechanical ventilation at the time of the study. None received medical/surgical treatment for patent ductus arteriosus (PDA) at the time of the study; however, eight infants did later require treatment.

The regional SctO₂ are shown in **Table 2**. When infants with severe grade IVH were first excluded, the baseline bilateral SctO₂ with the head in midline ranged between 72.3 and 75.0%. There was a statistically significant decrease (-1.5% in the first 10-minute epoch after head position change [$p = 0.050$]; -1.7% in the second 10-minute epoch [$p = 0.04$]) in SctO₂ on the left side of the brain when the head was turned toward the left side from a midline position. When the two infants with grade IV IVH (clinical characteristics are shown in **Table 1**) were included in the analyses, similar amount of decreases (-1.6% [$p = 0.041$ and 0.050] in both 10-minute epochs) in SctO₂ was noted again only on the left side when the head was turned toward the left.

No statistically significant changes were noted in any other channels, during either 10-minute epochs, on either side of the brain when the head was turned toward the right side (**Table 2**). Statistical comparisons were made only within the same channels (measuring the same side of the brain) due to the inherent within-tissue and within-subject variabilities. Furthermore, when the cohort was stratified by a cutoff birth weight of 800 g ($n = 9$), there was no statistically significant difference in SctO₂ associated with head positioning change observed in any channel during any epoch (**Table 3**).

No statistical differences were found in heart rate, transcutaneous oxygen saturation via pulse oximeter, and mean arterial blood pressure during this period. While most infants tolerated the head position change without significant apnea, bradycardia, or desaturation episodes, four infants required up to 80 seconds to allow for initial transition between head position changes. None of the infants received inotropic agents during the study period or received fluid bolus within 4 hours of the study period.

Given the current sample size and observed data distributions between the two NIRS channels, a post hoc analysis shows sufficient power (96%) to detect a SctO₂ difference of

10% between the left and right channels (with $\alpha = 0.05$). A 10% difference in SctO₂ between the left and right side of the brain is arbitrarily chosen to be clinically significant, considering the precision of the instrument.

Discussion

Neutral head positioning in the very preterm infants during early transitional periods is being explored as a potential method for IVH prevention.^{14–16,28} In this cohort of relatively stable very preterm infants during the first 3 days of life, we describe the normal, bilateral regional SctO₂ levels with the head in midline. Although we noted a statistically significant decrease in SctO₂ on the ipsilateral side of the brain when the head was turned toward the left, this small decrease in SctO₂ (< 2%) is likely not clinically significant given the precision of the NIRS instrument, potentially small changes in PaO₂, cerebral perfusion/autoregulation, cerebral metabolism, etc., over this period of time. Interestingly, when the study cohort is further stratified by a birth weight of 800 g, no significant decrease in SctO₂ associated with head turning was noted in any channels during any epoch. It is important to note that the overall SctO₂ remains within the expected normal range regardless of head position, even in those infants with birth weight < 800 g. Thus, brief changes in head position (which may occur as part of normal neonatal nursing care) do not seem to affect regional saturations in this cohort of stable infants.

NIRS has been used extensively in monitoring cerebral hemodynamics in the neonatal population.^{18,22} It may be even better suited for evaluating processes that alter regional SctO₂ due to significant venous drainage disturbance (assuming stable arterial oxygen supply and tissue consumption) because SctO₂ measurements are heavily weighted toward the venous compartment. While the development of IVH is certainly multifactorial, the primary aim of this study is to evaluate whether short-term head position changes are associated with acute SctO₂ difference due to potential ipsilateral venous congestion.

There is currently no consensus on proper head positioning when caring for very preterm infants during the early days of life. Small studies suggest that lower SctO₂ is associated with brain injury⁵ and head turning alters cerebral hemodynamics (more specifically, ipsilateral venous drainage) in term-born infants.¹¹ However, studies aimed at investigating the potential effect of head/body positioning in preterm infants thus far have shown discrepant results likely due to the differences in study designs and the cerebral hemodynamic measurements reported.^{23–25} Pellicer et al evaluated a heterogeneous group of 21 infants (24–37 weeks EGA, studied on days of life 1–33)²⁵ and found an acute and significant increase (up to 37%) in cerebral blood volume (CBV; parameter extrapolated from traditional NIRS measures) when the head was turned laterally. Infants in this study who weighed less than 1200 g showed higher variability in CBV (perhaps, due to venous congestion) compared with those who were heavier and presumably more mature in gestational age. The change in CBV is not surprising, as

premature infants have been shown to have significant impairment in cerebral autoregulation, especially early in the postnatal course.²⁹ Since only frontal-midline measurements of CBV are available in this study, it is not clear whether the head turning exerts a global or more regional effect. Ancora et al (2011) studied cerebral tissue oxygenation in midline frontal region in 24 nonmechanically ventilated infants (27.5 ± 2.8 weeks EGA) in the second week of life.²⁴ They found no significant differences in cerebral tissue oxygenation in these infants with changes in body position (in either prone or supine), head rotation, and bed elevation (with or without elevating the head of the bed). Since measurements were taken only from the midline frontal region, potential changes in regional cerebral saturation differences were not explored. The effect of body positioning on cerebral oxygenation was studied by Bembich et al (2012) who used a multichannel NIRS system to study 20 preterm infants (25–34 weeks EGA) between 2 and 48 days of life.²³ They noted a higher overall cerebral oxygenation in the supine/head midline position than in the prone position with head toward the side. These measurements at each body position were performed 1 day apart, but there were no significant differences in capillary pCO₂, blood pressure, heart rate, and transcutaneous oxygen saturation between the two consecutive days. More mature infants (i.e., later gestational age at birth and older postnatal age) were included in this study, and the effect on the younger subgroups was not explored.

In contrast to these studies, our study included a relatively more homogeneous group of preterm infants (26.5 ± 1.7 weeks EGA) monitored exclusively during the early postnatal period (first 3 days of age) when the incidence of IVH is high. It is also important to point out that our cohort of very preterm infants was relatively stable at the time of study (► **Table 1**) as the majority did not require significant mechanical ventilatory support and none required inotropes or fluid boluses for hypotension; only 1 of the 20 infants analyzed in this study had any IVH. The inclusion of two infants with severe IVH did not alter the changes in ipsilateral regional SctO₂ noted on turning the head to the left.

Our findings suggest that head positioning change in the first 3 days of life does not acutely nor progressively lead to clinically significant changes in cerebral hemodynamics in relatively stable preterm infants. The head turning intervention was limited to only 30 minutes at each position in this study. Based on our experience, certain infants (especially infants requiring high-frequency ventilation) may have their heads placed in one position for much longer periods of time. Therefore, it is unclear whether prolonged head turning may lead to bigger changes in SctO₂. Furthermore, we cannot extrapolate the current finding to infants with higher acuity levels. Transient bilateral cerebral tissue oxygenation differences (unrelated to head rotation) were previously seen in preterm infants during systemic desaturations³⁰ but not in stable term and preterm infants without brain injury.²¹ It may be reasonable to postulate that sicker preterm infants may exhibit wider differences in regional SctO₂ with changes in head position, due to factors that may combine to exacerbate

venous congestion (therefore alter $SctO_2$). These factors may include prolonged head turning, impaired cerebral autoregulation, signs of early neonatal sepsis, hypotension requiring fluid resuscitation and/or inotropic support, symptomatic PDA, and/or significant respiratory insufficiency requiring high ventilatory support which can lead to high mean airway pressures.

This study is the first to demonstrate the steady and normal bilateral regional $SctO_2$ levels with head in midline and to investigate the acute effects of head turning in a relatively homogenous cohort during the critical period when the incidence of IVH is high. While similar to aforementioned studies, our study is limited by a small sample size. Post hoc analysis showed the current sample size to have sufficient power to detect larger and more clinically meaningful differences in bilateral cerebral tissue oxygenation. Also, there are other potential confounders that may be difficult to address in an observational study, e.g., inter-subject differences in ventilation requirement, PCO_2 , cardiac function, and cerebral autoregulation, etc. Nevertheless, the effects of inter-subject variability might be minimized because the pre- and post-head turn measurements in each infant were made by the same probe, at the same spot on the head, and only within a relatively brief period of time during which no dramatic differences in some of these physiologic variables were expected. Furthermore, none of the infants in our cohort experienced significant changes in arterial blood pressure, and none required ventilatory setting changes during our brief study period. The four infants who required transient increase in FiO_2 support after head position change returned quickly to baseline FiO_2 (without changes in ventilator setting changes). Other factors such as cardiac function⁵ and the direction of blood flow across the ductus arteriosus may influence cerebral hemodynamics, particularly as preterm infants have been reported to have asymmetrical cerebral injury patterns, with the left side more frequently and/or more severely injured than the right side.³¹ Since the ductus arteriosus is anatomically closer to the left than to the right carotid artery, a symptomatic PDA early in the postnatal period may functionally steal more blood away from the left side of the brain,^{32,33} leading to the asymmetrical injury patterns. This is an interesting finding given our data in relatively stable, noninjured preterm infants. We did not obtain concurrent echocardiograms to evaluate for PDA, but presumably most infants during the early days of life would have had a PDA and indeed eight infants in our cohort later required intervention. While no infant in this study received medical or surgical PDA treatment at the time of our study, the dynamic nature of PDA during early postnatal age is hard to control given the limits of the study design.

Conclusion

In summary, clinically stable preterm infants appeared to maintain stable bilateral $SctO_2$ levels with their head in midline and also tolerated short-term head positioning changes well based on bilateral NIRS monitoring. Although we found a statistically significant decrease in ipsilateral

$SctO_2$ from baseline in response to turning the head to the left from midline, these may not be clinically significant in this cohort of relatively stable very preterm infants during the first 3 days of life. While previous IVH prevention bundles (including neutral head positioning) have shown improvement in various outcomes,^{14,15} our future research efforts will focus specifically on the effect of head positioning in infants with higher acuity (e.g., hypotensive, pressure passive states, etc.) as well as explore the effect of PDA on cerebral hemodynamics.

Conflict of Interest

The NIRS instrument and probes were partially provided by CAS Medical Systems, Inc (Branford, CT) without any contribution to any other phase of the study.

Acknowledgments

We thank Anthony Barton for his effort in recruitment and data management. We also thank Dr. Michael Wallendorf, a senior biomedical statistician, for reviewing our statistical methods. The project is supported by a career development grant UL1 TR000448, sub-award KL2 TR000450 (PI: Liao), and a pilot grant from ICTS NIH/NCATS/UL1 TR000448 (PI: Mathur).
