Contents

- General Introduction
- Aims and hypotheses
- 3 climate chamber experiments:
 - role of RH and roots' signals in fully developed leaves (Exp.1)
 - role of RH during leaf development (Exp. 2)
 - effect of RH on stomatal initiation and development (Exp. 3)
- Final conclusions

Long-term high relative air humidity (RH>85%) during cultivation downgrades keeping quality in cut flowers

- Light intensity, light quality, CO₂ fertilization, **air humidity**, water stress
- Xylem, stomatal, cuticle properties, hydrosensitivity of Ψ , flower opening

Not only obtain, but sustain quality

High RH is common in winter months in Northern Europe in greenhouse cultivation

Closed greenhouse (closed ventilation windows)

□ high RH levels

High RH during cultivation □ increased water loss during post-harvest (stomatal malfunction)

□ poor keeping quality

Cultivar dependent quality decrease

Manipulate humidity

during or after leaf development: **compensate?**

OR

?

Stomatal adaptation (or NOT) to new RH environment in fully developed leaves

Species	Moderate → High RH	High → Moderate RH
<i>Phaseolus vulgaris</i> ¹	√ (7 days)	√ (7 days)
<i>Tradescantia virginiana</i> ²	√ (4 days)	× (6 days)
<i>Rosa hybrida</i> ³	× (21 days)	× (21 days)

- Species dependent
- Certain amount of ABA is required **during** and **after** leaf development for functional stomata²

¹ Pospisilova (1996); ² Rezaei Nejad and Van Meeteren (2006); ³ Mortensen and Gislerød (2000)

Hypotheses

- Humidity level
- Root (hormonal & hydraulic) signals after leaf development do NOT affect stomatal functionality

Materials & Methods

- Three climate chamber experiments ALL WITH:
 - cv: Prophyta (sensitive to high RH)
 - 2 RH: High RH (90%); Moderate RH (60%)
 - Light: $300 \pm 20 \mu\text{mol m}^{-2}\text{s}^{-1}$, 18 h/d
 - 19°C day/night, ambient CO₂

Role of RH and root signals' in fully developed leaves

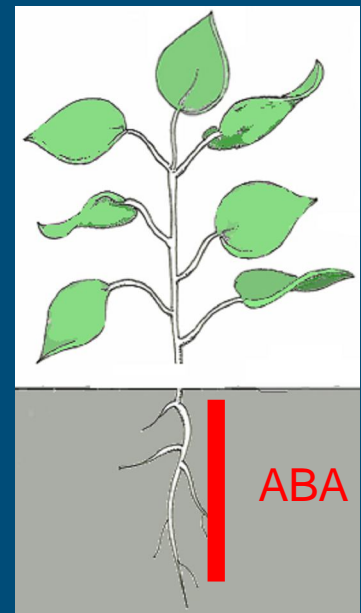

(Exp. 1)

Fully grown plants (flower stage 2):

- transferred to humidity other than growth (60%→90%; 90% →60%)
- cut roses, placed in vases in evaluation room (for 60% RH only)
(20°C, RH: 50%, 10-12 $\mu\text{mol m}^{-2}\text{s}^{-1}$, 12 h/d)

Stage 2

Measurements (Exp. 1)

- Stomatal responses to desiccation were followed every 2d
 - new humidity: 14 replicates, 1 leaf/ plant
 - cut roses: 8 replicates; 1 leaf/ stem
- Rehydrated terminal (detached) leaflets
- T: 21°C, RH: 50±3 % (1.47 kPa VPD), & 50 $\mu\text{mol m}^{-2} \text{s}^{-1}$
- Transpiration rate measured gravimetrically

Stomatal responses to desiccation

$$\text{Relative Water Content} = \left[\frac{\text{FW} - \text{DW}}{\text{SFW} - \text{DW}} \right] * 100$$

- Iwanoff effect
- High RH affects speed and degree of stomata closure
- End value can be misleading

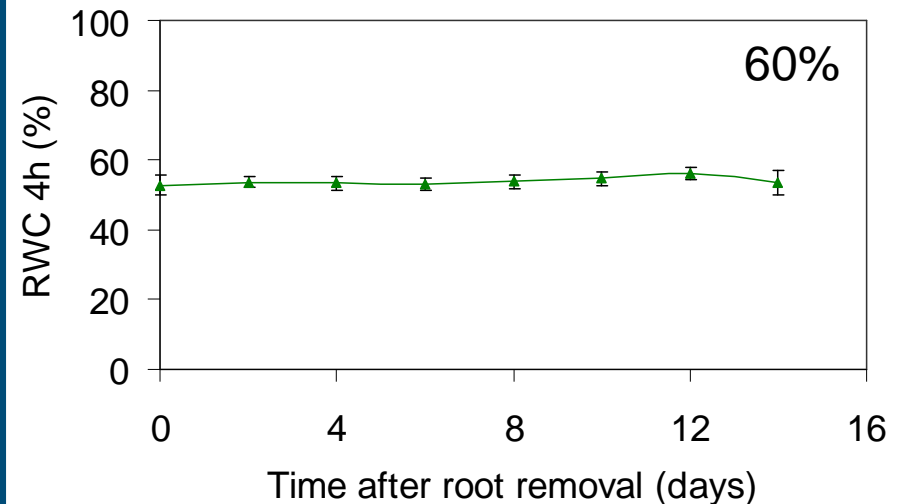

RWC 4h after desiccation (role of RH and of roots)

Role of RH

Role of roots

- No stomatal adaptation after 14d in new RH environment
- Vase life: stomata stay functional even after 14d without root signals (hormonal & hydraulic)

New research questions

- Is the high RH effect on stomatal behaviour gradual during leaf development?
- Are the non fully developed leaves able to adapt to a new RH environment? To which extent?

Role of RH during leaf development (Exp. 2)

Five weeks after bud break (1st leaf ≈ 20% final length), plants transferred to:

- New RH environment (60% → 90%; 90% → 60%)
- treated with 30 μm ABA twice a day (1st leaf only)

Measurements (Exp. 2)

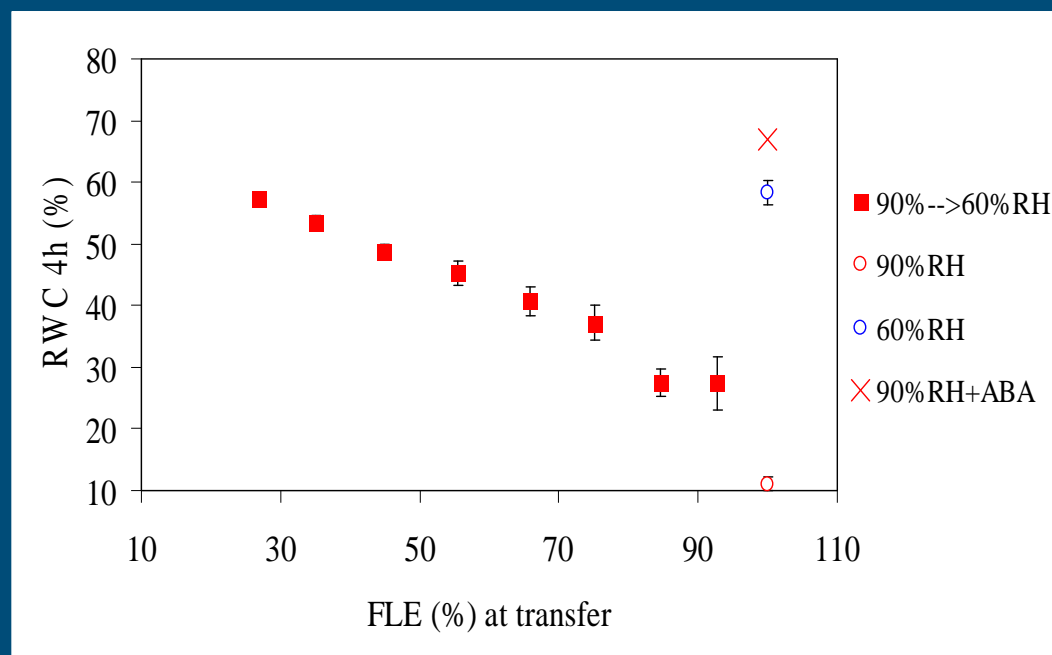

- Leaf expansion was followed daily (measuring leaf length of top 5 leaves)
- Fully developed leaf (100% FLE) → leaf length is constant for 3 consecutive days
criterion = 100%FLE and not time in the new humidity (Exp.1)
- Stomatal responses to desiccation in fully expanded leaves (3 repetitions, n>18)

Similarly to Exp. 1:

- Rehydrated terminal (detached) leaflets
- RH :50±3 %, T:21°C (1.47 kPa VPD), & 50 $\mu\text{mol m}^{-2} \text{s}^{-1}$
- Transpiration rate measured gravimetrically

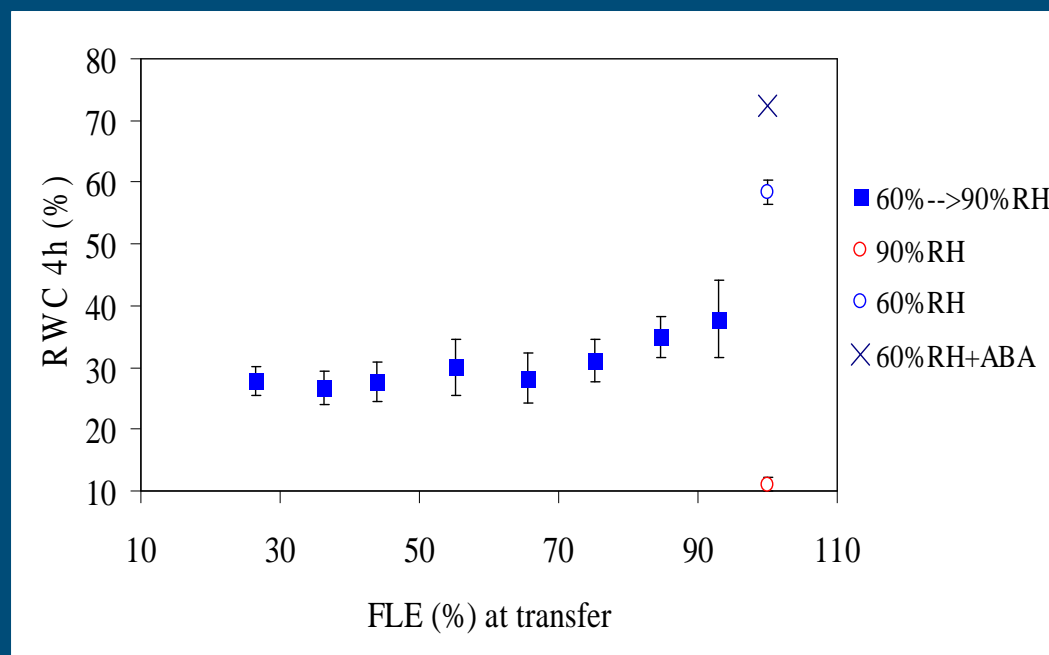

Role of RH during leaf development (90%→60%)

- 27% FLE behave as control moderate RH; 10% step in FLE: different behavior (even >90% FLE before transfer is better than high RH control)
- not complete, but partial adaptation
- ABA application induced very active stomatal functioning

Role of RH during leaf development (60%→90%)

- High RH during the last part of leaf expansion is detrimental irrespective the FLE at the time of transfer (FLE<80%)
- No differentiation between different FLE classes
- Not complete, but partial adaptation
- ABA application induced very active stomatal functioning

New research questions

- Is the gradual effect of moderate RH due to gradual stomatal initiation during leaf expansion?
- Does the different humidity effect come from different stomatal initiation/appearance?

Stomatal initiation and development (Exp. 3)

- 35, 50, 65, 100% FLE (leaf order 1)
(4 leaflets/ stage and humidity level)
- Paired sampling
(always control was 100% lateral leaflet)

Measurements:

- Silicon rubber impression technique
- ¹Sampling area 1x1 cm
- Stomatal density

FLE
LA

35%

7%

50%

19%

65%

38%

100%

100%

¹Poole et al (1996)

Stomatal initiation during leaf expansion

absolute stomata number = density × area

- Stomatal initiation pattern was not affected by humidity of growth
- At 65% FLE (or 40%LA) over 95% of stomata are present

Conclusions

- Stomatal physiology is determined **during leaf development**
In fully developed leaves the RH level or presence of roots signals' are NOT important
- When last part of leaf development = moderate RH:
the earlier the switch (i.e. lower FLE) the better
(*partial adaptation*; **different potential**)
- When last part of leaf development = high RH
the time of the switch (FLE<80%): minor effect
(*partial adaptation*; vulnerable till 95%FLE)
- ABA application during leaf development: induces very active stomatal control
- Adaptation dynamics: **stomatal development** (maturation)
NOT stomatal appearance (initiation)
