# THE PERFORMANCE OF DENSITY FUNCTIONALS 

WITH RESPECT TO THE CORRELATION

CONSISTENT BASIS SETS

Xuelin Wang, B.S., M.S

Dissertation Prepared for the Degree of DOCTOR OF PHILOSOPHY

## UNIVERSITY OF NORTH TEXAS

August 2005

## APPROVED:

Angela K. Wilson, Major Professor Martin Schwartz, Committee Member Thomas R. Cundari, Committee Member Teresa D. Golden, Committee Member
Ruthanne D. Thomas, Chair of the Department of Chemistry
Sandra L. Terrell, Dean of the Robert
B.Toulouse School of Graduates Studies

Wang, Xuelin, The performance of density functional theory with the correlation consistent basis sets. Doctor of Philosophy (Chemistry), August 2005, 216 pp., 49 tables, 12 illustrations, 165 references.

Density functional theory has been used in combination with the correlation consistent and polarization consistent basis sets to investigate the structures and energetics for a series of first-row closed shell and several second-row molecules of potential importance in atmospheric chemistry. The impact of basis set choice upon molecular description has been examined, and irregular convergence of molecular properties with respect to increasing basis set size for several functionals and molecules has been observed. The possible reasons and solutions for this unexpected behavior including the effect of contraction and uncontraction, of the basis set diffuse $s p$ basis functions, basis set superposition error (BSSE) and core-valence sets also have been examined.

## ACKNOWLEDGEMENTS

I would like to thank my advisor Dr. Angela K. Wilson for allowing me to join and grow in her research group. It is her effort that directs me to walk into the kingdom of computational chemistry. Without her, this dissertation would not have been possible. I thank her for her patience and encouragement that help me go through difficult times, for her valuable insight and suggestions that contribute greatly to my dissertation, and for her generously supporting me to take part in numerous academic meetings. To the members of my committee: I thank Professor Martin Schwartz, Professor Thomas Cundari, Professor Teresa Golden, and Professor Kirk A. Peterson for their patience, valuable feedback to my research, and their kind recommendations.

I also want to thank the guys in our research group- Scott, Brian, Ben, and Pankaj et al., who have helped me go through the English for my dissertation. Thank you for the wonderful time we have spent together.

## CHAPTER 1

## INTRODUCTION

Density functional theory (DFT) has become a widely used tool for describing the electronic structure of a wide range of systems. In DFT, the ground state energy of a system of interacting electrons can be expressed as a function of the electron density. The complexity of DFT is to find an "exact" link (functional) between the electron density and the kinetic and potential energies. Early DFT approaches such as the Thomas-Fermi model involved numerous theoretical difficulties, and the predicted molecular properties obtained using this early approach were not satisfying.[1, 2] Thus, DFT was not at all widely used in the chemistry community until many years later and until methodologies evolved further. Key to widespread use was the introduction of the Kohn-Sham approach to DFT.[3] Kohn and Sham used a non-interacting reference system, where no interactions between electrons were considered, to represent an interacting system (a full molecule), and also introduced the use of orbitals into density functional theory. These developments helped to enable an improved description of the kinetic energy and the potential energy arising from nucleus-electron and electron-electron interactions. However, further improvement in the kinetic energy is needed, and this remaining not-yetdescribed energy can be merged with residual corrections arising from the use of a noninteracting system into another energy term, -exchange-correlation energy-, which has to be treated approximately, and typically is treated in two different terms - an exchange term and a
correlation term. Much effort has been focused upon developing an approach to describe this exchange-correlation energy. In fact, DFT has experienced several generations of developments to accomplish this goal.

One of the simplest Kohn-Sham approaches is called the local density approximation (LDA) and is based on the uniform electron gas. The exchange-correlation energy density of a uniform electron gas is used to approximately represent that of a real inhomogeneous system. The exchange-correlation energy per particle of a uniform electron gas can be calculated accurately from quantum Monte Carlo calculations. In the early stages of DFT use, this simple approximation was remarkablely successful in many applications. Even presently, the LDA is still active in the simulation of solid state systems. One of the most popular LDA methods is SVWN, which uses Slater exchange (S)[4] and Vosko, Wilk, and Nusair 1980 correlation functionals (VWN).[5] However, the LDA methods have some cumbersome deficiencies, where the LDA is not adequate to describe systems such as those which are highly inhomogeneous (the uniform gas approximation works well for systems in which the electron density changes slowly throughout the system).

Since the LDA is often not adequate to provide reasonable accuracy for many systems, attempts to go beyond the LDA are necessary. One natural extension of the LDA is the improvement of the description of the exchange-correlation functional by including the gradient of the electron density. The functionals coined in this approach are the so-called general gradient approximation (GGA) methods, which are constructed to retain the correct features of LDA, while making further improvements. GGA methods consider the correction arising from electron gradient for both exchange and correlation functionals. However, due to the dominant exchange effect in the exchange-correlation functional, only the correction to exchange functional is
addressed here. The common procedure to form GGA exchange functionals is to multiply the LDA functional by $F_{x}$, a function of the density gradient. Varied GGA exchange functionals have different $F_{x}$, which were originally obtained numerically in order for the exchange functional to obey physicalcriteria. For example, Becke's B88 (B) exchange[6] uses Equation(1-1) as $\mathrm{F}_{\mathrm{x}}$,

$$
\begin{equation*}
F_{x}(s)=1+\frac{\beta s^{2}}{1+\gamma s^{2}} \tag{1-1}
\end{equation*}
$$

where s is proportional to $\nabla \rho(\mathrm{r}) / \rho(\mathrm{r})$ where $\rho(\mathrm{r})$ is the electron density at distance r .The parameters $\beta$ and $\gamma$ are constants, which were fit to the exchange energies of a large number of atoms. This form satisfies the observation that when the density gradient becomes large, gradient corrections are insignificant. Many modifications to exchange functionals have been proposed, and further details about these developments can be found in the literature. For example, the current study utilized three pure GGA methods including BLYP,[6] [7] BPW91[8] and BP86.[9]

At present, one of the most widely used DFT functional is B3LYP.[10] It is a typical hybrid functional. The so-called hybrid means a mixing of Hartree-Fock exchange energy and pure DFT exchange energy (including local and gradient correction) weighted by several empirical parameters, which were obtained based on empirical calibration procedures. B3LYP has achieved great success for many chemical problems such as in the prediction of geometries, thermodynamics properties, and the understanding of chemical reactions. Although new functionals and mechanisms continue to be developed, B3LYP is still used widely due to its well-established performance. Examples of hybrid functionals include B3PW91, B3P86, and BHandHLYP. In this study, B3LYP, B3PW91, and B3P86are investigated.

To date, DFT $[3,11]$ has become one of the most prominent tools in describing the electronic structure of molecules due to its low cost and consideration of electron correlation. With its $\mathrm{N}^{3}$ scaling ( N is the number of basis functions), DFT has a similar computational cost as compared with the Hartree-Fock (HF) approach. However, DFT accounts for more of the electron correlation than does HF. Although DFT has many advantages, a range of problems still exist such as self-interaction error [12] (the error resulting from an inability for the coulomb and exchange interactions of an electron with itself to cancel out), poor predictions of dispersion forces, $[13,14]$ and lack of correct asymptotic decay of potential. A variety of density functionals have been proposed, and the development of new functionals continues to be an active area of research. With the availability of a variety of functionals, a question arises: How can the "best" functional be chosen for a given scientific problem?

A hierarchy of the performance arising from the use of density functionals has not been established due to the lack of a systematic way of improving the wavefunctions, especially the exchange-correlation potential. As a result, correct electronic structure of molecules cannot be achieved in a stepwise, well-defined manner. To better understand the successes and failures of DFT, a general and effective means to evaluate the performance of different functionals is needed. One possible means is the use of the correlation consistent basis sets,[15] cc-pVxZ $(x=\mathrm{D}(2), \mathrm{T}(3), \mathrm{Q}(4)$ and 5), which have been used extensively with ab initio methods. The correlation consistent basis sets are based on a detailed analysis of correlation energy in an atom. The main advantage of the correlation consistent basis sets is that they are built to systematically recover the correlation energy. The results obtained from a series of calculations with the correlation consistent basis sets can be extrapolated to the complete basis set (CBS) limit, where the remaining error arises from the method used to approximate the electronic Schrödinger
equation. Using this approach, the performance of various theoretical approaches can be assessed.

A number of studies have proven the usefulness of the correlation consistent basis sets with high accuracy $a b$ initio methods.[16-20] However, it is not clear whether the correlation consistent basis sets can be applied to assess the performance of density functionals since they are optimized using the configuration interaction plus single and double excitation (CISD) method. In this study, our goal is to evaluate and compare the performance of various functionals with the correlation consistent basis sets by carrying out a series of benchmark calculations. We explore the possibility of using the correlation consistent basis sets as an effective means to assess the reliability of density functionals.

In this study, benchmark calculations were carried out for a set of 17 closed shell firstrow molecules by using several density functionals with the correlation consistent basis sets. The accuracy and precision of the various density functionals were analyzed, along with the convergence of atomization energy with respect to increasing basis set size. The performance of the systematically developed polarization consistent basis set -designed especially for DFT were also investigated. Following these benchmark studies, other factors including basis set uncontraction, basis set superposition error, diffuse basis functions, and core-valence functions, which may affect the convergence of molecular properties with respect to correlation consistent basis sets, were also examined.

Additonal work has included the use of DFT methods in combination with the newly developed tight $d$-augmented correlation consistent basis sets to study several second-row molecules including $\mathrm{SO}_{2}, \mathrm{CCl}, \mathrm{ClO}_{2}, \mathrm{HSO}$, and HOS. The tight $d$-augmented sets include a tight $d$ function at each basis set level (as well as modifications to the standard set of $d$ functions), and
were developed to reduce the deficiencies noted in the standard basis sets for second-row atoms, especially for sulfur. In previous studies, it has shown that the effect of tight $d$ functions is quite substantial, particularly at the double- and triple-zeta levels for the sulfur species. The molecules mentioned above have a strong basis set dependence. The calculations with small basis sets (ccpVDZ and cc-pVTZ) result in large errors in atomization energy for $\mathrm{SO}_{2}, \mathrm{CCl}, \mathrm{ClO}_{2}$ and an incorrect prediction of the relative stability of HSO and HOS isomers. In this study, the effect of the tight $d$-augmented sets on the structures, frequencies, and energies of these molecules is discussed in detail. In addition to these properties, the effect of tight $d$ on the enthalpies of formation of HSO and the reaction barrier of $\mathrm{HSO} / \mathrm{HOS}$ isomerization reaction are also investigated.

## CHAPTER 2

## THE PERFORMANCE OF DENSITY

## FUNCTIONALS WITH RESPECT TO BASIS SET: <br> CORRELATION CONSISTENT BASIS SETS

### 2.1 Introduction

The early success of density functional theory is based on the local density approximation (LDA), where the exchange-correlation energy generally consists of the Slater exchange energy[4] and the Vosko-Wilk-Nusair correlation energy.[5] However, LDA exhibits deficiencies in the calculation of thermochemical properties. The deficiencies are improved significantly by generalized gradient approximation (GGA) methods like BLYP[6, 7] and BPW91[21], where the gradient of electron density is included in the exchange-correlation functional. Later, even better performance was obtained for so-called hybrid density functionals that include the exact Hartree-Fock exchange energy. A typical example, B3LYP,[10] is constructed by a linear combination of local density approximation, Becke's gradient correction, and the Hartree-Fock exchange energy. The linear coefficients were determined by a fitting of the heats of formation of 55 molecules. Since the advent of B3LYP, hybrid density functionals have been extensively used in describing thermochemical properties, structures, and harmonic frequencies of a large range of molecules, and yields superior results to prior LDA and GGA methods. Recently, another type of approximation to exchange-correlation functional was
proposed. This approximation, called the meta-GGA,[22] requires the second derivative of electron density and kinetic energy densities as additional variables in the exchange-correlation functional. Although meta-GGA owns many of the known properties of the exact exchange and correlation energy, it is not clear whether new functionals can surpass B3LYP in popularity due to too few benchmark studies of functional performance.

Such a wide choice of functionals brings DFT users to a question: which functional is the best for a scientific problem of interest? As addressed in Chapter 1, a possible key to answer this question is to extend the basis set to the complete basis sets limit (or Kohn-Sham limit in the case of DFT), where no further improvement to the basis set is possible, and the remaining error is due to the method alone. At this point, the success and failure of density functionals may be assessed. However, systematic studies of the dependence of density functionals upon increasing basis set size are limited.[23-28] Several previous studies on basis set convergence for density functional theory are discussed below.

Martin evaluated basis set convergence in density functional theory by comparing a series of $a b$ initio and DFT benchmark studies.[29] Basis set convergence in DFT calculations is similar to that at the HF level, and is faster than in ab initio correlation calculations like MP2 and $\operatorname{CCSD}(\mathrm{T})$. Strong basis set dependence at the SCF level is also observed in DFT calculations like for the description of hydrogen bonds. For most properties, results near convergence to the basis set limit can generally be achieved using a basis set with $s p d f$ functions augmented with diffuse functions.

Gill, Johnson, and Pople examined the performance of BLYP with a variety of Pople basis sets, $[30] 6-31 G(d), 6-31+G(d), 6-311+G(2 d f, p)$, and $6-311+G(3 d f, 2 p)$. They found that the BLYP predicts the atomization energy, ionization potential and proton affinity well for the
extended G2 data set, even when BLYP is used in combination with the smallest basis set. The mean absolute deviation in the energy with respect to experiment decreases with increasing basis set size. When the "high-level correction" used in G2 theory was added to the BLYP results, the overall mean absolute error with $6-31 \mathrm{G}(\mathrm{d})$ is reduced from $6.45 \mathrm{kcal} / \mathrm{mol}$ to $4.18 \mathrm{kcal} / \mathrm{mol}$.

The above studies focus only upon both low-level basis sets and non-systematically developed basis sets. A number of studies have utilized higher-level basis sets. Martin compared the performance of B 3 LYP and $\operatorname{CCSD}(\mathrm{T})$ used with the correlation consistent basis sets for geometries and frequencies of a series of molecules including several large species such as furan and pyrrole.[26] At the double zeta level, B3LYP geometries are more accurate than the $\operatorname{CCSD}(\mathrm{T})$ results. B3LYP/cc-pVTZ predicts geometries to within $0.002 \AA$ of the experiment. However, unlike the case for $\operatorname{CCSD}(\mathrm{T})$, increasing basis set size to cc-pVQZ only made small improvement in the geometry over B3LYP/cc-pVDZ. Similar basis set convergence can also be found for harmonic frequency, with the exception of several cases where frequency has strong basis set dependence. B3LYP in combination with the cc-pVxZ basis set were also applied to determine the geometries and frequencies for a large range of small inorganics and their ions by Raymond and Wheeler.[31] The Kohn-Sham limit was obtained by extrapolating the cc-pVxZ results ( $x=\mathrm{D}, \mathrm{T}$ and Q ), and was compared with experiment.

Denis and Ventura calculated the enthalpy of formation of several species important in atmospheric chemistry using B3LYP and B3PW91 with the correlation consistent basis sets.[32] The predicted properties agree well with previous multireference configuration interaction (MRCI) results. The heats of hydrogenation for a few nitrogen compounds were calculated by Sekusak and Frenking[33] using the pure density functionals BLYP and BP86, as well as the hybrid functionals B3LYP, B3PW91, and B3P86. They employed several basis sets including
cc-pVxZ and aug-cc-pVxZ ( $x=\mathrm{D}, \mathrm{T}, \mathrm{Q}$ ). It was observed that B3LYP heats of reactions did not converge as the basis set size increased for both the cc- $\mathrm{pV} x \mathrm{Z}$ and aug-cc- $\mathrm{pV} x \mathrm{Z}$ families of basis sets. The irregular convergence was attributed to the possibility that the correlation consistent basis sets, which are optimized for $a b$ initio methods, are not necessarily optimal for use with density functional theory.

The goal of this chapter is to study the systematic convergence behavior of DFT with respect to the correlation consistent basis sets. Structures and energies were determined using several popular functionals on a set of closed-shell first-row molecules, which were derived from preceding work by Martell and Goddard.[27] Several statistical methods including normal distribution and mean absolute deviation were utilized to assess the accuracy and precision of the calculated atomization energies. Two extrapolation schemes were used to estimate the KohnSham limits.

### 2.2 Methodology

In this study, two exchange density functionals, $B$ (B88)[6] and B3[34] (a threeparameter adiabatic connection exchange term), were used with three correlation functionals, Lee-Yang-Parr (LYP),[7] Perdew 1986 (P86),[9] and Perdew-Wang 1991 (PW91).[8] Combining these functionals produce six gradient corrected functionals: BLYP, BPW91, BP86, B3LYP, B3PW91, and B3P86. The numerical grid $(75,302)$ was used to evaluate the integral in exchange-correlation functionals. It includes 75 radial shells and 302 angular points per shell, resulting in approximately 7000 quadrature points per atom. This grid is specified as "finegrid" in the Gaussian 98 software package,[35] which was used throughout this study. Larger grids were also evaluated, but no impact was observed upon the molecular properties studied.

Standard and augmented correlation consistent basis sets (cc-pVxZ and aug-cc-pVxZ where $x=\mathrm{D}(2), \mathrm{T}(3), \mathrm{Q}(4)$ and 5$)$ were employed to determine the structures and atomization energies of $\mathrm{O}_{3}, \mathrm{H}_{2}, \mathrm{H}_{2} \mathrm{O}, \mathrm{HF}, \mathrm{HCN}, \mathrm{CO}, \mathrm{N}_{2}, \mathrm{HNO}, \mathrm{H}_{2} \mathrm{O}_{2}, \mathrm{HOF}, \mathrm{F}_{2}, \mathrm{CO}_{2}, \mathrm{H}_{2} \mathrm{CO}, \mathrm{CH}_{3} \mathrm{NH}_{2}$, $\mathrm{CH}_{3} \mathrm{OH}, \mathrm{N}_{2} \mathrm{H}_{4}$, and $\mathrm{CH}_{3} \mathrm{~F}$. Geometry optimizations and frequency calculations were performed for each method/basis set combination. The atomization energy includes the zero-point energy correction, which was taken directly from the frequency calculations. For energy calculations on the atoms, the tight convergence criterion $\left(10^{-8}\right)$ on density was requested to keep the same level of accuracy between atoms and molecules. When this option is not used, the default convergence criterion $\left(10^{-4}\right)$ is used, and, as a result, very unusual convergence behavior is observed. Typically, this unusual behavior is expressed as an energy fluctuation with respect to increasing basis set size.

Two popular empirical extrapolation schemes were used to obtain the complete basis set (CBS) limit, or Kohn-Sham (KS) limit, in the case of DFT. One is Feller's exponential scheme,[36] which is used frequently in ab initio methods for the correlation consistent basis sets.

$$
\begin{equation*}
\mathrm{D}_{\mathrm{e}}(\mathrm{x})=\mathrm{D}_{e}(\infty)+\mathrm{Ae}^{-\mathrm{Bx}} \tag{2-1}
\end{equation*}
$$

$x$ is the cardinal number of the basis set (i.e. for cc-pVDZ, $x=2$; for cc-pVTZ, $x=3$ ), $\mathrm{D}_{\mathrm{e}}(\mathrm{x})$ represents some property at the " $x$ " level, and $\mathrm{D}_{\mathrm{e}}(\infty)$ represents the extrapolated KS limit. The parameters A and B are determined in the curve fit. At least three points are needed in the nonlinear fitting scheme.

Another extrapolation scheme is the two-point extrapolation by Halkier et al,[37] given below:

$$
\begin{equation*}
\mathrm{D}_{\mathrm{e}}(\infty)=\frac{\left(\mathrm{D}_{\mathrm{e}}(x) \times x^{3}\right)-\left(\mathrm{D}_{\mathrm{e}}(x-1) \times(x-1)^{3}\right)}{x^{3}-(x-1)^{3}} \tag{2-2}
\end{equation*}
$$

The advantage of this scheme over Feller's exponential extrapolation is that only two points are necessary.

### 2.3 Discussion and Results

### 2.3.1 Geometry

The structures of 17 molecules were optimized using the six outlined methods and the correlation consistent basis sets, and are reported in Table 2.1. Overall, the structures converge quickly with respect to increasing basis set size, and are nearly converged at the triple zeta level. Increasing the basis set size beyond the triple zeta level only provides a minor improvement to the geometries. The bond lengths are within $0.015 \AA$ of experiments at the triple zeta level. However, several exceptions were noted: the $\mathrm{H}-\mathrm{N}$ bond in HNO for all hybrid functionals; the $\mathrm{O}-$ O bond in $\mathrm{H}_{2} \mathrm{O}_{2}$ for B3PW91, B3P86, and BLYP; the O-F bond in HOF for B3PW91 and B3P86; the F-F bond in $\mathrm{F}_{2}$ for B3PW91 and B3P86; the $\mathrm{N}-\mathrm{N}$ bond in $\mathrm{N}_{2} \mathrm{H}_{4}$ for B3PW91 and B3P86; and the C-F bond in $\mathrm{CH}_{3} \mathrm{~F}$ for BLYP. These bond lengths differ from experiment by $0.025-0.035 \AA$. Most bond angles are within $2^{\circ}$ of experiment with the exceptions of the $\mathrm{H}-\mathrm{N}-\mathrm{C}$ angle in $\mathrm{CH}_{3} \mathrm{NH}_{2}$ and the $\mathrm{H}-\mathrm{N}-\mathrm{N}$ angle in $\mathrm{N}_{2} \mathrm{H}_{4}$ for all pure functionals, which differ from experiment by $2.5^{\circ}-3.0^{\circ}$. The convergence of the dihedral angle of $\mathrm{H}-\mathrm{O}-\mathrm{O}-\mathrm{H}$ is achieved at the
cc-pVQZ level, rather than at the cc-pVTZ level, while this is not true for the augmented correlation consistent basis sets where the dihedral angle is nearly converged with aug-cc-pVTZ.

Table 2.1 Optimized bond lengths and angles. Bond lengths are given in angstroms, and bond angles are given in degrees.

### 2.3.2. Atomic Energy

Total energies for hydrogen and four first-row atoms are presented in Table 2.2 and compared with accurate Davidson's atomic energies.[45] As shown in the table, the total energies decrease with respect to increasing basis set size. For methods with the same correlation
functional, the atomic energy obtained when the B3 exchange functional is used is lower than that from the B exchange functional. On the other hand, for the B3LYP, B3PW91, and B3P86 functionals, the sequence of atomic energy is given as follows: B3PW91 > B3LYP $>$ B3P86. This trend is true for all of the atoms, with the exception of hydrogen. However, no general trend is observed for BLYP, BPW91, and BP86 functionals. Overall, at the quintuple zeta level, BLYP gives the best agreement with the Davidson energies, with differences of 0.002 hartree, 0.004 hartree, and 0.003 hartree for $\mathrm{H}, \mathrm{C}$, and N , respectively. The best atomic energies for other atoms are obtained with B3PW91, with differences of 0.002 hartree for O and 0.003 hartree for F .

### 2.3.3 Atomization Energy

Generally, the atomization energies from DFT converge rapidly as the basis set size increases, as shown in Table 2.3. In fact, unlike geometries, atomization energies are nearly converged at the quadruple zeta level. For B3LYP and B3PW91, most of the atomization energies are underestimated when the low-level basis sets are used. With increasing basis set size, the energies approach the experimental energies. However, for the other four functionals,

Table 2.2 Total energies for atoms in hartrees.

[^2]the atomization energies are overestimated for a number of molecules, even with the low-level basis sets. Further, atomization energies become further from experiment as the basis set size increases. Typical examples are $\mathrm{O}_{3}, \mathrm{HCN}, \mathrm{F}_{2}, \mathrm{CO}_{2}$, and $\mathrm{H}_{2} \mathrm{CO}$.

Interestingly, the atomization energies for a number of molecules do not converge with increasing basis set size. This is particularly evident when pure density functionals are utilized, and there are two types of irregular convergence patterns have been observed. Generally, a slight energy dip occurs at the quintuple zeta level. The dip is small ( $<0.5 \mathrm{kcal} / \mathrm{mol}$ ), and the most pronounced example is $\mathrm{CO}_{2}$ with a dip of $0.9 \mathrm{kcal} / \mathrm{mol}$ at the $\mathrm{BLYP} / \mathrm{cc}-\mathrm{pV} 5 \mathrm{Z}$ level. This type of convergence pattern occurs for most of the molecules. Another irregular convergence pattern is for $\mathrm{F}_{2}$ and $\mathrm{O}_{3}$. The convergence of $\mathrm{F}_{2}$ is very irregular, even for B3LYP and B3PW91. The maximum value of the $\mathrm{F}_{2}$ atomization energy occurs at the triple zeta level. For $\mathrm{O}_{3}$, using BLYP with the correlation consistent basis sets results in a fluctuation in energy: $168.32 \mathrm{kcal} / \mathrm{mol}$ for cc-pVDZ, $166.96 \mathrm{kcal} / \mathrm{mol}$ for cc-pVTZ, $167.28 \mathrm{kcal} / \mathrm{mol}$ for $\mathrm{cc}-\mathrm{pVQZ}$, and $166.79 \mathrm{kcal} / \mathrm{mol}$ for cc-pV5Z.

The augmented correlation consistent basis sets can help remedy the irregular convergence problem, but not for all cases. The dip still occurs at the aug-cc-pV5Z level for HF, $\mathrm{F}_{2}$, HOF , and $\mathrm{CO}_{2}$, but is less pronounced ( $<0.2 \mathrm{kcal} / \mathrm{mol}$ ). Additionally, the diffuse functions in the augmented correlation consistent basis sets cannot improve the convergence behavior of the atomization energies for $\mathrm{F}_{2}$ and $\mathrm{O}_{3}$.

### 2.3.4. Statistical Analysis

The mean error, mean absolute error (MAE), and normal distribution were utilized to compare the performance of the density functionals when used with the correlation consistent
basis sets. The mean energies are listed in Table 2.4 and normal distributions are plotted in Figs. 2.1 and 2.2. In terms of the mean errors, atomization energies are underestimated by B3LYP and B3PW91, whereas they are overestimated by the other four functionals. The best result is obtained using B3LYP and aug-cc-pV5Z, with a MAE of $2.19 \mathrm{kcal} / \mathrm{mol}$. For B3P86, BLYP, BPW91, and BP86, the results nearest to experiment are achieved at the double zeta level. The MAE gets larger when the basis set size increases.

Based on the normal distributions of the atomization energies of DFT with the correlation consistent basis sets, the hybrid density functionals B3LYP and B3PW91 perform much better than other density functionals. As the basis set size increases, both the accuracy (represented by the location of the peak) and precision (represented by the width of peak) improve. The curves become narrower and move towards experiment. For the pure functionals, improvement of accuracy and precision seem not to occur as the basis set size increases. The curves are not sensitive to the increase in the size of the basis set, and a broad error distribution remains for all levels of basis sets. The normal distribution curve of B3P86 at the double zeta level is similar to that of B3LYP and B3PW91 at the double zeta level. However, as the basis set size increases, the curves broaden and migrate away from the experiment.

Table 2.3 Calculated atomization energies in $\mathrm{kcal} / \mathrm{mol}$. The errors in the calculated atomization energies, as compared with experiment are provided in parenthesis.

### 2.3.5. Kohn-Sham Limit

The atomization energies have been extrapolated to obtain the Kohn-Sham limits for B3LYP and B3PW91, since these two functionals gave the smallest MAEs compared with experiments. Three extrapolation schemes have been used: an exponential extrapolation using double, triple, and quadruple zeta results marked as $\mathrm{KS}_{\text {DTQ }}$; the two-point scheme using double and triple zeta results $\mathrm{KS}_{\mathrm{DT}}$; and the two-point scheme using triple and quadruple zeta results $\mathrm{KS}_{\mathrm{TQ}}$. The results are summarized in Table 2.5 and 2.6. For $\mathrm{KS}_{\mathrm{DTQ}}$ and $\mathrm{KS}_{\mathrm{TQ}}$ with the $\mathrm{cc}-\mathrm{pVxZ}$ basis sets, $\mathrm{F}_{2}$ is not included due to its irregular convergence behavior.

Table 2.4 Mean absolute errors (MAE) and mean errors (ME) for the atomization energies in $\mathrm{kcal} / \mathrm{mol}$.

| Basis set | B3LYP | B3PW91 | B3P86 | BLYP | BPW91 | BP86 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
|  |  |  |  |  |  |  |
| MAE |  |  |  |  |  |  |
| cc-pVDZ | 8.09 | 8.96 | 3.40 | 7.91 | 8.11 | 10.86 |
| cc-pVTZ | 2.36 | 3.24 | 7.68 | 7.18 | 7.37 | 15.24 |
| cc-pVQZ | 2.19 | 2.38 | 8.68 | 7.32 | 7.46 | 16.11 |

| cc-pVDZ | -8.09 | -8.96 | 1.49 | 0.33 | 0.07 | 9.86 |
| cc-pVTZ | -1.88 | -3.01 | 7.68 | 5.79 | 5.33 | 15.24 |
| cc-pVQZ | -0.85 | -2.05 | 8.68 | 6.70 | 6.19 | 16.11 |
| cc-pV5Z | -0.76 | -1.95 | 8.81 | 6.65 | 6.16 | 16.12 |
|  |  |  |  |  |  |  |
| aug-cc-pVDZ | -5.69 | -6.42 | 4.20 | 2.01 | 2.00 | 11.85 |
| aug-cc-pVTZ | -1.53 | -2.61 | 8.17 | 6.11 | 5.53 | 15.51 |
| aug-cc-pVQZ | -0.69 | -1.90 | 8.88 | 6.74 | 6.23 | 16.20 |
| aug-cc-pV5Z | -0.66 | -1.87 | 8.90 | 6.73 | 6.23 | 16.19 |

When the results are extrapolated to the KS limit, the atomization energies are improved slightly. Overall, extrapolation does not provide a substantial improvement in accuracy for B3LYP. Among all extrapolation schemes, $\mathrm{KS}_{\mathrm{Dt}}$ performs the worst. However, extrapolation leads to a substantial improvement for B3PW91 in particular for $\mathrm{KS}_{\mathrm{DT}}$, which yields a MAE of $1.87 \mathrm{kcal} / \mathrm{mol}$. This may be interpreted by the fact that B3LYP overestimates the extrapolations of the atomization energy for almost half of the molecules, while for B3PW91, this is the case for only three molecules.

### 2.4 Conclusions

In summary, both structures and atomization energies converge rapidly with respect to increasing basis set size. Structures are nearly converged at the triple zeta level, while the atomization energies are nearly converged at the quadruple zeta level. B3LYP and B3PW91 with aug-cc-pV5Z give the best atomization energies, showing deviations of 2.19 and $2.24 \mathrm{kcal} / \mathrm{mol}$, respectively. For B3LYP and B3PW91, both the accuracy and the precision of the atomization energies are improved as the basis set size is increased. In contrast, the accuracy and precision of the atomization energies are not sensitive to the size of the basis set for B3P86, BLYP, BPW91, and BP86.

The atomization energies for a number of molecules do not converge with increasing the size of the standard correlation consistent basis sets. This is especially true when these basis sets are used with the pure density functionals BLYP, BPW91, and BP86. Generally, this irregular convergence appears as a slight energy dip at the quintuple zeta level. The augmented correlation consistent basis sets can alleviate these irregular convergence problems, but not for all cases.

Table 2.5 Kohn-Sham atomization energy limits for B3LYP using the cc-pVxZ and aug-cc-pVxZ basis sets, and utilizing several different extrapolation schemes. Additionally, the mean absolute error resulting from the use of each extrapolation scheme and basis set is reported. The energies are reported in $\mathrm{kcal} / \mathrm{mol}$.

${ }^{a}$ Experimental values are from Ref.[46]. ${ }^{\text {b }}$ Due to the near-linear convergence of $\mathrm{O}_{3}$ as the augmented basis set size is increased from aug-cc-pVDZ through aug-cc-pVQZ, the three-point extrapolations included the aug-cc-pVTZ, aug-cc-pVQZ, and aug-cc-pV5Z results. ${ }^{\text {c }}$ Due to the unusual behavior of $F_{2}$ atomization energies beyond the triple zeta level for the cc-pVxZ series, the $\mathrm{KS}_{\mathrm{DTQ}}$ and $\mathrm{KS}_{\mathrm{TQ}}$ extrapolations were not performed. ${ }^{\mathrm{d}}$ MAE was obtained omitting $\mathrm{F}_{2}$.

Figure 2.1 Normal distribution of the errors in the atomization energies with respect to experiment (the " 0 ") for the hybrid functionals B3LYP (a and b), B3P86 ( c and d), and B3PW91 (e and f ) with the cc-pVxZ and aug-cc-pVxZ basis sets.

Figure 2.2 Normal distribution of the errors in the atomization energies with respect to experiment (the "0") for the pure functionals BLYP (a and b), BP86 (c and d), and BPW91 (e and f) with the cc-pVxZ and aug-cc-pVxZ basis sets.

## CHAPTER 3

# THE PERFORMANCE OF DENSITY FUNCTIONALS <br> WITH RESPECT TO BASIS SET: POLARIZATION CONSISTENT BASIS SETS 

### 3.1 Introduction

As addressed in the last chapter, a simple and effective means to assess the performance of density functionals is needed. Such a means already exists for ab initio methods. The correlation consistent basis sets developed by Dunning and co-workers [15, 47-55] have proven to be an efficient tool in estimating the complete basis sets (CBS) limit, and then assessing the reliability of various theoretical approaches, as demonstrated by thousands of ab initio studies. However, the question is whether or not the correlation consistent basis sets can be used effectively when combined with density functional theory (DFT). In last chapter, we investigated the structures and energies of a series of molecules with potential importance in atmospheric chemistry using several popular density functionals and the correlation consistent basis sets. Unexpected convergence behavior in the atomization energies was observed for some functionals, however, the reason is not clear.

In this section, the performance of DFT with another type of systematically developed basis sets, the polarization consistent basis sets,[56] is examined. By comparing and analyzing the compositions and performance of these two types of basis sets, we try to understand the
reason for the unexpected convergence problem. A systematic sequence of basis sets, the polarization consistent basis sets $\mathrm{pc}-\mathrm{X}(\mathrm{X}=0,1,2,3,4)$, were developed by Jensen.[56] These basis sets were developed expressly for DFT via an analysis of the convergence of the total energy, using criteria similar to that used to develop the correlation consistent basis set. However, in contrast to the correlation consistent basis sets,[15] molecules were used as a target to optimize the exponents of the polarization functions since the polarization functions are not greatly dependent on the atomic DFT calculation. So far, the polarization consistent basis sets have been expanded to include the first-row and second-row atoms. In addition, a set of diffuse functions has been developed for the polarization consistent basis sets.[56-61]

Despite the fact that the polarization consistent basis sets were optimized for BLYP, it is not clear whether they can be applied to other density functionals in a systematic way. In this project, the convergence behavior of the polarization consistent basis sets, in combination with several popular functionals including BLYP,[6, 7] BPW91,[8] and BP86,[9] as well as B3LYP,[10] B3PW91, and B3P86, is investigated. To compare with the correlation consistent basis sets, we examine the structures and energies for the same set of molecules derived from Martell and Goddard's work[27] and discussed in Chapter 2 of this dissertation. Also, a full statistical error analysis is performed to understand the accuracy and the precision of structures and energies with respect to increasing basis set size.

### 3.2. Methodology

The basis sets used throughout the current project are the polarization consistent basis sets including pc-X $(\mathrm{X}=1,2,3,4)$. pc-1 was compared with cc-pVDZ because they have the same highest angular momentum; likewise pc-2 was compared with cc-pVTZ, etc. The pc-0
basis set was excluded because it is a single-zeta level basis set, and there is no single-zeta basis set for the correlation consistent basis set series. The density functionals include three pure functionals: BLYP, BPW91, and BP86, as well as three hybrid functionals: B3LYP, B3PW91, and B3P86. Geometry optimization and frequency calculations were carried out for each combination of the polarization consistent basis sets and density functionals. Zero point corrections were obtained from frequency calculations and are included in the atomization energies. All calculations were performed using the Gaussian 98 software package.[35] The default numerical grid $(75,302)$ was used to evaluate the exchange-correlation integral, and a tight convergence criterion on density was requested when calculating the total energies for the atoms. Two empirical extrapolation schemes, an exponential and a two-point extrapolation scheme, were utilized to extrapolate the Kohn-Sham (KS) limit. Both schemes were discussed in the "Methodology" section of the last chapter.

### 3.3 Results and Discussions

### 3.3.1. Geometry

Overall, the convergence of geometries, listed in Table 3.1, is fast with increasing basis set size, and the geometries reach near convergence at the pc-2 level. The bond lengths are within $0.02 \AA$ of experiment, while the bond angles are within $2^{\circ}$ of experiment at the $\mathrm{pc}-2$ level. The exceptions in bond length include: the $\mathrm{O}-\mathrm{O}$ bond in $\mathrm{O}_{3}$ and the $\mathrm{H}-\mathrm{N}$ bond in HNO for all hybrid functionals; the $\mathrm{O}-\mathrm{O}$ bond in $\mathrm{H}_{2} \mathrm{O}_{2}$, the $\mathrm{O}-\mathrm{F}$ bond in HOF , and the $\mathrm{F}-\mathrm{F}$ bond in $\mathrm{F}_{2}$ for B3PW91, B3P86, and BLYP; the H-O bond in HOF for all pure functionals; the $\mathrm{N}-\mathrm{N}$ bond in

Table 3.1 Optimized bond lengths and angles. Bond lengths are given in angstroms, and bond angles are given in degrees.

$\mathrm{N}_{2} \mathrm{H}_{4}$ for B3P86; and the C-F bond in $\mathrm{CH}_{3} \mathrm{~F}$ for BLYP. For bond angles, the exceptions include: the $\mathrm{O}-\mathrm{O}-\mathrm{O}$ angle in $\mathrm{O}_{3}$ for all functionals; the $\mathrm{H}-\mathrm{O}-\mathrm{O}$ angle in $\mathrm{H}_{2} \mathrm{O}_{2}$ and the $\mathrm{H}-\mathrm{O}-\mathrm{F}$ angle in HOF for all hybrid functionals; the $\mathrm{H}-\mathrm{N}-\mathrm{N}$ angle in $\mathrm{N}_{2} \mathrm{H}_{4}$ for all pure functionals. Additionally, the dihedral angle converges slightly slower than the bond angles. For example, the error at the pc-2 is about $2.5-5.6^{\circ}$ for $\mathrm{H}_{2} \mathrm{O}_{2}$, but with the larger basis set, pc-3, the error reduces to $0.5^{\mathrm{o}}$. Thus, it appears that at least a quadruple zeta level basis set should be used to reach convergence of the dihedral angle.

### 3.3.2. Atomic Energy

The total energies of hydrogen and four first-row atoms are listed in Table 3.2 with their respective Davidson energies.[45] Overall, B3PW91 results in the best agreement with Davidson energies for nitrogen, oxygen, and fluorine using the pc-3, or higher basis set. Differences of about 0.004 hartree for nitrogen, about 0.002 hartree for oxygen, and about 0.004 hartree for fluorine are observed. For the hydrogen, the smallest difference is about 0.0002 hartree using BP86 with the pc-2 or higher basis sets. Both BPW91 and BP86 result in an error of no more than 0.004 hartree for the carbon when using the pc-2 or higher basis sets. Interestingly, the B3LYP errors are higher for all atoms but hydrogen.

Table 3.2 Total energies for atoms given in hartrees.

### 3.3.3. Atomization Energy

As shown in Table 3.3, most of the atomization energies converge with respect to increasing size of the basis set. Basis set limits are nearly reached at the pc-3 level. The atomization energies of seven molecules were overestimated by B3LYP at the pc-4 level. In fact, the largest errors for B3LYP at the pc-4 level include $\mathrm{O}_{3}(-5.70 \mathrm{kcal} / \mathrm{mol}), \mathrm{CO}(-3.64 \mathrm{kcal} / \mathrm{mol})$, HOF ( $-2.78 \mathrm{kcal} / \mathrm{mol}$ ), $\mathrm{CH}_{3} \mathrm{NH}_{2}(2.45 \mathrm{kcal} / \mathrm{mol}), \mathrm{N}_{2} \mathrm{H}_{4}(5.97 \mathrm{kcal} / \mathrm{mol})$, and $\mathrm{CH}_{3} \mathrm{~F}(-4.36$ $\mathrm{kcal} / \mathrm{mol}$ ). Unlike B3LYP, only the atomization energies of two molecules are overestimated by B3PW91 at the pc-4 level. The errors are $2.43 \mathrm{kcal} / \mathrm{mol}$ for $\mathrm{CO}_{2}$ and $0.81 \mathrm{kcal} / \mathrm{mol}$ for $\mathrm{N}_{2} \mathrm{H}_{4}$. At the pc-4 level, molecules with atomization energies that are accurate to within $1 \mathrm{kcal} / \mathrm{mol}$ include: $\mathrm{HCN}(-0.90 \mathrm{kcal} / \mathrm{mol}), \mathrm{HNO}(-0.80 \mathrm{kcal} / \mathrm{mol}), \mathrm{H}_{2} \mathrm{CO}(-0.12 \mathrm{kcal} / \mathrm{mol}), \mathrm{CH}_{3} \mathrm{NH}_{2}(-0.02$ $\mathrm{kcal} / \mathrm{mol})$, and $\mathrm{N}_{2} \mathrm{H}_{4}(0.81 \mathrm{kcal} / \mathrm{mol})$. B3P86, BLYP, BPW91, and BP86 overestimate the atomization energy for most of molecules. The energies of those molecules are closest to experiment at the pc-1 level, with the energy deviating further from experiment with increasing basis set size. The atomization energy of $\mathrm{CH}_{3} \mathrm{NH}_{2}$ shows the maximum error for B 3 P 86 , while the maximum error for the three pure functionals arises from the atomization energy of $\mathrm{O}_{3}$.

The irregular convergence problem noted in the study of DFT with the correlation consistent basis sets also occurs for the polarization consistent basis sets. The atomization energies of several molecules such as $\mathrm{HF}, \mathrm{HOF}, \mathrm{F}_{2}, \mathrm{CO}, \mathrm{CO}_{2}$, and $\mathrm{H}_{2} \mathrm{CO}$ have a slight dip at the pc-4 level. The dips ( $<0.05 \mathrm{kcal} / \mathrm{mol}$ ) are much less pronounced than those observed for the correlation consistent basis sets. Interestingly, the irregular convergence behavior of $\mathrm{F}_{2}$ observed with the correlation consistent basis sets in the last project does not occur when using the polarization consistent basis sets. A possible reason for this may be from the scheme in developing the polarization consistent basis sets, in which $\mathrm{F}_{2}$ was used as a target molecule to
optimize the basis functions. However, the relative size of the basis sets should be considered when making this comparison. The primitive and contracted functions of hydrogen and four firstrow atoms for each level of the two basis sets are provided in Table 3.4.

For hydrogen, the polarization consistent basis sets have the same or more contracted functions than the correlation consistent basis sets. This is also the case for the uncontracted functions. The difference between uncontracted functions in both basis sets becomes more substantial in the larger basis sets. For example, the polarization consistent basis sets have one additional primitive $p$ function at the $\mathrm{pc}-3$ level and two additional primitive $p$ functions at the pc-4 level compared with the correlation consistent basis sets. The difference in both basis sets for first-row atoms is similar to that of hydrogen, except that the difference includes not only $s$ and $p$ functions, but also a higher angular momentum $d$ function for both contracted and uncontracted functions. Considering that the correlation consistent basis sets and the polarization consistent basis sets were developed for $a b$ initio and DFT, respectively, as well as the fact that DFT converges faster than $a b$ initio methods, the difference in the composition of each type of basis set is surprising. However, it is this difference in composition that leads to a slightly better convergence behavior for the polarization consistent basis sets. Although neither of the sets is necessarily ideal for DFT since a slight energy dip still exists for the polarization consistent basis sets.

Table 3.3 Calculated atomization energy in $\mathrm{kcal} / \mathrm{mol}$. The difference in the atomization energy, relative to experiment, is reported in parentheses.

### 3.3.4. Statistical Analysis

The mean errors (ME) and mean absolute errors (MAE) of the atomization energy are shown in Table 3.5. For B3LYP and B3PW91, the MAE decreases as the basis set size increases, with the smallest MAEs being 2.19 and $2.23 \mathrm{kcal} / \mathrm{mol}$, respectively. The other four density functionals follow a reverse trend: the MAE increases as the basis set size increases. B3P86 results are in best agreement with experiments at the pc-1 level, while the MAEs worsen when a larger basis set is used. BP86 overestimates almost all atomization energies, which leads to similar MEs and MAEs for each basis set level.

The MAEs of the atomization energies for the correlation consistent basis sets are also summarized in Table 3.5 for comparison with the polarization consistent basis sets. Although the difference in composition is substantial, similar performance is achieved for both basis sets, and both basis sets converge to the same basis set limit. However, the MAEs are slightly less for the polarization consistent basis sets than for the correlation consistent basis sets. For example, the differences in MAE between pc-4 and cc-pV5Z are $0.03 \mathrm{kcal} / \mathrm{mol}$ for B3LYP and 0.08 $\mathrm{kcal} / \mathrm{mol}$ for B3PW91.

The normal distributions for the atomization energy as compared with experimens are plotted in Figure 3.1 for the six density functionals with the polarization consistent basis sets. The advantage of the normal distribution is its ability to assess the precision (width of the peak) and the accuracy (location of the peak with respect to experiment) through visualization. The normal distribution curves for the polarization consistent basis sets are similar to those for the correlation consistent basis sets. For the hybrid functionals B3LYP and B3PW91, the peak narrows and moves towards to experiment as the basis set size increase. Thus, both the accuracy and the precision are improved. The normal distribution of B3P86 differs from other hybrid
functionals: the width of peak remains unchanged and the location of the peak moves further away from experiment when increasing the basis set size. Unlike B3LYP and B3PW91, the normal distributions of all pure functionals are not sensitive to basis set choice. Increasing the basis set size does not change the wide error distribution ( $\sim 40 \mathrm{kcal} / \mathrm{mol}$ ) and the location of the peak.

### 3.3.5. Kohn-Sham Limit

Since B3LYP and B3PW91 result in the smallest MAEs in the atomization energies compared with experiment at the pc-4 level, these two functionals were used to extrapolate to the KS limit. The two empirical extrapolation schemes, which were outlined in the previous project description, were used to obtain KS limits and are listed in Table 3.6 and 3.7. The notations for the different extrapolation methods are: the exponential scheme $\mathrm{KS}_{1234}$ using $\mathrm{pc}-1$, $\mathrm{pc}-2$, $\mathrm{pc}-3$, and $\mathrm{pc}-4$; the exponential scheme $\mathrm{KS}_{123}$ using $\mathrm{pc}-1$, $\mathrm{pc}-2$, and $\mathrm{pc}-3$; the exponential scheme $\mathrm{KS}_{234}$ using pc-2, pc-3, and pc-4; the two-point scheme $\mathrm{KS}_{12}$ using $\mathrm{pc}-1$ and $\mathrm{pc}-2$; and the twopoint scheme $\mathrm{KS}_{23}$ using $\mathrm{pc}-2$ and $\mathrm{pc}-3$.

For all extrapolation methods, $\mathrm{KS}_{23}$ provides the best agreement with experiment for B3LYP, with a deviation of $2.07 \mathrm{kcal} / \mathrm{mol}$, which was only $0.12 \mathrm{kcal} / \mathrm{mol}$ less than the MAE at the pc-4 level. The $\mathrm{KS}_{12}$ method is the only one in which the MAE of extrapolation is higher than the pc-4 level for B3LYP. However, it does perform best for B3PW91, with an extrapolated atomization energy that is $0.47 \mathrm{kcal} / \mathrm{mol}$ lower than the MAE at the pc-4 level. Different from the two-point scheme, whose performance depends on the individual functional, the exponential schemes perform consistently. A slight improvement is always achieved for exponential methods, no matter whether B3LYP or B3PW91 is used.

Figure 3.1 Normal distribution of the errors in the atomization energies with respect to experiment (the "0") for DFT methods B3LYP (a), BLYP (b), B3PW91 (c), BPW91 (d), B3P86 (e), and BP86 (f) with the pc-X basis sets.

|  |  |  |  |  |  |  |

### 3.4. Conclusions

For all density functionals studied, the geometries are nearly converged at the $\mathrm{pc}-2$ level. However, a basis set of at least pc-3 should be used to reach near convergence for the atomization energy. In general, the polarization consistent basis sets have more contracted and uncontracted functions than the correlation consistent basis sets, especially for the larger basis sets. This difference helps to lead to a slightly better convergence behavior for the polarization consistent basis sets with DFT. However, an unusual convergence problem, observed in the earlier study with the correlation consistent basis sets, occurs for the polarization consistent basis
sets as well, though the energy dip at the pc-4 level is less pronounced. The B3LYP and B3PW91 functionals perform best, with a MAE of $\sim 2 \mathrm{kcal} / \mathrm{mol}$ for atomization energies. The normal distribution of atomization energies for the six functionals shows that, for B3LYP and B3PW91, both the accuracy and the precision are improved as the basis set size increases. However, no improvement was observed for pure functionals with respect to basis set size.

Table 3.6 Kohn-Sham atomization energy limits and mean absolute errors for B3LYP determined using the pc-X basis sets and several different extrapolation schemes. The energies are reported in $\mathrm{kcal} / \mathrm{mol}$.

## CHAPTER 4

## THE PERFORMANCE OF DENSITY FUNCTIONALS

WITH RESPECT TO BASIS SET:

## BASIS SET CONTRACTION AND UNCONTRACTION

### 4.1 Introduction

In our earlier work (Chapter 2), several density functionals in conjunction with the correlation consistent basis sets were used to determine the structures and energies of a series of 17 molecules.[62] The convergence of the atomization energies toward the Kohn-Sham limit with respect to increasing basis set size was examined. We noted irregular convergence of atomization energies as the basis set size increases for a number of widely used density functionals. A similar problem was also observed in a previous study by Sekusak and Frenking, in which reaction enthalpies of the hydrogenation reaction of $\mathrm{N}_{2}$ were determined using several functionals.[33] A possible reason for this irregular convergence has been attributed to the construction of the correlation consistent basis sets, considering that the basis sets were optimized using CISD,[15] and it is not clear whether basis sets, derived from an ab initio method, are optimal for use with density functional theory. To understand this issue further, recently developed basis sets, the polarization consistent basis sets,[56, 58] have been utilized to carry out a parallel study (Chapter 3) to our correlation consistent benchmark study (Chapter 2). Analogous to the correlation consistent basis sets, the polarization consistent basis sets are
comprised of a systematically constructed series of basis sets, but they were optimized explicitly for density functional theory. As compared with the correlation consistent basis sets, the polarization consistent basis sets improve the irregular convergence problem of energetic properties with respect to increasing basis set size noted in our earlier studies, though it is not the solution for all irregular convergence cases noted previously. This improvement is partly related to the size of the polarization consistent basis sets, which have more basis functions than the correlation consistent basis sets at the triple-, quadruple-, and quintuple-zeta levels.

As addressed in the introduction to this thesis (Chapter 1), the correlation consistent basis sets may be a potential means to understand the performance of density functionals and develop a hierarchy of density functional approaches. Therefore, it is important to understand the underlying non-convergent behavior of energetics with respect to increasing size of the correlation consistent basis set. One possible reason is grid size. Inappropriate selection of grid size could result in unusual behavior of molecular properties. However, our calculations have ruled it out as a cause of the irregular convergence. Several other possibilities that could lead to the irregular convergence have been investigated. In this study, we will focus on the contraction of the basis sets.

Basis set contraction has been utilized in almost all popular basis sets. Through the contraction of some of the basis functions that are important in the description of energetic properties, but not important in the description of bonding, the efficiency of a calculation can be improved. In general, basis functions that describe core electrons are contracted, as core electrons are important in the overall energetics, but are less important in chemical bonding. The basis functions needed for the description of core electrons consist of a large number of functions, which play a critical role in describing the cusp that exists in the wavefunction near
the nucleus. However, as a consequence of contraction, the basis sets are less flexible, and there is often a slight increase in total energy.

Generally, two types of contraction schemes are used in the construction of basis sets: the general contraction scheme[63] and the segmented contraction scheme. In the general contraction scheme, each contracted basis function contains almost all the primitive functions. A typical example of a basis set, in which the general contraction scheme has been employed, is the correlation consistent basis set. In the segmented contraction scheme, the primitive functions included in the contracted function are different for each contracted basis function. A typical example is Dunning's [5s3p] basis set.[64]

In this study, we investigated the impact of basis set contraction on the convergence behavior of atomization energy. The performance of two density functionals, B3LYP and BLYP, is evaluated with respect to increasing size of the correlation consistent basis sets. Several different contraction schemes are examined.

### 4.2 Methodology

Two density functionals, BLYP and B3LYP, were selected based upon our previous work, and were used to investigate the effect of basis set uncontraction on convergence of atomization energies. In our previous study, irregular convergence of atomization energies with respect to increasing size of the correlation consistent basis set was observed for a number of molecules. Though irregular convergence of the atomization energies has been observed using all functionals studied to date, we narrow our focus to BLYP and B3LYP in this investigation, as they are representative examples of functional performance. As in our first and second chapters, the calculations are carried out on the same 17 closed-shell first-row molecules.

Table 4.1 The composition of primitive and contracted basis set size for correlation consistent for hydrogen and the first row atoms, boron through neon.

| Basis Set | Hydrogen <br> Primitive | Contracted | First Row Atoms <br> Primitive | Contracted |
| :--- | :--- | :--- | :--- | :--- |
|  |  |  |  |  |
| cc-pVDZ | $4 s 1 p$ | $2 s 1 p$ | $9 s 4 p 1 d$ | $3 s 2 p 1 d$ |
| cc-pVTZ | $5 s 2 p 1 d$ | $3 s 2 p 1 d$ | $10 s 5 p 2 d 1 f$ | $4 s 3 p 2 d 1 f$ |
| cc-pVQZ | $6 s 3 p 2 d 1 f$ | $4 s 3 p 2 d 1 f$ | $12 s 6 p 3 d 2 f 1 g$ | $5 s 4 p 3 d 2 f 1 g$ |
| cc-pV5Z | $8 s 4 p 3 d 2 f 1 g$ | $5 s 4 p 3 d 2 f 1 g$ | $14 s 8 p 4 d 3 f 2 g 1 h$ | $6 s 5 p 4 d 3 f 2 g 1 h$ |

As has been discussed in the introduction to this chapter, the general contraction scheme is used in the correlation consistent basis sets. As seen in Table 4.1, for the cc-pVDZ basis set of non-hydrogen atoms, the general contraction of the $9 s 4 p$ primitive functions contracts to [2s1p] and keeps the outermost primitive $s$ and $p$ function uncontracted (each contracted $s$ function comes from the same nine $s$ primitive functions, and each contracted $p$ function comes from the same four $p$ primitive functions). As a result, the $s p$ part of cc-pVDZ is $[3 s 2 p]$ and the contraction can be denoted as $\{9,9,1 / 4,1\}$ (in this notation, before "/", two " 9 "s are the number of primitive $s$ functions in the first and second contracted $s$ functions, respectively, and " 1 " is the number of primitive $s$ functions in the third contracted $s$ function. Likewise, after " $\rho$ ", " 4 " is the number of primitive $p$ functions in the first contracted $p$ function and " 1 " is the number of $p$ functions in the second contracted $p$ function) for $s$ and $p$ functions, respectively. The primitive functions that are contracted are weighted with contraction coefficients, which are taken from the atomic orbital coefficients for the $1 s, 2 s$ and $2 p$ atomic orbital at the Hartree-Fock level. The ccpVTZ contracts $10 s 5 p$ to $[2 s 1 p]$ and leaves the first and third outermost $s$ and two outermost $p$ primitive functions uncontracted, with a contraction $\{10,10,1,1 / 5,1,1\}$, which forms a $s p$ part of
[ $4 s 3 p]$. Likewise, the contractions for cc-pVQZ and cc-pV5Z are $\{12,12,1,1,1 / 6,1,1,1\}$ with three outermost $s$ and $p$ primitive functions uncontracted and $\{14,14,1,1,1,1 / 8,1,1,1,1\}$ with four outermost $s$ and $p$ primitive functions uncontracted, respectively. Finally, the polarization functions with high angular momentum $(d, f, g, h)$, which are optimized from CISD methods, (1d) for cc-pVDZ, ( $2 d 1 f$ ) for cc-pVTZ, $(3 d 2 f 1 g)$ for cc-pVQZ, and $(4 d 3 f 2 g 1 h)$ for cc-pV5Z, are combined with the $s p$ part to form the standard correlation consistent basis sets. The basis sets for hydrogen atom take the similar contraction scheme, with the difference in that only $s$ primitive functions are contracted and all $p$ functions keep uncontracted.

In this study, the standard correlation consistent basis sets are uncontracted according to several different procedures. The first type of uncontraction is a complete uncontraction of the $s$ and $p$ contracted functions, resulting in $(9 s 4 p 1 d)$ for $\mathrm{cc}-\mathrm{pVDZ}$, $(10 s 5 p 2 d 1 f)$ for $\mathrm{cc}-\mathrm{pVTZ}$, $(12 s 6 p 3 d 2 f 1 g)$ for cc-pVQZ, and $(14 s 8 p 4 d 3 f 2 g 1 h)$ for cc-pV5Z. A second type of uncontraction involves only the uncontraction of the $s$ functions, with the contracted $p$ functions unchanged. For the contracted $s$ functions, the outermost primitive function was uncontracted first, and then continuing inward until the basis set is completely uncontracted. For example, the resulting contraction scheme from partially uncontracting cc-pVDZ include: $\{8,8,1\},\{7,7,1,1\}$, $\{6,6,1,1,1\},\{5,5,1,1,1,1\}$ and so on. When the first primitive $s$ function is uncontracted from ccpVDZ , it is the exactly same uncontracted $s$ function already included in the standard cc-pVDZ set. Thus, the first uncontracted function is removed from the basis set in order to avoid having multi basis functions with same exponents in the calculations, and the contraction scheme is $\{8,8,1\}$ rather than $\{8,8,1,1\}$.

We performed single point energy calculations on atoms and molecules with each partially uncontracted basis set. Same to the calculations in previous chapters, all single point
energy calculations request the full convergence by setting the convergence criteria to $10^{-8}$ on density. The energy calculations on the molecules, which used the uncontracted basis sets, were based on the structure optimized using the standard correlation consistent basis sets since the partially uncontracted basis sets cause very little effect on the optimized geometries of the molecules. All calculations were carried out using the Gaussian 98 package.

### 4.3 Results and Riscussion

### 4.3.1 The Contraction Errors of DFT with the Correlation Consistent Basis Sets

As shown in Tables 4.2 and 4.3, atomic energies for $\mathrm{H}, \mathrm{C}, \mathrm{N}, \mathrm{O}$, and F , and atomization energies of several molecules $\left(\mathrm{N}_{2}, \mathrm{CO}, \mathrm{O}_{3}, \mathrm{H}_{2} \mathrm{O}\right.$, and HCN$)$ were calculated using BLYP with the standard correlation consistent basis sets and with the basis sets uncontracted as discussed in the previous section. The molecules were chosen due to the convergence behaviors of their atomization energies with respect to increasing basis set size observed in earlier studies by Wang and Wilson.[62] For the hybrid functional B3LYP, the atomization energies of $\mathrm{H}_{2} \mathrm{O}$ and $\mathrm{N}_{2}$ converge smoothly as the basis set size increases, while a slight energy dip occurs at the quintuple zeta level for $\mathrm{CO}, \mathrm{O}_{3}$, and HCN . When the pure functional BLYP is used, irregular convergence even gets worse, with an energy dip at the quintuple zeta level for $\mathrm{N}_{2}$, CO , and HCN and an irregular convergent behavior for $\mathrm{O}_{3}$. The contraction errors in the energies relative to the energies calculated using the standard contracted correlation consistent basis sets are also summarized in the tables. Overall, the contraction error is generally small for both the atomic energy and the atomization energies for higher-level basis sets, but more substantial at the double and triple zeta levels. For example with the F atom, the contraction error of the atomic energy is -6.07 mH at the double zeta level, and is decresed to -0.33 mH at the quintuple zeta level. For
$\mathrm{H}_{2} \mathrm{O}$, the contraction error of the atomization enery is $3.74 \mathrm{kcal} / \mathrm{mol}$ at the double-zeta level, while the contraction error is reduced to zero at the quadruple zeta level. As seen in Table 4.3, the completely uncontracted basis set cannot improve the convergence behavior of the atomization energy. The only change arises for $\mathrm{O}_{3}$. For completely uncontracted basis sets, the $\mathrm{O}_{3}$ atomization energies at the double-zeta level is smaller than that at the triple-zeta level, whereas the atomization energy at double-zeta level is larger than that at the triple-zeta level for the standard correlation consistent basis sets.

Table 4.2 The effect of the uncontraction of the correlation consistent basis sets on the BLYP atomic energies. The atomic energies are reported in Hartree $\left(\mathrm{E}_{\mathrm{h}}\right)$, while the change in the atomic energy arising from use of the uncontracted basis set is reported in millihartree $\left(\mathrm{mE}_{\mathrm{h}}\right)$.

|  |  |  |  |  |  |  |

As discussed, an uncontraction of only the $s$ functions was also examined, and the results for atomization energies are presented in Table 4.4. This uncontraction seems to have an effect upon the convergence behavior of the atomization energy, although the contraction error is still small. The impact is reflected as a decrease in the atomization energy at the quadruple-zeta level, while there is little change at the quintuple-zeta level. As a result, the energy dip at the quintuplezeta level present with the contracted sets was reduced or eliminated with the uncontracted sets. For example, using BLYP in combination with the uncontracted sets results in a well-behaved convergence occurs for $\mathrm{N}_{2}$ and a reduced energy dip for HCN. Furthermore, the irregular convergence of $\mathrm{O}_{3}$ atomization energy is improved, although the convergence is still not smooth.

Table 4.4 The effect of the uncontraction of $s$ functions on the BLYP atomization energy (in $\mathrm{kcal} / \mathrm{mol}$ ). Both the atomization energies and the change in atomization energy arising from the uncontraction are reported in $\mathrm{kcal} / \mathrm{mol}$

In order to better understand the impact of the uncontraction of the $s$ sets on the convergence of atomization energy, the variation of atomic energy with respect to the number of uncontracted $s$ functions was examined. Figure 4.1 and Figure 4.2 illustrate the total energy of N and $\mathrm{N}_{2}$ for each partially uncontracted basis sets, respectively. For double-, triple-, and quadruple-zeta level basis sets, the total energy decreases as the first several $s$ functions are uncontracted. The lowest atomic energy was observed as the fifth $s$ primitive function is uncontracted. After that, the energy remains constant. In contrast to the behavior noted for the other level of basis sets, little change occurs in the atomic energy with the quintuple-zeta level basis set. As a result, there is a faster convergence of the atomic energy for the uncontracted basis set than for the standard basis sets. As a test of the convergence rate, we calculated the difference between two atomic energies calculated with two next basis set levels, and listed them in Table 4.5. The data in Table 4.5 demonstrates that acceleration of the convergence is mainly expressed at the quadruple- and quintuple-zeta levels since the atomic energy at the quintuplezeta level is insensitive to the basis set uncontraction. Considering that the energy dip observed in earlier work occurs at the quintuple-zeta level, it indicates that uncontraction may help to remedy the irregular convergence problem. Unfortunately, this does not occur for all molecules.

4.3.3 The Effect of Partially Uncontracted Basis Sets on the Convergence

Although the reason for the irregular convergence problem is not fully understood, an observation can be made that, as compared with the convergence rate of the total energy of molecules, the convergence of atomic energy is slower. It is this difference in the convergence rate that contributes to a slight energy dip at the quintuple-zeta level. The convergence rate of total energy represent the ability to recover the DFT energy. A means to accelerate the convergence of the atomic energy may reduce the observed convergence problem in the atomization energy. This idea is tested by a use of dual basis set approach, using the
uncontracted basis sets to calculate the atomic energies and standard basis sets to calculate total energies for the molecules. The equation below is proposed as a possible means to calculate the atomization energy. Indeed, we need only the partially uncontracted basis sets rather than completely uncontracted basis sets since more than five $s$ primitive functions, contribute little to the atomic energy, while increasing the computational expense of the calculation. The compositions of the suggested partially uncontracted (noted uc-cc-pVxZ) basis sets are: uc-ccpVDZ: $7 s 2 p 1 d$; uc-cc-pVTZ: $7 s 3 p 2 d 1 f$; uc-cc-pVQZ: $7 s 4 p 3 d 2 f 1 g$; uc-cc-pV5Z: $7 s 5 p 4 d 3 f 2 g 1 h$.

$$
\Delta \mathrm{E}=\mathrm{E}_{A B}-\left(\mathrm{E}_{u c A}+\mathrm{E}_{u c B}\right)
$$

This dual basis set approach improves the convergence behavior of atomization energy for all molecules studied. The atomization energies of CO from the dual basis set approach are compared with those from the standard correlation consistent basis sets, as shown in Figure 4.3. The largest change are observed at the double-, triple- and quadruple-zeta basis set levels, with little difference observed at the quintuple-zeta level. The lowering of energies results in a betterbehaved convergence of atomization energies.

This dual basis set approach was also applied to B3LYP. In our earlier work, the best agreement with experiment was observed for B3LYP, as was the smoothest convergence behavior. Therefore, it is important to examine whether or not the proposed approach is still useful. The mean absolute errors (MAE) of the atomization eneries obtained with the standard sets and the dual basis set approach were listed in Table 4.6, and MAE of the Kohn-Sham limits obtained by using several extrapolation schemes were also included in Table 4.6. Using this dual basis set approach improves the convergence of atomization energies for all 17 molecules. however, relative to the MAE arising from the standard sets, the dual basis set approach
increases the MAE of atomization energy, in particular at the lower-level basis sets. At the double-zeta level, the MAE arising from dual basis set approach is $10.13 \mathrm{kcal} / \mathrm{mol}, 2.04 \mathrm{kcal} / \mathrm{mol}$ larger than MAE from standard sets. With increasing basis set size, the difference between MAEs arsing from two basis sets gets smaller, with a $0.11 \mathrm{kcal} / \mathrm{mol}$ difference at the quintuplezeta level. Among all extrapolation schemes used, $\mathrm{KS}_{\mathrm{Q} 5}$ results in the best agreement with experiments for the dual basis set approach. However, $\mathrm{KS}_{\mathrm{Q} 5}$ cannot be obtained for the standard sets due to the energy dip occurred at the quintuple-zeta level.

Figure 4.3 A comparison of the CO atomization energies calculated using standard and partially uncontracted correlation consistent basis sets. The atomization energy is in $\mathrm{kcal} / \mathrm{mol}$.

Table 4.6 Mean absolute errors of the atomization energy computed by B3LYP with partially uncontracted correlation consistent basis sets and of the Kohn-Sham atomization energy limits utilizing several different extrapolation schemes are provided. The corresponding results with the standard correlation consistent basis sets are also included for comparison. The energy is in $\mathrm{kcal} / \mathrm{mol}$.

### 4.4 Conclusions

The contraction error from DFT with the correlation consistent basis sets is small in general, and the maximum error is obtained at the double zeta level. Though the contraction error is relatively small. the uncontracting $s$ functions help to reduce the previously noted convergence problem in the atomization energy with respect to increasing basis set size, but not for all molecules. Based on a analysis of the total energies of atoms and molecules, it is found that the energy dip results from the different convergence rate of total energies for atoms and molecules. The uncontraction of inner $s$ functions accelerates the convergence of atomic energy. A dual basis set approach is proposed to reduce the convergence problem. Our results indicate that this approach improves the convergence behavior with slight impact on the accuracy.

## CHAPTER 5

# THE PERFORMANCE OF DENSITY FUNCTIONALS <br> WITH RESPECT TO BASIS SETS: <br> THE DIFFUSE $S$ AND $P$ FUNCTIONS 

### 5.1 Introduction

In the preceding chapters we examined the convergence of molecular properties with respect to the correlation consistent basis sets[15] for a series of molecules in the context of DFT. An unexpected convergence behavior was noted, especially for the pure density functionals. Using the augmented correlation consistent basis sets (aug-cc-pVxZ)[54] can help reduce the convergence problem, but not for all cases. Another means to reduce the convergence problems is via an uncontraction of the basis sets, though this does not provide a solution for all molecules. In the course of these studies, we found that the convergence problem for atomization energies arises from the relatively slow convergence rate of the total energies of the atoms, as compared with that of the molecule. Based on our prior calculations and analysis, it is evident that the unusual convergence behavior may be related to the construction of the correlation consistent basis sets. However, in addressing the convergence problem in terms of basis set construction, the best means is not clear - whether or not additional polarization or diffuse functions are needed, and, whether higher or lower angular momentum functions are needed. The general observations regarding basis set performance with respect to DFT suggests that lower
angular momentum functions will be more important. This chapter examines the impact of the correlation consistent basis sets augmented with low and high angular momentum diffuse functions on the convergence of energies and structures.

For anionic systems, additional diffuse functions (functions with small exponents) are necessary for accurate calculations with $a b$ initio or DFT methods.[54] Diffuse functions are required for describing molecular properties, like electron affinity, which rely on an accurate description of the wavefunction tail. Diffuse functions are included in a wide variety of basis sets such as $6-31+\mathrm{G}[65]$ and $\mathrm{DZP}++[66]$. The augmented correlation consistent basis sets (aug-cc$\mathrm{pV} x \mathrm{Z}$ ) were proposed in a study by Kendall, Dunning and Harrison,[54] and are one of the most popular basis sets with diffuse functions used today. In this study, Kendall et al. reported electron affinities for a series of first-row atoms and molecules using the multi-reference configuration interaction with single and double excitations (MRCISD) method in combination with the augmented correlation consistent basis sets. They noted that the addition of a set of diffuse functions to the standard basis sets (a diffuse function for each angular momentum type within a standard basis set - i.e., the aug-cc-pVTZ basis set includs diffuse $s, p, d$, and $f$ basis functions) was critical for accurate descriptions of the electron affinity of anions. Among the angular momentum diffuse functions ( $s, p, d, f, g$, and $h$ ), the improvement in the description of electron affinity due to the addition of $s$ and $p$ functions is dominant, and the addition of other diffuse functions ( $d, f, g$, and $h$ ) has a less substantial effect on the calculated electron affinities.

The polarization consistent basis sets,[56] designed explicitly for DFT, and discussed in an earlier chapter (Chapter 3) of this dissertation, also have an augmented form.[59] Unlike the correlation consistent basis sets, these sets, which were introduced after the current study was completed, simply include $s$ and $p$ diffuse functions.

A number of previous studies have shown that density functionals perform well for electron affinity predictions. [30, 67-69] For example, BLYP gave average errors of $\sim 0.2 \mathrm{eV}$ for a set of small molecules. [70] However, it is surprising that several density functionals predicted positive HOMO energies for stable bound anionic systems, [71-73] which indicates that, according to Koopmans' theorem, an anionic system is not stable and prone to loose an electron. Studies by Perdew et al. attribute this controversy to the self-interaction error, $[67,74,75]$ which is the error resulting from the Coulomb and exchange interaction of an electron with itself, which can be cancelled out in the context of $a b$ initio, but not in DFT. As a result, electron density decays exponentially, rather than a physically correct decay of $1 / \mathrm{r}$ ( r is the distance of the electron from the nucleus). For anionic systems, which contain an additional electron, the selfinteraction error is more severe and is reflected as the HOMO energy increases to become positive in the Kohn-Sham scheme of DFT.

Since the Schaefer group discussed the positive HOMO energy calculated with DFT for anionic systems in 1996, [69] an extended investigation on whether DFT is applicable to these systems has been carried out by several groups. Galbraith and Schaefer examined the F and $\mathrm{F}_{2}$ electron affinities and HOMO energies at the complete basis set limit using several density functionals with the augmented correlation consistent basis sets. [76] It was found that the extra electron in $\mathrm{F}^{-}$did show tendency to remain bound even though the HOMO energy was positive. They concluded that Koopmans' theorem may not be applied to DFT in determining the electron affinity for anionic systems. In a later study by Jarecki and Davidson, [77] a negative HOMO energy for $\mathrm{F}^{-}$was obtained by utilizing very large diffuse basis sets with LDA and BLYP functionals. From this study, it is evident that the positive HOMO energies of $\mathrm{F}^{-}$obtained with DFT functionals is caused by using too incomplete of a basis set.

Furthermore, other calculations have shown that the positive HOMO energies cannot be obtained in every calculation, and have a strong dependence on the system studied and density functionals used. For example, with B3LYP the correct electron affinity and negative HOMO energy can be obtained, [78] since mixing in a portion of the HF exchange energy alleviates the self-interaction error. In a DFT electron affinity study by Curtiss et al., [79] larger deviations from experiment were noted for 10 molecules, whose neutral species are closed-shell molecules.

In a recent benchmark study by the Schaefer group, a total of 110 atomic and molecular electron affinities were obtained using B3LYP, B3P86, BHLYP, BLYP, BP86, and LSDA density functionals with DZP++ basis sets. [80] Among all functionals, B3LYP and BLYP perform best with an average absolute error of 0.19 eV . When the data set was refined to a smaller set with accurate experimental electron affinities, the absolute average error is reduced to 0.16 and 0.15 eV for B3LYP and BLYP, respectively. Overall, despite the deficiencies in predicting the HOMO energies, DFT can provide reasonable estimates of electron affinities.

While the reasonable description of electron affinities requires diffuse functions to be present in a basis set, our focus here is upon a possible improvement in basis set convergence behavior with respect to increasing basis set size of properties such as atomization energy. We examine how different angular momentum diffuse functions affect this convergence. This idea is from our earlier observations that additional diffuse functions may play an important role in improving the unexpected convergence problem. [62]

### 5.2 Methodology

All DFT calculations were carried out using the Gaussian 98 software suite. [35] Optimization and frequency calculations were performed for each functional and basis set
combination. Zero-point energy corrections were obtained from frequency calculations and included in the calculations of atomization energies. In order to achieve the same accuracy for the calculations of atoms and molecules, the tight convergence criteria on the density were requested.

The Kohn-Sham (KS) limits were obtained for atomization energies by using an empirical exponential scheme, [36] which has already been addressed in previous chapters.

$$
\begin{equation*}
D_{e}(x)=D_{e}(\infty)+A e^{-B x} \tag{5-1}
\end{equation*}
$$

Besides using cc-pVxZ and aug-cc-pVxZ in the calculations of the atomization energy of 17 molecules, two truncated series of basis sets were constructed by truncating the aug-cc-pVxZ sets. The first basis sets are denoted as cc-pVxZ+sp, which are constructed by removing all diffuse functions but the $s$ and $p$ functions, and the second basis sets are cc- $\mathrm{pV} x \mathrm{Z}+s p d$, which are constructed by removing all diffuse functions but the $s, p$, and $d$ functions. Likewise, other truncated basis sets are constructed by removing the higher angular momentum functions like $g$ and $h$ functions. For the hydrogen atom, the same procedure is taken to remove higher angular momentum diffuse functions from aug-cc-pVxZ to form cc-pVxZ+sp and cc-pV $x \mathrm{Z}+s p d$ except for aug-cc-pVDZ, which only has diffuse $s$ and $p$ functions. For the basis set of hydrogen, diffuse functions from aug-cc-pVDZ are used to construct cc-pVDZ $+s p$ and $\mathrm{cc}-\mathrm{pVDZ}+s p d$. Throughout this chapter, these truncated basis sets are used to evaluate the impact of diffuse functions with different angular momentum on the convergence of energy and structure.

### 5.3 Results and Discussion

### 5.3.1 Geometry

The optimized geometries using B3LYP and BLYP with four series of basis sets are listed in Table 5.1. The diffuse $s, p$, and $d$ functions have a small impact at the double- and triplezeta basis set levels and almost no impact beyond the triple-zeta level. In general, the additional diffuse $s p$ functions have little impact on the bond lengths ( $<0.01$ angstrom) and on the bond angles $\left(<1^{\circ}\right)$. The most remarkable effect is observed for dihedral angles. The additional $d$ function reduces the dihedral angle of HOOH from 117.70 to $113.18^{\circ}$ at the double-zeta level and 114.16 to $113.33^{0}$ at the triple-zeta level. The cc-pV $x \mathrm{Z}+s p$ and $\mathrm{cc}-\mathrm{pV} x \mathrm{Z}+s p d$ have a similar effect on the dihedral angle of HOOH .

### 5.3.2 Atomic Energy

Table 5.2 contains the atomic energies for hydrogen and four first-row atoms calculated using B3LYP and BLYP with the four series of basis sets. The addition of diffuse $s$ and $p$ functions amounts to most of the energy change between $\mathrm{cc}-\mathrm{pV} x \mathrm{Z}$ and aug-cc-pVxZ. For the total energies of the atoms, the diffuse $d$ function is less important than the diffuse $s$ and $p$ functions, and only makes a difference of $\sim 0.06$ mhartree. Similar to the effect on geometry, diffuse $s$ and $p$ functions only have an impact on total energies at the lower level basis sets.

Table 5.1 Optimized bond lengths and angles. Bond lengths are given in angstroms, and bond angles are given in degrees.

${ }^{\mathrm{a}}$ Davidson estimates of the atomic energies, which are from reference [45].

### 5.3.3 Atomization Energy

The atomization energies from B3LYP and BLYP with the different basis sets are given in Table 5.3. In terms of previous studies, BLYP with the correlation consistent basis sets performs poorly in determining energies for the molecules tested, while B3LYP improves the accuracy greatly (but they are still not close to "chemical accuracy"). In this section, the focus is on the convergence behavior, as the accuracy will be discussed in a later part.

The convergence problem is evident for atomization energies determined by using BLYP and B3LYP with standard correlation consistent basis sets. For several molecules, both functionals do not converge smoothly, suffering from a small dip at the quintuple-zeta level. Using cc-pVxZ $+s p$ remedies the convergence problem. Relative to the atomization energy with cc-pVxZ, the energy change due to the additional diffuse $s$ and $p$ functions is greater at lowerlevel basis sets, compared with the higher-level basis sets. For example in $\mathrm{CO}_{2}$, as compared with the cc-pVxZ atomization energy, the changes of the atomization energy due to diffuse $s$ and $p$ functions are $4.58 \mathrm{kcal} / \mathrm{mol}, 1.65 \mathrm{kcal} / \mathrm{mol}, 0.76 \mathrm{kcal} / \mathrm{mol}$, and $0.13 \mathrm{kcal} / \mathrm{mol}$ for BLYP with the double-, triple-, quadruple-, and quintuple-zeta level, respectively. It is the energy change which occurs for low-level basis sets that helps improve the convergence behavior. Improved convergence behavior is also observed for cc-pVxZ+spd. It is not surprising considering the fact that cc-pVxZ + spd and aug-cc-pVxZ have similar performance in determining energy and that aug-cc-pVxZ improves the convergence behavior (already noted in the preceding study). However, improved convergence behavior is not evident for all molecules, the exceptions being $\mathrm{O}_{3}$ and $\mathrm{F}_{2}$. The dependence of the atomization energy of $\mathrm{CO}_{2}$ on the different basis sets is plotted in Figure 5.1.

Figure 5.1 Comparison of the BLYP atomization energies of $\mathrm{CO}_{2}$ with four sets of basis sets. (note that cc-pVDZ $+s p d$ is identical to aug-cc-pVDZ.)

The convergent behavior of $\mathrm{CO}_{2}$ is somewhat surprising. What was expected was that the cc$\mathrm{pV} x \mathrm{Z}+s p$ or $\mathrm{cc}-\mathrm{pV} x \mathrm{Z}+s p d$ atomization energy would converge between the atomization energies from the standard and augmented correlation consistent basis sets, based on their respective size. However, the cc-pVxZ+spd and cc-pVxZ+sp atomization energies do not fall in between the atomization energy with cc- $\mathrm{pV} x \mathrm{Z}$ and aug-cc-pVxZ, although the cc-pVxZ + spd atomization energies are closer to those with the aug-cc-pVxZ set. Compared with cc-pVxZ atomization energies, the energy changes due to additional $s$ and $p(\mathrm{cc}-\mathrm{pV} x \mathrm{Z}+s p)$ and additional $s, p$, and $d$ ( $\mathrm{cc}-\mathrm{pV} x \mathrm{Z}+s p d$ ) have larger impacts at the double-, triple-, and, in particular, the quadruple-zeta levels, but only a slight impact at the quintuple-zeta level. These effects directly result in the
improvement of convergence by lowering the atomization energies at double-, triple-, and quadruple-zeta levels. Also, we noticed for this case that the diffuse $f$ function has a larger effect on the energy at the triple-zeta level than the diffuse $d$ function.

More attention is paid to two "difficult" molecules, $\mathrm{F}_{2}$ and $\mathrm{O}_{3}$, whose DFT atomization energies have problematic convergence when standard and augmented correlation consistent basis sets are used. Interestingly, when the two new series of basis sets are used, cc-pVxZ+sp improves the convergence and results in smooth convergence, while cc-pVxZ+spd does not. The atomization energies of $\mathrm{F}_{2}$ and $\mathrm{O}_{3}$ calculated with four sets of basis sets are compared in Figure 5.2 and Figure 5.3 for the BLYP functional, respectively. The most pronounced energy difference between cc-pVxZ and cc-pVxZ $+s p$ is observed at the double-zeta level with a 7 $\mathrm{kcal} / \mathrm{mol}$ reduction for both $\mathrm{F}_{2}$ and $\mathrm{O}_{3}$. With increasing basis set size, the energy difference decreases. As a result, atomization energies of these two molecules can converge smoothly when combined with cc-pV $x \mathrm{Z}+s p$. Unlike the diffuse $s$ and $p$ functions, the diffuse $d$ functions cannot improve the convergence behavior, they only reduce the atomization energy at the double-zeta level. The large reduction of atomization energy at the double-zeta level is related to the different convergence patterns of total energies of atoms and molecules. It is found that the total energies of atoms, when using cc- $\mathrm{pV} x \mathrm{Z}+s p$, are almost the same as those when using aug-cc-pV $x \mathrm{Z}$, while the total energies of the molecules are between those obtained with standard and augmented correlation consistent basis sets.

Besides the diffuse $s$ and $p$ functions, functions with higher angular momentum were also considered. Comparing the slight converge dip in aug-cc-pVxZ with the smooth convergent behavior in cc-pV $x \mathrm{Z}+s p$, it is obvious that the convergence behavior deteriorates with the high angular momentum diffuse functions. The BLYP $\mathrm{CO}_{2}$ atomization energies for quadruple- and

Figure 5.2 Comparison of the BLYP atomization energies of $\mathrm{F}_{2}$ with four sets of basis sets

Figure 5.3 Comparison of the BLYP atomization energies of $\mathrm{O}_{3}$ with four sets of basis sets

quintuple-zeta level basis sets with different high angular momentum diffuse functions are listed in Table 5.4. As seen in the table, using cc-pV $x \mathrm{Z}+s p$ sets decreases the cc-pV $x \mathrm{Z}$ atomization energy. However, relative to $\mathrm{cc}-\mathrm{pV} x \mathrm{Z}+s p$ atomization energy, adding higher angular momentum functions $d, f, g$, and $h$ increases the atomization energy. Although the increase is small, the energy change for quadruple-zeta level is more than that of quintuple-zeta level when the higher angular momentum functions are added to $\mathrm{cc}-\mathrm{pV} x \mathrm{Z}+s p$. As a result, aug-cc- $\mathrm{pV} x \mathrm{Z}$ cannot converge smoothly due to a slight dip at the quintuple-zeta level. In this case, among all energy contributions, the diffuse $g$ function has the biggest impact on the quadruple-zeta level basis set and results in the convergence dip for the aug-cc-pVxZ.

Table 5.3 Calculated atomization energies in $\mathrm{kcal} / \mathrm{mol}$.

### 5.3.4 Statistical Analysis

The MEs and MAEs of atomization energy (relative to experiment) are calculated for BLYP and B3LYP in combination with all levels of basis sets and are listed in Table 5.5. The MEs and MAEs of extrapolated atomization energies are also included in the table. Overall, the best results, in terms of mean absolute error, are found with the B3LYP functional with aug-cc$\mathrm{pV} x \mathrm{Z}$, with deviations of $5.69 \mathrm{kcal} / \mathrm{mol}$ for double-zeta, $2.34 \mathrm{kcal} / \mathrm{mol}$ for triple-zeta, 2.19 $\mathrm{kcal} / \mathrm{mol}$ for quadruple-zeta, and $2.19 \mathrm{kcal} / \mathrm{mol}$ for quintuple-zeta. Except at the double-zeta level, the other levels of cc-pVxZ+sp basis sets perform slightly worse than the standard and augmented correlation consistent basis sets. However, considering the strong basis set dependence of many larger systems, the basis sets, which enable to smooth convergence behavior, are recommended. For BLYP, since it overestimates the atomization energies for most
of molecules, the reduction of energy due to the use of cc-pVxZ+sp slightly improves the accuracy, in particular at the low-level basis sets. As compared with MAE at the quintuple-zeta level basis set, the extrapolation decreases the MAE for B3LYP and increases MAE for BLYP slightly.

Interestingly, the mean errors of cc-pV $x \mathrm{Z}+s p$ are between those of cc-pV $x \mathrm{Z}$ and aug-cc$\mathrm{pV} x \mathrm{Z}$ for B3LYP. The absolute values of ME are decreased from 7.84 to $0.68 \mathrm{kcal} / \mathrm{mol}$ with respect to increasing basis set size. On the contrary, the MEs increase for BLYP as the basis sets increase, with the smallest error at double-zeta level ( $2.01 \mathrm{kcal} / \mathrm{mol}$ ). The smallest ME at the double-zeta level may be attributed to fortuitous cancellation of errors, which is reflected in the large difference between MEs and MAEs at the double-zeta level.

Table 5.5 Mean absolute errors (MAE) and mean errors (ME) for the atomization energies in $\mathrm{kcal} / \mathrm{mol}$.

### 5.4 Conclusions

In the present study, a set of truncated correlation consistent basis sets, $\mathrm{cc}-\mathrm{pV} x \mathrm{Z}+s p$, are proposed. Using these truncated basis sets in combination with BLYP and B3LYP reduces the convergence problem observed with the standard correlation consistent basis sets, and does not cause a significant deterioration of the structures and atomization energy for the molecules tested. A detailed analysis has shown that use of lower angular momentum diffuse $s$ and $p$ functions is important in order to improve the convergence of molecular properties with respect to increasing basis set size for DFT, even for molecules such as $\mathrm{O}_{3}$ and $\mathrm{F}_{2}$, where the standard and augmented correlation consistent basis sets can not converge smoothly at all. The improvement is reflected in a large reduction of atomization energy at the double-, triple-, and quadruple-zeta levels. Compared with the standard correlation consistent basis sets, cc-pV $x \mathrm{Z}+s p$ is more desirable as it provides smooth convergence needed to achieve Kohn-Sham limits, especially for the strongly basis set dependent systems, without the additional computational expense of using the fully augmented basis sets.

## CHAPTER 6

## THE PERFORMANCE OF DENSITY FUNCTIONALS WITH RESPECT TO BASIS SETS: <br> THE BASIS SET SUPERPOSITION ERROR (BSSE)

### 6.1 Introduction

Basis set superposition error (BSSE) originates from the finite size of the basis sets used in the calculation of interaction energy between monomers, where the interaction energy is obtained by taking the difference between the energy of the complex and the sum of the energies of the monomers. The energy of the complex benefits from the basis sets of the monomers, but the monomers only make use of their own basis set, which leads to the overestimation of the interaction energy between monomers. This effect is called the basis set superposition error (BSSE), which was first proposed by Liu and Mclean [81]. In particular, basis set superposition error plays an important role in the computation of interaction energies of weakly bound systems. Usually, two kinds of approaches are used to correct BSSE, the counterpoise approach or the use of a very large basis set. In the counterpoise approach by Boys and Bernardi, [82] the energies of the individual monomers and the complex are evaluated using the basis set of the complex. Even though debates about the appropriateness of the counterpoise approach continue, as it is thought to overcorrect the interaction energy, [83] this approach is the only practical method to correct BSSE. Other alternatives [84-91] to the counterpoise method were found to
produce unsatisfactory results. [83, 92] Another approach in correcting BSSE is to use a very large basis set. There is little or no BSSE if the basis set is saturated, or near the complete basis sets limit. However, it is not always practical to perform calculations with very large basis sets.

In addition to its use in determining accurate interaction energy in weakly bound systems, accounting for BSSE also plays an important role in improving the convergence of molecular properties with respect to the correlation consistent basis sets. A number of calculations of weakly bound systems have demonstrated that energies corrected and uncorrected for BSSE energies will converge to the same basis set limit when using the correlation consistent basis sets. [36, 93-98] However, for the low-level basis sets, the effect of BSSE on energy is very significant. Some previous studies [36, 93-99] on weakly bound systems using ab initio correlated methods with the correlation consistent basis sets have shown that uncorrected results do not converge smoothly, and the irregular convergence of computed results with increasing basis set size was observed. This convergence problem can be remedied by correcting BSSE. As compared with uncorrected results, the corrected results provide better convergence behavior. Most the previous studies have used correlated ab initio methods like MP2 and $\operatorname{CCSD}(\mathrm{T})$. There have only been a few reported studies on the effect of BSSE in DFT calculations (due to the deficiency of DFT in predicting weakly bound systems). In a paper by Rappe and Bernstein, [100] the binding energies for several non-bonded systems were investigated using a series of theoretical approaches including HF, MP2, $\operatorname{CCSD}(\mathrm{T})$, and B3LYP with the correlation consistent and Pople basis sets. Even though DFT methods are inadequate at predicting the energetics of non-bonded systems, correcting BSSE improves the convergent behavior of the binding energies computed with the correlation consistent basis sets. Correcting BSSE not only improves the convergence behavior of molecular properties for weakly bounded systems, but also for the
strongly bound systems. van Mourik et al. have investigated the effect of BSSE on strongly bound systems using correlated ab initio methods with correlation consistent basis sets. [49, 95, 101] They found that the effect of BSSE on the strongly bound systems is not insignificant, especially for the low-level basis sets.

In the previous section, an unexpected convergence problem was reported in prior chapters when several density functionals combined with the standard and augmented correlation consistent basis sets were used to determine the structures and energies of 17 strongly bound systems. Moreover, in Chapter 3, which focused upon basis set uncontraction, the convergence problem was improved by using contracted and uncontracted basis sets to calculate molecule and atoms separately. Considering the definition of BSSE and the effect of BSSE on the convergence behavior reported in previous sections of this dissertation, it is natural to assume that correcting BSSE might also help to reduce the convergence problem.

In this section, we examine the effect of BSSE on the convergence behavior of atomization energy computed from several density functionals with standard and augmented correlation consistent basis sets. Also, the effect of BSSE on the structures and frequencies is investigated in particular for the small basis sets.

### 6.2 Methodology

BSSE was corrected using the counterpoise methods, as implemented in the Gaussian 98 package suite.[35] The molecular property examined in this study is atomization energy, which is defined as Equation (6-1),

$$
\begin{equation*}
\Delta E(R)=E_{A B}(R)-\left(E_{A}+E_{B}\right) \tag{6-1}
\end{equation*}
$$

where $E_{A B}(R)$ is the total energy of molecule at a distance R , and $E_{\mathrm{A}}$ and $E_{\mathrm{B}}$ are the total energies of the two atoms. According to the counterpoise method, the overestimation of the interaction energy can be corrected by the use of Equation (6-2):

$$
\begin{equation*}
\Delta E^{\bullet}(R)=E_{A B}(R)-\left(E_{A(B)}(R)+E_{B(A)}(R)\right) \tag{6-2}
\end{equation*}
$$

Where $E_{A(B)}(R)$ is the total energy of atom A calculated using the basis sets on both A and B, and $E_{B(A)}(R)$ is the total energy of atom B calculated using both A and B basis sets. The difference between $\Delta E^{\bullet}(R)$ and $\Delta E(R)$ is considered the BSSE when the counterpoise method is used, as shown in Equation (6-3).

$$
\begin{equation*}
E_{C P}(R)=\Delta E^{\bullet}(R)-\Delta E(R)=E_{A}(R)-E_{A(B)}(R)+E_{B}(R)-E_{B(A)}(R) \tag{6-3}
\end{equation*}
$$

Furthermore, BSSE can impact not only the interaction energy, but also the geometries, zero-point energy, and vibrational frequencies. Thus, optimization and frequency calculations correcting BSSE were performed for each combination of density functional and basis set using the counterpoise scheme. These results are compared with those obtained from calculations which did not include the BSSE correction. BSSE corrected and uncorrected zero-point energies were obtained from the corresponding frequency calculations and included in the BSSE corrected and uncorrected atomization energies, respectively.

### 6.3 Result and Discussions

### 6.3.1 The Effect of BSSE on Structures and Frequencies

Table 6.1 lists the BSSE uncorrected and corrected geometries calculated using six density functionals with cc-pVxZ and aug-cc-pVxZ for eight molecules, $\mathrm{H}_{2} \mathrm{O}, \mathrm{HF}, \mathrm{HCN}, \mathrm{CO}, \mathrm{N}_{2}$, HNO , HOF , and $\mathrm{CO}_{2}$, which were chosen due to the convergence behavior of their atomization energies with respect to increasing basis set size observed in our earlier studies Overall, for the molecules studied, the effect of BSSE on geometries is small, even at the double-zeta basis set level. The impact of BSSE upon bond length is less than $0.001 \AA$, and upon bond angle is less than $0.2^{\circ}$, with the exception of the HOH angle, where the impact is $\sim 0.5^{\circ}$ for all functionals. When the aug-cc-pVxZ basis sets is used, the effect of BSSE on geometries is insignificant. With increasing basis set size, both BSSE uncorrected and corrected geometries converge to the same basis set limit.

Table 6.2 gives the uncorrected and corrected harmonic frequencies. Analogous to the geometries, in general, the harmonic frequencies are only slightly affected by the counterpoise correction. The corrected frequencies are $\sim 10 \mathrm{~cm}^{-1}$ less than the uncorrected results at the doublezeta level for most of the functionals. The most substantial differences in the frequencies was noted when using BP86 and B3P86. The variation of frequencies for several molecules is more than $\sim 100 \mathrm{~cm}^{-1}$. Examples include $\omega_{1}$ and $\omega_{2}$ for $\mathrm{H}_{2} \mathrm{O}, \omega_{1}$ and $\omega_{2}$ for HCN , and $\omega_{2}$ for HNO . Overall, at the quintuple-zeta level, there is very little difference, if any, in the corrected and uncorrected frequencies.

Table 6.1 The BSSE uncorrected (no corr.) and corrected (corr.) optimized geometries using DFT with the correlation consistent basis sets.

Generally, molecular properties, that are less related to energy, do not necessarily converge with increasing basis set size. For geometries, the bond lengths and angles converge to the basis set limit, but the convergence is not best described by an exponential function. The variation of frequencies with increasing basis set size is more involved. No general trend was observed for the BSSE uncorrected and corrected frequencies.

### 6.3.2 Basis Set Superposition Error in Atomization Energy

It is assumed that, for strongly bound molecules, the effect of BSSE on energy is trivial for $a b$ initio and DFT methods, and that BSSE plays a much smaller role in DFT than in ab initio correlated methods, due to the faster convergence of DFT energy with respect to basis set size. However, earlier work by Wilson et al. [49] has found that, for advanced correlated ab initio methods with small basis sets, BSSE is not insignificant in calculating the energy of strongly bound systems. For example, a BSSE of $5 \mathrm{kcal} / \mathrm{mol}$ for the $\mathrm{N}_{2}$ binding energy at the $\operatorname{CCSD}(\mathrm{T}) / \mathrm{cc}-\mathrm{pVDZ}$ level was observed. In the present study, the effect of BSSE on strongly bound systems using density functional methods were investigated. The BSSE for atomization energies of eight strongly bound molecules using six density functionals and the standard and augmented correlation consistent basis sets are presented in Table 6.3.

As shown in the table, the largest BSSE was observed at the double-zeta level, and the BSSE decreases with increasing basis set size. For example, with the BLYP/cc-pVDZ, the BSSE of $\mathrm{CO}_{2}$ is $7.11 \mathrm{kcal} / \mathrm{mol}$, and it rapidly drops to $2.25 \mathrm{kcal} / \mathrm{mol}$ at the triple-zeta level, 1.36 $\mathrm{kcal} / \mathrm{mol}$ at the quadruple-zeta level, and finally to $0.28 \mathrm{kcal} / \mathrm{mol}$ at the quintuple-zeta level. It has been stated in previous ab initio studies that the effectiveness of the counterpoise correction approach at the self-consistent-field level mainly relies on the quality of the basis sets.[102] For example, BSSE is larger when using cc-pVxZ, as compared with aug-cc-pVxZ basis sets. Like
for $a b$ initio methods, DFT in combination with aug-cc-pVxZ shows less BSSE as compared with cc-pV $x \mathrm{Z}$, especially with the low-level basis sets. For example, the BSSE is reduced to 1.86 $\mathrm{kcal} / \mathrm{mol}$ for $\mathrm{CO}_{2}$ with aug-cc-pVDZ, as compared to the BSSE ( $7.11 \mathrm{kcal} / \mathrm{mol}$ ) with cc-pVDZ. In general, the BSSE does decrease as the basis set size increases. For several cases, similar amounts of BSSE were achieved at the triple- and quadruple-zeta level basis sets like B3LYP/cc$\mathrm{pV} x \mathrm{Z}$ BSSE for $\mathrm{H}_{2} \mathrm{O}$, all functionals/cc-pVxZ BSSE for $\mathrm{N}_{2}$, while the BSSE at the quintuple-zeta level is trivial ( $<0.2 \mathrm{kcal} / \mathrm{mol}$ ). For all molecules but HF, pure functionals, BLYP, BPW91, and BP86, result in a larger BSSE at the double-zeta level, as compared with hybrid functionals, B3LYP, B3PW91, and B3P86, respectively. For HF, BLYP predicts a larger BSSE than B3LYP, while BPW91 and BP86 give smaller BSSE than B3PW91 and B3P86.

### 6.3.3 The Effect of BSSE on the Convergence of Atomization Energy

The BSSE corrected and uncorrected atomization energies for eight molecules are presented in Table 6.4. The previous section discussed that, for DFT, the BSSE is non-negligible at the double-zeta level, even for strongly bound systems. However, relative to the energy change due to the basis set effect (difference between energies calculated at the double and quintuple zeta levels), the energy change arising from BSSE is small. For the B3LYP/cc-pVDZ atomization energy of $\mathrm{H}_{2} \mathrm{O}$, the energy change due to the basis set effect is about $11 \mathrm{kcal} / \mathrm{mol}$, while the BSSE results in an energy change of $3.51 \mathrm{kcal} / \mathrm{mol}$. It must be noted that these two effects are in opposite directions. The basis sets effect increases the atomization energy, whereas the BSSE effect decreases the atomization energy.

Another effect of BSSE on the atomization energy is that the convergence behavior of atomization energy is improved for most of the molecules. As compared with the irregular convergence behavior of the uncorrected energies, which have a slight dip at the quintuple-zeta level, the corrected atomization energies generally converge smoothly to the complete basis set limit. However, this improvement is not applicable to all molecules and functionals. In general,
the convergence problem with hybrid functionals has been improved for almost all molecules. For pure functionals, the convergence behavior of some of the molecules like HCN for BLYP and BP86 with cc-pVxZ and CO for BLYP, BPW91, and BP86 with cc-pVxZ is not improved at all, and even gets worse.

The uncorrected and corrected B3LYP/cc-pVxZ atomization energies for $\mathrm{CO}_{2}$ with increasing basis set size are provided in Figure 6.1. Among all of the molecules studied, $\mathrm{CO}_{2}$ shows the largest $\operatorname{dip}(\sim 0.5 \mathrm{kcal} / \mathrm{mol})$ for the uncorrected atomization energies. To be expected, both uncorrected and corrected atomization energies converge to the same basis set limit. The main difference resulting from the BSSE corrections occurs for energies at the double-, triple-, and quadruple-zeta levels. These corrections lead to improved convergence behavior of the energies.

### 6.4 Conclusions

For DFT methods, the effect of BSSE on the geometries and harmonic frequencies is small, which indicates that computed geometries and harmonic frequencies are not sensitive to BSSE corrections. For strongly bound systems, the BSSE is not insignificant, with the largest error occuring at the double-zeta level, and decreasing with increasing basis set size. As expected, both uncorrected and corrected energies converge to the same basis set limit. In a number of cases, the unexpected convergence problem observed in previous studies is improved when using the counterpoise correction. For HCN and CO , addressing the BSSE did not resolve the convergence problem, especially using pure density functionals. The improvement is mainly attributed to the energy changes at the triple- and quadruple-zeta levels.

Figure 6.1 The comparison of BSSE corrected and uncorrected atomization energies for $\mathrm{CO}_{2}$ in $\mathrm{kcal} / \mathrm{mol}$.

## CHAPTER 7

## THE PERFORMANCE OF DENSITY FUNCTIONALS

# WITH RESPECT TO BASIS SETS: 

## THE CORE-VALENCE EFFECT

### 7.1 Introduction

The chemical properties of atoms and molecules are mainly determined by the valence electrons. So in general, most theoretical studies largely focus on the description of valence electrons. Furthermore, this preference is also reflected in theoretical models, such as the frozencore approximation, in which the orbitals occupied by core electrons are constrained to remain doubly occupied in all configurations. This approximation assumes that the correlation effect arising from the core electrons can be neglected, since the error resulting from the frozen-core approximation is smaller than other errors, such as from an incomplete basis set or an inadequate description of electron correlation. From the basis set perspective, most popular basis sets were developed to better describe the valence electrons than the core electrons. Typically, basis functions used to describe core orbitals were optimized for Hartree-Fock and may not describe the core-core and core-valence correlation effects.

In order to describe molecular properties accurately or to understand properties that involve core electrons, basis functions accounting for the core correlation must be included in a basis set. The most widely used basis sets for the description of core correlation are the polarized
core-valence correlation consistent basis sets by Dunning and co-workers. [48, 53] Two series of core-valence correlation consistent basis sets are available: cc-pCVxZ [48] and cc-pwCVxZ. [53] The cc-pCVxZ was optimized to recover the core-core and core-valence correlation energy. A set of optimized functions was added to the $\mathrm{cc}-\mathrm{pV} x \mathrm{Z}$ sets, i.e., ( $1 s 1 p$ ) to cc-pVDZ to form the ccpCVDZ set, $(2 s 2 p 1 d)$ to cc-pVTZ to form the cc-pCVTZ set, and so on. Atomic calculations show that using cc-pCVxZ sets recovers the core-core and core-valence correlation energy effectively. As for the cc-pVxZ, calculations with the cc-pCVxZ sets enable systematical convergence to the complete basis set limit. However, it was noted that the core correlation energy including core-core and core-valence correlation energy can not converge very well.[53] The basis set of cc-pwCVxZ was developed based on a different strategy, which was motivated by the observation that the core-valence correlation is the dominant effect of the core correlation effects. Properties described using these basis sets can converge more quickly and smoothly than for the cc-pVxZ sets, as only core-valence correlation and a small amount of core-core correlation were considered. Since the contribution of core-core correlation energy is controlled by a weighting factor, the basis sets are named weighted core-valence sets. The success of ccpwCVxZ sets was expressed in the number of calculations of molecular properties including dissociation energies, geometries, and harmonic frequencies for a set of homonuclear diatomic molecules. These two types of basis sets have been applied extensively to investigate molecular properties including energies and spectroscopic constants. [48, 53, 103-110] However, almost all calculations with the core-valence correlation consistent basis sets involved correlated ab initio methods like $\operatorname{CCSD}(T)$. Systematic studies on the dependence of DFT used in combination with core-valence sets are rarely reported. Some studies related to our research are discussed below briefly.

Helgaker et al. investigated the performance of B3LYP for the calculation of indirect nuclear spin-spin coupling constants in substituted hydrocarbons. [111] They observed that coupling constants show a severe basis-set dependence, and do not converge smoothly with respect to cc- $\mathrm{pV} x \mathrm{Z}$ and cc-pCVxZ. Uncontracting the original $s$ functions and adding tight $s$ functions to each level of basis set can remedy this irregular convergence problem. B3LYP and core-valence sets were also utilized in the work by Carmichael et al., who studied the geometries, frequencies and anharmonic correction of $\mathrm{HPO}_{2}$ and HOPO . [112] Erratic and slow convergence of the Fermi contact terms for ${ }^{31} \mathrm{P}$ with respect to increasing basis set size was noted. Adding energy optimized and high-exponent $s$ functions to aug-cc-pCVxZ improve the convergence, but the converged result was still far from the experiment. This deviation may be attributed to the deficiency of the functional, since B3LYP was parameterized mainly from thermochemical data.

Kupka et al. used B3PW91 and HF with cc-pVxZ, aug-cc-pVxZ, cc-pCVxZ, and aug-cc$\mathrm{pCV} x \mathrm{Z}$ to calculate the NMR parameters for a set of first-row element compounds. [113] The results were extrapolated to the complete basis set limits for each series of basis set, and compared with experimental and ab initio results. They found that the core-valence basis sets yield slightly lower total energies than the valence sets at the low-level basis sets. For the NMR parameters, the core-valence sets converge more rapidly than the valence set, but this faster convergence was only observed for the heavy nuclei (non-hydrogen). The effect of core electrons on the geometries was examined by Swart et al. for a set of small and several large metallocene molecules. [114] As seen in this study, using all-electron and frozen-core basis sets made little difference, and the former performs slightly better than the latter for the smaller basis sets.

As seen in the above work, the use of core-valence sets was centered on accurate determination of spectroscopic parameters due to their strong dependence on core electrons. The effect of using core-valence sets in combination with DFT on energies is not very clear. The convergence of the core-valence sets has not been studied systematically. In this study, the performance of two popular density functionals, BLYP and B3LYP, used with the core-valence basis sets are evaluated for a number of molecules. We focus on the convergence behavior of structures and atomization energies with respect to increasing the basis set size. The convergence behavior is compared with that of the standard correlation consistent basis sets. The accuracy of these two functionals in combination with the core-valence sets has been assessed using several means of statistical analysis.

### 7.2 Computational Methodology

Two density functionals, BLYP [6, 8] and B3LYP, [10] were combined with six series of basis sets, the polarized core-valence (cc-pCVxZ), [48] the polarized core-valence $+s p$ (cc$\mathrm{pCV} x \mathrm{Z}+s p$ ), the augmented polarized core-valence (aug-cc-pCV $x \mathrm{Z}$ ), the polarized weighted core-valence (cc-pwCVxZ), [53] the polarized weighted core-valence $+s p(c c-p w C V x \mathrm{Z}+s p)$ and the augmented polarized weighted core-valence (aug-cc-pwCVxZ) correlation consistent basis sets, where $x=\mathrm{D}, \mathrm{T}, \mathrm{Q}$ and 5 , to determine the structures and atomization energies of a number of molecules, which were chosen due to their typical convergence behaviors in the earlier studies. The cc-pCV $x \mathrm{Z}$ and cc-pwCV $x \mathrm{Z}$ basis sets were obtained from the online EMSL Gaussian Basis Set Library (www.emsl.pnl.gov/forms/basisform.html). The aug-cc-pCV $x \mathrm{Z}$ and aug-cc-pwCV $x \mathrm{Z}$ basis sets were derived from the cc-pCVxZ and cc-pwCVxZ sets, respectively, by addition of a set of diffuse functions, which were taken from the augmented correlation consistent basis sets
(aug-cc-pV $x \mathrm{Z}$ ). The $\mathrm{cc}-\mathrm{pCV} x \mathrm{Z}+s p$ and $\mathrm{cc}-\mathrm{pwCV} x \mathrm{Z}+s p$ were constructed by adding only diffuse $s$ and $p$ functions to cc-pCVxZ and cc-pwCVxZ, respectively.

All calculations were carried out utilizing the G98 package. [35] The geometries and energies were optimized using each combination of density functional and basis set. The atomization energies listed in the tables consider the contribution from the zero-point energy, which was obtained from frequency calculations. As done in the previous study, the tight convergence criteria on density were requested for atomic calculations.

### 7.3 Results and Discussion

### 7.3.1 Structures

The optimized structures are summarized in Table 7.1. Overall, the bond lengths and angles are not sensitive to the type of basis sets used, and different compositions of basis sets cause only a slight change in geometries. The geometries are nearly converged at the triple-zeta level for all basis sets studied. The polarized core-valence and weighted core-valence basis sets have a similar performance at the triple-zeta level for both functionals. Beyond the triple-zeta level, the polarized core-valence and the polarized valence basis sets converge to the same limits. The largest difference in bond lengths between the polarized valence and the polarized corevalence basis sets arises from the double-zeta level, with a difference of $0.001 \AA$.

### 7.3.2 Atomic Energy

The total energies of the $\mathrm{H}, \mathrm{C}, \mathrm{N}, \mathrm{O}$, and F atoms calculated using BLYP and B3LYP with the six series of core-valence basis sets are listed in Table 7.2. The results with the standard and augmented basis sets (cc-pVxZ, cc-pVxZ $+s p$ and aug-cc-pVxZ) and accurate Davidson atomic energies [45] are also listed for comparison. Overall, the total energies decrease with increasing the basis set size. The basis sets of cc-pCVxZ and cc-pwCVxZ predict nearly the same

Table 7.1 Optimized bond lengths and angles. Bond lengths are given in angstroms, and bond angles are given in degree

energy at the quintuple-zeta level. A similar observation can be made on cc-pCV $x \mathrm{Z}+s p$ and the cc-pwCV $x \mathrm{Z}+s p$ as well as on the aug-cc-pCV $x \mathrm{Z}$ and aug-cc-pwCV $x \mathrm{Z}$ basis sets. For each level of correlation consistent basis set, the total energy decreases in the following sequence: cc$\mathrm{pCV} x \mathrm{Z}>\mathrm{cc}-\mathrm{pCV} x \mathrm{Z}+s p>$ aug-cc-pCV $x \mathrm{Z}$ (or cc-pwCV $x \mathrm{Z}>\mathrm{cc}-\mathrm{pwCV} x \mathrm{Z}+s p>$ aug-cc-pwCV $x \mathrm{Z}$ ). This sequence is in accord with the number of basis functions. The additional diffuse $s p$ functions account for most of the energy difference between the standard core-valence and augmented core-valence sets. For example, at the double-zeta level, the energy difference of the O atom between $\mathrm{cc}-\mathrm{pwCV} x \mathrm{Z}$ and aug-cc-pwCVxZ is 0.01067 hartree, while the difference between cc-pwCV $x \mathrm{Z}$ and $\mathrm{cc}-\mathrm{pwCV} x \mathrm{Z}+s p$ is 0.01060 hartree. As compared with Davidson energies, all calculated results are underestimated at the quintuple-zeta level for BLYP and B3LYP.

### 7.3.3 Atomization Energy

The computed atomization energies and experimental results are presented in Table 7.3. The atomization energies are nearly converged at the triple-zeta level. The atomization energies with the polarized core-valence, the polarized weighted core-valence, and standard correlation consistent basis sets converge to the same limit, as expected. This seems to indicate that the basis set limit has been reached, at least for atomization energy. Although the additional functions for core correlation did not affect the basis set limit, the atomization energy at the double-zeta level was affected slightly. For example, the BLYP atomization energy of HCN with cc-pVDZ is $303.84 \mathrm{kcal} / \mathrm{mol}$, about $1 \mathrm{kcal} / \mathrm{mol}$ lower than that with cc-pCVDZ, and about $2 \mathrm{kcal} / \mathrm{mol}$ lower than that with cc-pwCVDZ. The impact is decreased as the basis set size is increased. In general, the impact is insignificant at the triple- and higher basis set level.

The unexpected convergence problem was also observed for the polarized core-valence and the polarized weighted core-valence basis sets (cc-pCVxZ and cc-pwCV $x \mathrm{Z}$ ). For $\mathrm{CO}, \mathrm{CO}_{2}$, and HOF, a slight energy dip occurs when the pure functional BLYP was used with both the cc$\mathrm{pCV} x \mathrm{Z}$ and cc-pwCVxZ basis sets. However, unlike for cc-pVxZ where the energy dip was observed at the quintuple-zeta level, the energy dip occurs at the quadruple-zeta level, which is due to the substantial increase on energy at the triple-zeta level. For example, the BLYP/cc$\mathrm{pCV} x \mathrm{Z}$ atomization energies of CO are $257.10,259.91,259.80$, and $259.31 \mathrm{kcal} / \mathrm{mol}$ for the double-, triple-, quadruple-, and quintuple-zeta levels, respectively. An energy dip is observed at the quadruple-zeta level with the largest energy, $259.91 \mathrm{kcal} / \mathrm{mol}$, at the triple-zeta level. When B3LYP was used, the polarized core-valence and the polarized weighted core-valence sets result in an energy dip at the quintuple-zeta level as for $\mathrm{cc}-\mathrm{pV} x \mathrm{Z}$, but differ from the cc-pVxZ, the B3LYP/cc-pCV $x \mathrm{Z}$ or B3LYP/cc-pwCV $x \mathrm{Z}$ atomization energy at the quintuple-zeta level which is lower than the energy at the triple-zeta level. It appears that additional core-correlation functions have a larger effect on the quintuple zeta level than the triple-zeta level. The nonconvergent behavior of the polarized core-valence and the polarized weighted core-valence sets can be alleviated through the use of additional diffuse functions (aug-cc-pCVxZ and aug-cc$\mathrm{pwCV} \mathrm{Z} Z$ ) for both density functionals. An example is the atomization energies of CO. For the other two molecules, the dip still exists at the quintuple-zeta level, but is less pronounced ( $\sim 0.05$ $\mathrm{kcal} / \mathrm{mol})$. According to the difference in construction between $\mathrm{cc}-\mathrm{pV} x \mathrm{Z}$ and cc-pCVxZ or cc$\operatorname{pwCV} x Z$, the energy dip occurred earlier in core-valence sets may be caused by the additional core correlated functions, especially high angular momentum functions. In the previous chapter, how the convergence deteriorates with such functions has been addressed.

Among all molecules studied, $\mathrm{O}_{3}$ and $\mathrm{F}_{2}$ have an irregular convergence behavior of their atomization energies with respect to increasing basis set size, which has already been observed in our previous studies. For $\mathrm{F}_{2}$, the BLYP/cc-pCVxZ and BLYP/cc-pwCV $x \mathrm{Z}$ atomization energies decrease as the basis set size increases, but the atomization energies can not converge exponentially. When B3LYP was used, an energy dip occurs at the triple-zeta level for both the cc-pCVxZ and cc-pwCV $x$ Z sets. As compared with the cc-pVxZ sets, the addition of core correlation functions does not improve the convergence behavior of BLYP and B3LYP atomization energies, but the addition of diffuse functions can affect the convergence behavior for BLYP and B3LYP with the cc-pVxZ set. Unfortunately, the dip still exists for the augmented polarized core-valence and the polarized weighted core-valence sets (aug-cc-pCV $x \mathrm{Z}$ and aug-cc$\mathrm{pwCV} x \mathrm{Z})$. For $\mathrm{O}_{3}$, the BLYP/cc-pVxZ results in an energy fluctuation with increasing basis set size: $168.32,166.96,167.28$ and $166.79 \mathrm{kcal} / \mathrm{mol}$ for double-, triple-, quadruple- and quintuplezeta level, respectively. BLYP/cc-pCVxZ results in an increase of the atomization energy at the triple-zeta level, but the convergence of atomization energies are still not smooth. BLYP/cc$\operatorname{pwCV} x \mathrm{Z}$ decreases the atomization energy at the double-zeta level and increases the atomization energy at the triple-zeta level, as compared with BLYP/cc-pVxZ results. As a result, an energy dip occurs at the quadruple-zeta level. For B3LYP, all three types of basis sets (cc-pVxZ, cc$\mathrm{pCV} x \mathrm{Z}$ and cc-pwCVxZ) result in similar convergence behavior with an energy dip at the quintuple-zeta level. The convergence problem can not be alleviated by the addition of diffuse functions for BLYP, whereas B3LYP/aug-cc-pCVxZ and B3LYP/aug-cc-pwCVxZ improve the irregular convergence behavior. Although the dip still exists, it was reduced to $\sim 0.03 \mathrm{kcal} / \mathrm{mol}$ for the aug-cc-pwCV $x \mathrm{Z}$ and aug-cc-pCV $x \mathrm{Z}$ sets.

On the other hand, the convergence problem can be avoided by using cc-pCV $x \mathrm{Z}+s p$ sets. This can be applied to all molecules studied in this study. This observation is in accord with our earlier investigations (Chapter 5), which has shown the impact of additional diffuse $s p$ functions on the convergence behavior.

For the other molecules, the convergence dip observed for the cc-pVxZ sets also occurs for the polarized core-valence and the polarized weighted core-valence sets. The augmented sets (aug-cc-pCVxZ and aug-cc-pwCVxZ) improved the convergence behavior.

### 7.3.4 Statistical Analysis

The statistical results including mean error (ME) and mean absolute error (MAE) are listed in Table 7.4. As shown by the mean errors, B3LYP underestimates the atomization energy, while BLYP overestimates the atomization energy.

Based on the MAE of the atomization energy as compared with experiment, the best result comes from using B3LYP with the cc-pwCVTZ and cc-pCVTZ basis sets, which give MAE of 1.83 and $1.85 \mathrm{kcal} / \mathrm{mol}$, respectively. These smallese deviations (relative to the MAE for BLYP) may be attributed to that the triple-zeta set produces the largest atomization energies for most of molecules, and to the fact that almost all atomization energies were underestimated by B3LYP. In contrast to B3LYP, BLYP/cc-pCVTZ and BLYP/cc-pwCVTZ result in the largest MAE, with deviations of 12.10 and $12.08 \mathrm{kcal} / \mathrm{mol}$, respectively. This deviation corresponds to the largest atomization energies at the triple-zeta level and the overestimation of the atomization energies by BLYP.

The aug-cc-pCVxZ and aug-cc-pwCV $x \mathrm{Z}$ basis sets improve the convergence behavior of the non-augmented corresponding sets. Accordingly, for these two sets, the mean absolute errors
deviate further from experiment for BLYP, and get closer to experiment for B3LYP with respect to increasing basis set size, which is also the case for cc-pCV $x \mathrm{Z}+s p$ and $\mathrm{cc}-\mathrm{pwCV} x \mathrm{Z}+\mathrm{sp}$.

### 7.4 Conclusion

Overall, the core correlation functions have a small effect on the calculated geometries, atomic energies, and atomization energies, due to the small number of core electrons for firstrow elements. For atomization energies with the polarized core-valence and the polarized weighted core-valence sets, unexpected convergence problems occur for a number of molecules and functionals studied. As compared with standard correlation consistent basis sets, the convergence behavior deteriorates with the additional functions for core correlation. The possible reasons include: the additional core-correlation sets were optimized using the CISD method and the core-valence sets include too many high angular momentum functions, which have been proven in this study as a potential factor corresponding to the non-convengence problem The fact is exemplified by an earlier occurrence of the energy dip for the core-valence sets as compared to the standard sets. The inclusion of additional diffuse functions to core-valence sets (cc-pCVxZ and cc-pwCVxZ) can help alleviate the unexpected behavior, but not for all molecules. However, the convergence problem observed in the core-valence sets can be avoided completely by just adding diffuse $s p$ functions to cc-pCV $x \mathrm{Z}$ and cc-pwCV $x \mathrm{Z}$. This agrees with the observations made in Chapter 5.

## CHAPTER 8

## THE PERFORMANCE OF DENSITY FUNCTIONALS WITH RESPECT TO BASIS SETS: THE TIGHT $d$ EFFECT ON SO $2, \mathrm{CCl}, \mathrm{AND} \mathrm{ClO}_{2}$ <br> 8.1 Introduction

Since the development of correlation consistent basis sets, [15] there have been thousands of successful studies using them. Using $\operatorname{CCSD}(\mathrm{T})$ with the correlation consistent basis sets has become a standard approach to provide some of the most accurate information on molecular properties. However, these basis sets are not without questions. The weakness of the correlation consistent basis sets was observed first in the work of Bauschlicher and Patridge in 1995. [115] They found the dissociation energy of $\mathrm{SO}_{2}$ was underestimated by $6.2 \mathrm{kcal} / \mathrm{mol}$ with results obtained from $\operatorname{CCSD}(\mathrm{T})$ calculations. The addition of a tight $d$ function (high exponent) in the sulfur basis sets reduces the error significantly to $-1.9 \mathrm{kcal} / \mathrm{mol}$. Other studies have shown this problem also exists in SO and other systems containing second-row atoms. [116, 117]

The means to alleviate this problem has been proposed. Martin suggested a systematic procedure to add higher angular momentum functions for sulfur: a (1d) set to the cc-pVTZ set, a ( $2 d 1 f$ ) set to the cc-pVQZ set, and a ( $3 d 2 f 1 g$ ) set to the cc-pV5Z set. [116] These functions result in significant improvements in the extrapolated binding energies. Bauschlicher and Ricca also added the additional higher-angular momentum functions to the correlation consistent basis sets
for sulfur. [118] They suggested an optimal adding of (2d) set to each level of basis set. Dunning, Peterson and Wilson reinvestigated the basis set deficiencies, [52] and found that the cause of these errors in the standard sets arise from near duplication of the exponents in two of the $d$ sets and a lack of high-exponent functions. A strategy was developed to revise the standard correlation consistent basis sets: adding a high-exponent function to each level of basis set, and higher basis sets (cc-pVQZ and cc-pV5Z) required reexamination of the basis set convergence. The key to this revision is that systematic behavior to provide extrapolations to the CBS limit is preserved. As a consequence, an improved family of the correlation consistent basis set, denoted as cc-pV(x+d)Z, where $x=\mathrm{D}(2), \mathrm{T}(3), \mathrm{Q}(4)$, and 5 , was formulated. To date, these newly developed correlation consistent basis sets have been used in a number of ab initio studies on the second row atoms, [52, 119-125] and the significant improvements in energies have been observed.

So far, extensive studies using tight $d$-augmented correlation consistent basis sets predominantly have been done by our group, and more recently by the Denis group. Studies to date have primarily focused on the thermodynamic properties, energies, and structures of sulfur species of importance in atmospheric chemistry. Wilson and Dunning investigated structures and energetics of the HSO/HOS isomers and their relative stability using $\operatorname{CCSD}(\mathrm{T})$ with the tight $d$ augmented correlation consistent basis sets. [119] As compared with standard correlation consistent basis sets, the impact of the tight $d$ functions is most important at the double- and triple-zeta levels. The energy difference between the two isomers converges faster for tight $d$ sets over the standard sets. The detailed discussion can be seen in the next chapter. The conclusion that tight $d$-augmented sets have an important effect on energy at the low level basis sets was also observed in other studies such as Bell and Wilson, who investigated the effect of tight $d$
functions on the atomization energy of $\mathrm{SO}_{3}$. [121] Furthermore, for species with strong basis set dependence, the impact of the tight $d$-augmented sets is not limited to low-level basis sets. Denis et al determined enthalpies of formation for a series of thionitroso and thiazyl isomers using $\operatorname{CCSD}(\mathrm{T}) / \mathrm{cc}-\mathrm{pV} x \mathrm{Z}$, aug-cc-pV $(x+d) \mathrm{Z}$, and B3LYP/6-311+G(3df,2p).[123] They found that for species, which include second-row atoms, $\operatorname{CCSD}(\mathrm{T})$ enthalpies of formations have essentially converged with the aug-cc-pV(5+d)Z basis set. However, for the cc-pVxZ basis sets, even the results with cc-pV6Z are not fully converged. This observation demonstrates the significance of tight $d$ functions on energy at the higher-level basis sets.

Advanced ab initio correlated methods like $\operatorname{CCSD}(\mathrm{T})$ coupled with tight $d$ sets or tight $d$ augmented correlation consistent basis sets have been used as a reliable approach to predict molecular properties accurately. Peterson and Dixon used $\operatorname{CCSD}(\mathrm{T})$ with tight $d$ correlation consistent basis sets through sextuple-zeta to calculate the heats of formation of CCl and $\mathrm{CCl}_{2}$. [126] The results, after an additional correction for several relativistic effects, are in excellent agreement with the latest experiments. The $\operatorname{CCSD}(\mathrm{T})$ with tight $d$-augmented sets was also applied to predict the heat of formation of HSO and the enthalpies of formation of a series of sulfur molecules. [124, 125]

In this chapter, density functionals are combined with the newly revised tight $d$ augmented correlation consistent basis sets to investigate the atomization energy of several molecules consisting of second-row atoms. The molecules, $\mathrm{SO}_{2}, \mathrm{CCl}$, and $\mathrm{ClO}_{2}$, are derived from a study by Martell et al. of the impact of functional and basis set choice on the atomization energies of a series of 44 molecules. [27] For the dissociation energy, the errors of these molecules, as compared with experiment, were most severe: -19.4 for $\mathrm{SO}_{2},-11.9$ for $\mathrm{ClO}_{2}$, and
$14.4 \mathrm{kcal} / \mathrm{mol}$ for CCl at the B3LYP/cc-pVTZ//cc-pVDZ level. However, it must be noted that the largest basis sets used in this study were of triple-zeta quality.

Two density functionals, B3LYP and B3PW91, are coupled with the standard and revised correlation consistent basis sets, to examine the impact of the additional $d$ functions on the structures and energies of $\mathrm{SO}_{2}, \mathrm{CCl}$, and $\mathrm{ClO}_{2}$. Additionally, as a result of their systematic construction, results obtained for each level of basis set with a given method can be extrapolated to the Kohn-Sham (KS) limit. This enables a better understanding of the performance of computational methods due to elimination of the basis set error. In this study, two schemes often used to estimate complete basis set limits were utilized to determine KS limits for each DFT approach.

### 8.2 Methodology

In this study, four series of the correlation consistent basis sets were used in combination with B3LYP [7, 10] and B3PW91 [8]: the standard correlation consistent basis sets, cc-pVxZ; the tight $d$-augmented sets, cc- $\mathrm{pV}(x+d) \mathrm{Z}$; the augmented correlation consistent basis sets, aug-cc$\mathrm{pV} x \mathrm{Z}$; and the augmented tight $d$-augmented sets, which include diffuse functions, aug-cc$\mathrm{pV}(x+d) \mathrm{Z}(x=\mathrm{D}(2), \mathrm{T}(3), \mathrm{Q}(4), 5)$. Geometry optimizations and frequency calculations were carried out for each combination of density functional and basis set. The zero-point energy correction was taken from the frequency calculations and was included in the atomization energies. All calculations were performed using the Gaussian 98 package.

Two empirical extrapolation schemes were used to estimate the Kohn-Sham limit: an exponential and a two-point extrapolation scheme. Both schemes have been discussed in the previous chapter.

### 8.3 Results and Discussion

8.3.1 $\mathrm{SO}_{2}$

All calculated structures and atomization energies of $\mathrm{SO}_{2}$ using B3LYP and B3PW91 with four series of basis sets are given in Table 8.1. For both functionals, the bond length decreases as the basis set size increases. The difference in bond lengths between double- and the quintuple- zeta level basis sets is $\sim 0.05 \AA$ for cc-pVxZ and aug-cc-pV $x \mathrm{Z}$, while the difference is reduced to $\sim 0.02 \AA$ for cc-pV(x+d)Z and aug-cc-pV(x+d)Z). For the bond angles, the impact of tight $d$ functions is more evident. The difference of bond angle between double- and quintuplezeta level basis sets is reduced from $\sim 1.5^{\circ}$ to $\sim 0.2^{\circ}$ when tight $d$ functions were included in cc$\mathrm{pV} x \mathrm{Z}$ or aug-cc-pVxZ.

As shown in Table 8.1, B3LYP and B3PW91 atomization energies increase with respect to basis set size. For cc-pVxZ, the atomization energy converges slowly for both B3LYP and B3PW91, compared with the tight $d$ sets. B3LYP/cc-pV5Z and B3PW91/cc-pV5Z still result in an increase in energy, 5.23 and $4.95 \mathrm{kcal} / \mathrm{mol}$, respectively, over that of cc-pVQZ. The convergence of energies is dramatically affected by the tight $d$ functions. In comparison with cc$\mathrm{pV} x \mathrm{Z}$ basis sets, the cc-pV(x+d)Z sets reach convergence more quickly. The difference in energy between quadruple- and quintuple- zeta level basis sets drops to $0.52 \mathrm{kcal} / \mathrm{mol}$ for B3LYP and $0.58 \mathrm{kcal} / \mathrm{mol}$ for B3PW91. In addition, substantial improvement in energy was observed at the low-level basis sets. For example, the tight $d$ basis set improves the atomization energy by 17.3 and $10.24 \mathrm{kcal} / \mathrm{mol}$ at the B3LYP/cc-pVDZ and B3LYP/cc-pVTZ levels, respectively, while the tight $d$ basis set results in an improvement of $5.79 \mathrm{kcal} / \mathrm{mol}$ at the cc-pVQZ level and 1.08 $\mathrm{kcal} / \mathrm{mol}$ at the cc-pV5Z level.

For augmented correlation consistent basis sets, the effect of the tight $d$ functions on the convergence of atomization energy is similar to that of the standard correlation consistent basis sets. Compared with non-augmented correlation consistent basis sets (cc-pVxZ and cc$\mathrm{pV}(x+d) \mathrm{Z}$ ), the additional diffuse functions in augmented sets (aug-cc-pVxZ and aug-cc$\mathrm{pV}(x+d) \mathrm{Z})$ causes less of an improvement than the tight $d$ functions. At the double zeta level for B3LYP, the augmented basis sets result in an increase of $5.67 \mathrm{kcal} / \mathrm{mol}$ in atomization energy, which is less substantial than the improvement arising from the tight $d$ functions (17.30 $\mathrm{kcal} / \mathrm{mol})$.

We compared the convergence behavior of atomization energy with both B3LYP/cc$\mathrm{pV} x \mathrm{Z}$ and B3LYP/cc- $\mathrm{pV}(x+d) \mathrm{Z}$, as shown in Figure 8.1. The atomization energies at the double-, triple- and quadruple-zeta levels are significantly affected by tight $d$ functions, which result in a faster convergence for the tight $d$ sets than the standard correlation consistent basis sets. However, we note that both series of atomization energies converge to nearly the same limit. The same behavior was observed for the augmented sets, shown in Figure 8.2, which is also for the B3LYP functional.

Figure 8.1 The comparison of the atomization energy of SO2 obtained with BLYP/cc-pVxZ and BLYP/cc-pV $(x+d)$ Z

Figure 8.2 The comparison of the atomization energy of SO2 obtained with BLYP/cc-pVxZ and BLYP/cc-pV $(x+d)$ Z

An interesting phenomenon was noted when comparing the results with tight $d$ sets (cc$\mathrm{pV}(x+d) \mathrm{Z}$, aug-cc-pV(x+d)Z) and standard sets (cc-pVxZ and aug-cc-pVxZ). For each level of basis set, the effect of adding a tight $d$ function on the atomization energy of $\mathrm{SO}_{2}$ is similar for the B3LYP and B3PW91. For example, at the double-zeta level, the B3LYP energy difference due to tight $d$ functions is $17.3 \mathrm{kcal} / \mathrm{mol}$, while the B3PW91 energy difference is $17.46 \mathrm{kcal} / \mathrm{mol}$. This is also the case for augmented correlation consistent basis sets. This similarity suggests that there exists an additivity arising from the density functional effect and tight $d$ function effect. For each level of correlation consistent basis set, the energy of a given functional/tight $d$ set can be determined approximately by combining the energy at a same functional/standard set and energy
difference due to tight $d$ functions from another density functional. This can be expressed in equation below:

$$
\begin{aligned}
& \mathrm{D}_{\mathrm{e}}(\text { B3LYP } / \mathrm{cc}-\mathrm{pV}(x+d) \mathrm{Z})=\mathrm{D}_{\mathrm{e}}(\text { B3LYP/cc-pV } x \mathrm{Z})+ \\
& \left.\mathrm{D}_{\mathrm{e}}(\text { B3PW91/cc-pV }(x+d) \mathrm{Z})-\mathrm{D}_{\mathrm{e}}(\text { B3PW91/cc-pV } x \mathrm{Z})\right)
\end{aligned}
$$

We used results at the cc-pVDZ level as an example. The B3LYP/cc-pV(D+d)Z atomization energy derived from the above approximate approach is $227.48 \mathrm{kcal} / \mathrm{mol}$, which is in excellent agreement with the computed result, with a small difference of $0.16 \mathrm{kcal} / \mathrm{mol}$. Since B3LYP and B3PW91 have similar performance and computational costs, the improvement of computational expense is not substantial. This approach can also be applied to $a b$ initio methods like HF and $\operatorname{CCSD}(\mathrm{T})$. The reliability of this approach has been proven by earlier calculations of Wilson and Dunning, [119] where the atomization energy of $\mathrm{SO}_{2}$ was determined using $\operatorname{CCSD}(\mathrm{T})$ with tight $d$ and standard correlation consistent basis sets:

$$
\begin{aligned}
& \mathrm{D}_{\mathrm{e}}(\mathrm{CCSD}(\mathrm{~T}) / \mathrm{cc}-\mathrm{pV}(x+d) \mathrm{Z})=\mathrm{D}_{\mathrm{e}}(\mathrm{CCSD}(\mathrm{~T}) / \mathrm{cc}-\mathrm{pV} x \mathrm{Z})+ \\
& \left.\mathrm{D}_{\mathrm{e}}(\mathrm{HF} / \mathrm{cc}-\mathrm{pV}(x+d) \mathrm{Z})-\mathrm{D}_{\mathrm{e}}(\mathrm{HF} / \mathrm{cc}-\mathrm{pV} x \mathrm{Z})\right)
\end{aligned}
$$

Using the above equation results in the values of $148.68,170.55,177.33$, and $179.89 \mathrm{kcal} / \mathrm{mol}$ for the $\operatorname{CCSD}(\mathrm{T}) / \mathrm{cc}-\mathrm{pV}(\mathrm{D}+d) \mathrm{Z}, \operatorname{CCSD}(\mathrm{T}) / \mathrm{cc}-\mathrm{pV}(\mathrm{T}+d) \mathrm{Z}, \operatorname{CCSD}(\mathrm{T}) / \mathrm{cc}-\mathrm{pV}(\mathrm{Q}+d) \mathrm{Z}$ and $\operatorname{CCSD}(\mathrm{T}) /$ cc-pV $(5+d) \mathrm{Z}$ atomization energies of HSO, respectively. These derived results are within 0.12 $\mathrm{kcal} / \mathrm{mol}$ of the computed results. As a consequence, the additional cost due to tight $d$ functions can be avoided using the additivity property of tight $d$ functions in the correlation consistent basis sets.

The Kohn-Sham limits are obtained by extrapolating the results from a series of calculations with the correlation consistent basis sets and the tight $d$ revised sets. Results from the exponential scheme and from a two-point scheme are listed in Tables 8.1 and 8.2, respectively. For the exponential scheme, the B3PW91/aug-cc-pVxZ Kohn-Sham limit results in $1.79 \mathrm{kcal} / \mathrm{mol}$ improvement over the atomization energy at the aug-cc-pVQZ level, and provides

${ }^{a}$ DT represents extrapolation using cc-pVDZ and cc-pVTZ, TQ represent extrapolation using ccpVTZ and cc-pVQZ, . . . $\infty$ represents the extrapolated Kohn-Sham limit
the best agreement with experiment, with a deviation of $2.37 \mathrm{kcal} / \mathrm{mol}$. The tight $d$ sets have little impact on the Kohn-Sham limit, although a dramatic impact on the atomization energy at the low-level basis sets was observed. In Table 8.2, several extrapolation methods based on the twopoint scheme are compared. For the standard correlation consistent basis sets (cc-pVxZ and aug-cc-pVxZ), the extrapolated B3LYP Kohn-Sham limit using results at the quadruple- and quintuple-zeta basis sets give the best agreement with experiment, with errors of $0.98 \mathrm{kcal} / \mathrm{mol}$
for cc-pVxZ and $0.79 \mathrm{kcal} / \mathrm{mol}$ for aug-cc-pV $x \mathrm{Z}$. Decreasing the number of basis sets included in the extrapolation of the Kohn-Sham limit leads to a lowering of Kohn-Sham limit. To contrast, for the tight $d$ revised sets (cc-pV(x+d)Z and aug-cc-pV(x+d)Z), Increasing basis set levels results in a lowering of Kohn-Sham limit. As a consequence, the best B3LYP Kohn-Sham limit, as compared with experiment, was obtained by using the results at the cc-pV( $\mathrm{D}+d) \mathrm{Z}$ (aug-cc$\mathrm{pV}(x+d) \mathrm{Z})$ and cc-pV(T+d)Z (aug-pV(T+d)Z), with errors of $0.23 \mathrm{kcal} / \mathrm{mol}$ and $2.14 \mathrm{kcal} / \mathrm{mol}$, respectively.

### 8.3.2 CCl

Optimized geometries and atomization energies are presented for CCl in Table 8.3. In general, bond lengths are predicted to within $0.01 \AA$ at the quintuple-zeta level, compared with experiment. Bond lengths are nearly converged at the triple-zeta level for tight $d$ revised sets (cc$\mathrm{pV}(x+d) \mathrm{Z}$ and aug-cc-pV(x+d)Z), while bond lengths reach near convergence at the quadruplezeta level for the standard sets (cc-pVxZ and aug-cc-pVxZ).

The reason that theoretical chemists pay more attention to CCl is the large deviation in atomization energy between experiment and theoretical studies. The G2 scheme predicted an atomization energy of $95.9 \mathrm{kcal} / \mathrm{mol}$ for CCl , [127] with a difference of $\sim 10 \mathrm{kcal} / \mathrm{mol}$ from previous experiment ( $80 \pm 5 \mathrm{kcal} / \mathrm{mol}$ ).[128] Considering that the atomization energies obtained using G2 methods are usually accurate to within $2-3 \mathrm{kcal} / \mathrm{mol}$, a doubt was cast on the reliability of the experimental value. Recently, other experimental atomization energies have been reported. Jesinger et al gives a atomization energy of $93.8 \mathrm{kcal} / \mathrm{mol}$ which is derived from an accurate experimental determination of the heat of formation of CCl and known heats of formation of $\mathrm{C}(\mathrm{g})$ and $\mathrm{Cl}(\mathrm{g})[129]$ Also, the NIST reports a value of $94.4 \mathrm{kcal} / \mathrm{mol}$. [46] These values are in better agreement with the G2 result. A recent high-level $a b$ initio study by Dixon and

Peterson[126] also supports the new experimental results. An atomization energy of $95.5 \pm 0.3$ $\mathrm{kcal} / \mathrm{mol}$ was obtained using a CBS limit of $\operatorname{CCSD}(\mathrm{T})$ with aug-cc-pVxZ plus several relativistic effect corrections including: core valence, scalar relativity, and spin-orbit.

In analogy to $\mathrm{SO}_{2}$, the tight $d$ sets improve the atomization energy of CCl especially for the low-level basis sets, as compared with the standard correlation consistent basis sets. The diffuse functions in augmented sets also improve the atomization energy, but with less of an impact than from the tight $d$ sets. For example, for B3LYP with the double-zeta basis set, the augmented sets increase the atomization energy by $0.48 \mathrm{kcal} / \mathrm{mol}$, and the tight $d$ sets increase the atomization energy by $1.72 \mathrm{kcal} / \mathrm{mol}$. Overall, the tight $d$ sets lead to a faster convergence to the Kohn-Sham limit than standard sets. In contrast to $\mathrm{SO}_{2}$, the atomization energies of CCl , as compared with experiment, were overestimated at the basis set limit, with $\sim 2 \mathrm{kcal} / \mathrm{mol}$ and $\sim 5$ $\mathrm{kcal} / \mathrm{mol}$ greater than experiment for B3LYP and B3PW91, respectively.

Estimated Kohn-Sham limits for two extrapolation schemes are given in Tables 8.3 and 8.4. The improvement in energy due to the extrapolation to Kohn-Sham limit is less substantial. For the two-point extrapolation, a $\sim 2 \mathrm{kcal} / \mathrm{mol}$ energy change was observed according to the selected two points in the extrapolation for the standard sets, while very little energy fluctuation occurs for tight $d$ sets.

### 8.3.3 $\mathrm{ClO}_{2}$

The optimized structures for $\mathrm{ClO}_{2}$ at the quintuple zeta level are in good agreement with experiment. Bond lengths are within $0.01 \AA$ and bond angles are within $0.3^{\circ}$, as shown in Table
8.5. Atomization energies are also listed in Table 8.5. Both impacts of additional diffuse and tight $d$ functions on the atomization energy are significant. At the B3LYP/cc-pVDZ level, the augmented set increases the atomization energy by $9.16 \mathrm{kcal} / \mathrm{mol}$, while the tight $d$ sets increase the atomization energy by $13.26 \mathrm{kcal} / \mathrm{mol}$. Overall, an increase of $22.42 \mathrm{kcal} / \mathrm{mol}$ in energy was obtained by including the tight $d$ and diffuse functions in the standard sets. The improvement in energy due to tight $d$ and diffuse functions decreases when the basis set size increases. At the quintuple-zeta level, the energy change arising from tight $d$ and diffuse functions are reduced to $1.14 \mathrm{kcal} / \mathrm{mol}$ and $0.5 \mathrm{kcal} / \mathrm{mol}$, respectively.

Estimated Kohn-Sham limits from the exponential scheme are listed in Table 8.5, and the limits from the two-point extrapolation are listed in Table 8.6. For the Kohn-Sham limits from the exponential scheme, B3LYP overestimates the atomization energy by $\sim 0.5 \mathrm{kcal} / \mathrm{mol}$ for all basis sets but aug-cc-pVxZ, compared with experiment. B3PW91 overestimates the atomization energy by $4.0-6.0 \mathrm{kcal} / \mathrm{mol}$ for all basis sets. For standard sets, the two-point extrapolation scheme results in a large energy fluctuation $(\sim 10 \mathrm{kcal} / \mathrm{mol})$ due to the selected two basis sets, but results in a relative small fluctuation $(\sim 2 \mathrm{kcal} / \mathrm{mol})$ for the tight $d$ sets.

[^19]
### 8.4 Conclusions

For the three molecules studied, all show smooth convergence towards a limit as the basis set size increases. The newly developed tight $d$ correlation consistent basis sets have a significant impact on the convergence of the structures and energies. This impact decreases with respect to increasing basis set size for both density functionals. Though the rate of convergence is increased, the convergence limits undergoes little change. Substantial improvement due to the tight $d$ functions was observed at the double- and triple-zeta levels. The revised tight $d$ sets are recommended in future calculations using basis sets no larger than double- and triple-zeta.

## CHAPTER 9

## THE PERFORMANCE OF DENSITY FUNCTIONALS

WITH RESPECT TO BASIS SETS:

## THE TIGHT $d$ EFFECT ON HSO and HOS

### 9.1 Introduction

The correlation consistent basis sets have been shown in thousands of studies reported in the literature to be important in the high accuracy description of molecular properties and energetics. [15, 47-51, 53-55, 130, 131] One of the early successes of the correlation consistent basis sets was for the HSO and HOS isomers. Prior theoretical studies all had predicted that HOS was the more stable of the two isomers, [132-135] while experiments had predicted the HSO isomer to be more stable. [136, 137] In 1993, Xantheas and Dunning carried out two studies on these species, $[138,139]$ and by using more advanced methodology (CASSCF) in combination with correlation consistent basis sets of at least triple-zeta quality, correctly predicted HSO to be the more stable isomer. They also found that the HSO-HOS energy difference converged slowly as the basis set size increases, and with small basis sets (cc-pVDZ and cc-pVTZ) they predicted HOS to be the more stable isomer. This observation also shed light on the results of previous computational studies of $\mathrm{HSO} / \mathrm{HOS}$, considering that these previous calculations only used small basis sets.

After Xantheas and Dunning's work, a number of additional computational studies on these isomers were carried out. [32, 140-146] All calculations made the correct prediction that HSO is the more stable isomer. In general, a large basis set and a high-level correlated ab initio method like MP4, $\operatorname{QCISD}(\mathrm{T})$ etc. is needed to result in a correct prediction. However, none of the studies discussed the slow convergence behavior of the HSO/HOS energy difference, even though a similar problem was noted in a study of the enthalpy of formation of HSO by Denis and Ventura using DFT (B3LYP and B3PW91) with the correlation consistent basis sets. [147]

Recently, Wilson and Dunning revisited the HSO and HOS isomers using $\operatorname{CCSD}(\mathrm{T})$ with the newly developed tight $d$-augmented correlation consistent basis sets. [119] They found that the correct prediction about the stability of the isomers occurs with lower level basis sets of tight $d$-augmented sets compared to that of the regular sets. The relative energy difference converges more rapidly for tight $d$ sets than for regular sets, and the impact of tight $d$ sets on the dissociation energy is most significant at the double- and triple-zeta levels.

Another property worthy being mentioned is the enthalpy of formation of HSO. A number of theoretical studies give varied results. Xantheas and Dunning reported a value of -6.1 $\pm 1.3 \mathrm{kcal} / \mathrm{mol}$ by extrapolating the results of MRCI with a series of correlation consistent basis sets. [139] Essefar et al. [142] and Marshall et al [141] used similar G2 approachs to derive a value of $-4.9 \pm 1.3$ and $-4.8 \mathrm{kcal} / \mathrm{mol}$, respectively. Wilson and Hurst predicted a value of -4.8 $\mathrm{kcal} / \mathrm{mol}$ using modified G2 calculations. [143] Using different theoretical methods, B3LYP and B3PW91, Denis and Ventura determined a value of $-6.6 \mathrm{kcal} / \mathrm{mol}$. [147] However, these results are in sharp contrast with the latest experimental results, $-3.0 \mathrm{kcal} / \mathrm{mol}$, which was measured in a crossed beam study by Balucani et al. [148] More recently, Denis employed the $\operatorname{CCSD}(\mathrm{T})$ with aug-cc-pV $(x+d) \mathrm{Z}$ and determined a value of $-5.2 \pm 0.5 \mathrm{kcal} / \mathrm{mol} .[125]$ But, this is still 2.2
$\mathrm{kcal} / \mathrm{mol}$ away from experimental result. In Denis paper, the difference between the calculation and experiment is attributed to the very elongated transition state of the reaction $\mathrm{O}+\mathrm{H}_{2} \mathrm{~S} \rightarrow \mathrm{H}+$ HSO, which was used to determine the experimental result.

This chapter covers the second part of the performance of DFT with respect to tight $d$ correlation consistent basis sets on the structure and energies of molecules with second row atoms. In this study, we are not focused on the accurate determination of HSO enthalpy of formation. We aim to examine the impact of tight $d$ functions on the convergence behavior of HSO/HOS energy difference and enthalpy of formation of HSO in density functional theory. To our knowledge, this is the first density functional benchmark study on the impact of the tight $d$ species upon the enthalpies of formation of sulfur species. Two density functionals, B3LYP and B3PW91, with the tight $d$ sets are used to determine the relative energies of the two isomers and the enthalpy of formation of HSO for several reactions. By comparing with the results with standard sets, a better understanding of the impact of tight $d$ functions on energy and thermodynamic properties are expected.

### 9.2 Computational Details

Three functionals, B3LYP,[7, 149] B3PW91,[150] and PBE[151, 152] were used in the calculations and were combined with the two new families of correlation consistent basis sets: cc-pV $(x+d) \mathrm{Z}$ and aug-cc-pV(x+d)Z. For the PBE functional, calculations were also performed using the cc-pVxZ and aug-cc-pVxZ basis sets. All calculations were performed using the Gaussian 98 and Gaussian 03 program suites.[35, 153]Geometry optimizations and frequency calculations were done for each functional and basis set combination. Zero point energy corrections were taken directly from the frequency calculations without scaling and were
included in the final energies reported. To evaluate the density functional integrals, the default numerical grid $(75,302)$ provided in the Gaussian program was used. This grid includes 75 radial shells and 302 angular points per shell, resulting in approximately 7000 quadrature points per atom. In general, this grid is known to provide energies accurate to five places past the decimal.

The Gaussian 03 program suite was used to determine the vibrational averaged structures and anharmonic frequencies via numerical differentiation along the normal modes.[154-157] Calculations to obtain the anharmonic properties were done for all three density functionals in combination with both the standard and tight $d$-augmented correlation consistent basis sets. The SURFIT program [158] was used to confirm the anharmonic frequencies obtained. For each molecule, a total of 125 points was calculated in a range of $0.4 \mathrm{a}_{0} \geq \Delta r \geq-0.4 \mathrm{a}_{0}$ and $40^{\circ} \geq \theta \geq-$ $40^{\circ}$. Spectroscopic parameters were determined from the potential curve generated by these points. The anharmonic frequencies obtained are similar to those determined using Gaussian 03, with slight differences of no more than a few wavenumbers.

Two schemes have been used to extrapolate the energetic results obtained from calculations using a series of the correlation consistent basis sets to the Kohn-Sham limit. The first approach is the exponential scheme:

$$
\begin{equation*}
D_{e}(x)=D_{e}(\infty)+A e^{-B x} \tag{1}
\end{equation*}
$$

This approach has been used extensively to approximate CBS limits for ab initio methods such as HF, MP2, CISD, and CCSD(T) since Feller first introduced the scheme in 1992. [36] More recently, the scheme has been used successfully to approximate Kohn-Sham (KS) limits for a number of density functional methods. [31, 113, 159] Within the extrapolation scheme, $x$ is the
cardinal number of the basis set (i.e. for cc-pVDZ, $x=2$; for cc-pVTZ, $x=3$ ), $D_{e}(x)$ represents the energy at the " $x$ " level, and $D_{e}(\infty)$ represents the extrapolated energy at the CBS limit, or KS limit in the case of DFT. $A$ and $B$ are parameters that are determined in the fit. Using this scheme, at least three data points are necessary. In this study, two exponential fits were used to obtain the KS limits. The first, denoted $\mathrm{KS}_{\text {DTQ } 5}$, includes four data points, where "D" represents the data obtained using a double-zeta level basis set, "T" represents the triple-zeta level, "Q" represents the quadruple-zeta level, and " 5 " represents the quintuple-zeta level. The second, denoted $\mathrm{KS}_{\mathrm{DTQ}}$, includes results from double-, triple-, and quadruple-zeta level basis sets.

Another commonly used extrapolation scheme is a two-point extrapolation approach introduced by Halkier, et al. [37] The formulation is as follows:

$$
\begin{equation*}
D_{e}(\infty)=\frac{\left(D_{e}(x) \times x^{3}\right)-\left(D_{e}(x-1) \times(x-1)^{3}\right)}{x^{3}-(x-1)^{3}} \tag{2}
\end{equation*}
$$

For this scheme, three extrapolations were done: $\mathrm{KS}_{\mathrm{DT}}, \mathrm{KS}_{\mathrm{TQ}}$, and $\mathrm{KS}_{\mathrm{Q} 5}$ where "DT" refers to the inclusion of double- and triple-zeta level results in the fit, and, similarly for the other pairings. Again, $x$ represents the cardinal number of the basis set.

### 9.3 Results and Discussion

### 9.3.1 Structures of the HSO and HOS Isomers

Optimized structures and vibrationally averaged structures obtained using B3LYP, B3PW91, and PBE in combination with the cc-pV(x+d)Z and aug-cc-pV $(x+d) \mathrm{Z}$ basis sets are provided in Tables 9.1 and 9.2. In order to examine the overall impact of the tight $d$-augmented basis sets, results from Denis and Ventura's earlier study [32] using the standard correlation
consistent basis sets are included in Table 1 for comparison for B3LYP and B3PW91. As shown in the tables, the bond lengths of H-S and S-O for HSO and S-O for HOS converge more rapidly when the tight $d$-augmented basis sets are used than for the standard correlation consistent basis sets. For example, the bond length of S-O in HSO, which experiences the greatest impact, is nearly converged at the cc-pV(T+d)Z level, while with the standard basis sets, the bond length does not approach convergence until the cc-pVQZ or cc-pV5Z level. The effect upon the S-H bond length in HSO is minimal, with the greatest difference of $0.004 \AA$ at the double-zeta level for PBE. Additional diffuse functions (aug-cc-pV(x+d)Z) result in a small difference in the bond lengths as compared with those obtained using the regular tight $d$-augmented basis sets (cc$\mathrm{pV}(x+d) \mathrm{Z})$, with differences ranging from $0.001-0.007 \AA$. In general, cc-pV(T+d)Z structures are similar to those obtained using the cc-pVQZ or cc-pV5Z basis sets.

Overall, the bond angles are affected very slightly $\left(<1.0^{\circ}\right)$ by the tight $d$ functions, with the greater impact occurring for the smaller basis sets. Interestingly, the HSO bond angle increases for the cc-pVxZ series as the basis set size increases, while it decreases for cc$\mathrm{pV}(x+d) \mathrm{Z}$ when the basis set size increases. The opposite trend occurs for the HOS angle.

In comparing B3LYP and B3PW91, both result in nearly identical structures. Both methods are in good agreement with experimental geometries for HSO, [160] with a converged bond distance for S-H in error from experiment by $0.015 \AA$ for B3LYP and for B3PW91, and the S-O bond distance differing by $0.006 \AA$ for B3LYP and in agreement with experiment for B3PW91. The bond angle differs from experiment by $\sim 2.0^{\circ}$. In comparing previous studies shown in Table 9.1, such as work by Wilson and Dunning which used $\operatorname{CCSD}(\mathrm{T})$ in combination with regular and tight $d$ correlation consistent basis sets, [119] the calculated bond angle of the present study is in near agreement, just slightly below $105^{\circ}$. PBE predicts slightly longer bond
lengths for S-H and S-O, differing by $0.003 \AA$ and $0.018 \AA$, respectively, from experiment. The bond angle of H-S-O is underestimated by $\sim 1.6^{\circ}$.

The vibrationally averaged structures of HSO and HOS have also been determined and are provided in Table 9.2. When the dynamic correction is considered, the error as compared with experiment for the S-H bond distance is decreased to $0.001 \AA$ for B3LYP and B3PW91, while the error of the S-O bond distance is increased to $0.01 \AA$ for B3LYP and $0.005 \AA$ for B3PW91. The error in the bond angle is decreased to $\sim 1.7^{\circ}$. For PBE, the dynamic correction increases the error of the S-H and S-O bond distances to $0.021 \AA$ and $0.022 \AA$, respectively, while it decreases the error of the bond angle to $\sim 1.4^{\circ}$.

Table 9.1 Optimized geometries for HSO and HOS. Bond angles are in degrees and bond lengths are in angstroms.

As shown in Table 9.3, the tight $d$-augmented basis sets result in very little change in the computed vibrational frequencies as compared with the standard correlation consistent basis sets. For example, the frequency corresponding to the S-O stretch of HSO results in a value of 944 $\mathrm{cm}^{-1}$ with the cc-pVDZ basis set, while it is $973 \mathrm{~cm}^{-1}$ with the $\mathrm{cc}-\mathrm{pV}(\mathrm{D}+d) \mathrm{Z}$ basis set for B3LYP. The convergence, however, is faster with the tight $d$-augmented basis sets. As shown for the $\mathrm{S}-\mathrm{O}$ stretch of HSO, the B3LYP/cc-pV5Z frequency is identical to that of the B3LYP/cc-pV(T+d)Z frequency (which is essentially converged).

As compared to experiment, the converged B3LYP/cc-pV(x+d)Z S-O stretch frequencies (generally occurring at the triple-zeta level) are within a few wavenumbers of experiment (1013, $\left.1026 \mathrm{~cm}^{-1}\right) \cdot[160,161]$ For B3PW91, the calculated value of $1033 \mathrm{~cm}^{-1}$ is just slightly above the two experimental predictions, whereas PBE predicts a value of $998 \mathrm{~cm}^{-1}$, which is lower than experiment. The H-S-O bend has been calculated as $1092 \mathrm{~cm}^{-1}$ (B3LYP/cc-pV(T+d)Z) and 1106 $\mathrm{cm}^{-1}$ (B3PW91/cc-pV(T+d)Z), falling between the experimental frequencies $\left(1063,1164 \mathrm{~cm}^{-}\right.$
$\left.{ }^{1}\right),[160,161]$ while the $\mathrm{PBE} / \mathrm{cc}-\mathrm{pV}(\mathrm{T}+d) \mathrm{Z}$ result of $1057 \mathrm{~cm}^{-1}$ is slightly below the experimental values. For the S-H stretch of HSO, the B3LYP/cc-pV(T+d)Z, B3PW91/cc-pV(T+d)Z, and PBE/cc-pV $(\mathrm{T}+d) \mathrm{Z}$ predictions of 2408,2430 , and $2301 \mathrm{~cm}^{-1}$, respectively, are within the experimental values $\left(2271,2570 \mathrm{~cm}^{-1}\right) .[160,161]$ For the anharmonic frequencies reported in Table 9.4, all were decreased by $\sim 10 \mathrm{~cm}^{1}$ for the S-O stretch and the H-S-O bend and $\sim 150 \mathrm{~cm}^{-1}$ for the $\mathrm{S}-\mathrm{H}$ stretch as compared with the harmonic frequencies.

Overall, as shown by the comparison of frequencies given in Table 9.3, there is little fluctuation in the values obtained from B3LYP, B3PW91, and CCSD(T).

9.3.3 Relative Energies of HSO and HOS

In Table 9.5, relative energy differences between the HSO and HOS isomers calculated with B3LYP, B3PW91, and PBE in combination with the cc-pV(x+d)Z and aug-cc-pV(x+d)Z basis set series are provided. Additionally, for comparison, previous B3LYP and B3PW91 results of Dennis and Ventura, [32] CASSCF results of Xantheas and Dunning, [139] and $\operatorname{CCSD}(\mathrm{T})$ results of Wilson and Dunning, [119] have been given.

For the zero-point corrected relative energy, $\Delta \mathrm{E}_{0}$, B3LYP, B3PW91, and PBE incorrectly predict that HOS is the more stable isomer when a cc-pVDZ basis set is used. Using a cc-pVTZ basis set or larger results in the prediction that HSO is the more stable isomer. Combining these methods with a cc-pV $(x+d) \mathrm{Z}$ level of basis sets results in the correct prediction, even at the double-zeta level, that HSO is the more stable isomer. In earlier work by Wilson and Dunning with $\operatorname{CCSD}(\mathrm{T})$, even the tight $d$-augmented sets did not result in the correct qualitative picture at the double-zeta level.

The tight $d$ functions have a significant impact on the small basis sets, in particular. For example, B3LYP/cc-pVDZ yields an $\Delta \mathrm{E}_{\mathrm{o}}$ of $-2.41 \mathrm{kcal} / \mathrm{mol}$, while cc-pV( $\left.\mathrm{D}+d\right) \mathrm{Z}$ results in 1.36 $\mathrm{kcal} / \mathrm{mol}$ - an energy difference of $3.77 \mathrm{kcal} / \mathrm{mol}$, which also results in a change in qualitative picture. The diffuse functions (aug-cc-pV(x+d)Z) increase this difference by another 1.29 $\mathrm{kcal} / \mathrm{mol}$ to an $\Delta \mathrm{E}_{\mathrm{o}}$ of $2.65 \mathrm{kcal} / \mathrm{mol}$. For the larger basis sets, the differences are less
pronounced with differences of $1.41 \mathrm{kcal} / \mathrm{mol}$ between $\mathrm{B} 3 \mathrm{LYP} / \mathrm{cc}-\mathrm{pVQZ}\left(\Delta \mathrm{E}_{\mathrm{o}}\right.$ of $\left.3.20 \mathrm{kcal} / \mathrm{mol}\right)$ and B3LYP/cc-pV(Q+d)Z $\left(\Delta \mathrm{E}_{\mathrm{o}}\right.$ of $\left.4.61 \mathrm{kcal} / \mathrm{mol}\right)$ and $0.28 \mathrm{kcal} / \mathrm{mol}$ between B3LYP/cc-pV5Z $\left(\Delta \mathrm{E}_{0}\right.$ of $\left.4.64 \mathrm{kcal} / \mathrm{mol}\right)$ and $\mathrm{B} 3 \mathrm{LYP} / \mathrm{cc}-\mathrm{pV}(5+d) \mathrm{Z}\left(\Delta \mathrm{E}_{0}\right.$ of $\left.4.92 \mathrm{kcal} / \mathrm{mol}\right)$.

The tight $d$-augmented sets result in much faster convergence towards a limit, as shown in Table 9.5. For B3LYP, the difference in the $\Delta \mathrm{E}_{\mathrm{o}}$ obtained occurring between the cc-pVQZ ( $3.20 \mathrm{kcal} / \mathrm{mol}$ ) and cc-pV5Z ( $4.64 \mathrm{kcal} / \mathrm{mol}$ ) basis sets is still $1.44 \mathrm{kcal} / \mathrm{mol}(31 \%$ of the cc$\mathrm{pV} 5 \mathrm{Z} \Delta \mathrm{E}_{\mathrm{o}}$ ), where the tight $d$-augmented sets result in a difference in the $\Delta \mathrm{E}_{\mathrm{o}}$ of only 0.31 $\mathrm{kcal} / \mathrm{mol}\left(6 \%\right.$ of the $\left.\mathrm{cc}-\mathrm{pV}(5+d) \mathrm{Z} \Delta \mathrm{E}_{\mathrm{o}}\right)$, between the cc-pV(Q+d)Z(4.61 kcal/mol) and cc$\mathrm{pV}(5+d) \mathrm{Z}(4.92 \mathrm{kcal} / \mathrm{mol})$ basis sets. The B3PW91 and PBE results are very similar to these B3LYP results. In comparing previous results, similar improvement in convergence behavior is noted for $\operatorname{CSD}(\mathrm{T})$ in combination with the correlation consistent basis sets, [119] though with overall slower convergence ( $49 \%$ and $17 \%$ using the types of comparisons discussed above).

Our best results for $\Delta \mathrm{E}_{0}, 5.59 \mathrm{kcal} / \mathrm{mol}$ for B3PW91/aug-cc-pV(5+d)Z and $4.98 \mathrm{kcal} / \mathrm{mol}$ for B3LYP/aug-cc-pV $(5+d) \mathrm{Z}$ can be compared with the CASSCF $+1+2$ and then extrapolated result of $5.4 \mathrm{kcal} / \mathrm{mol}$ by Xantheas and Dunning. [139] PBE/aug-cc-pV(5+d) provides an $\Delta \mathrm{E}_{\mathrm{o}}$ of $6.99 \mathrm{kcal} / \mathrm{mol}$, which is $1.59 \mathrm{kcal} / \mathrm{mol}$ larger than the $\mathrm{CASSCF}+1+2$. A more recent theoretical $\Delta \mathrm{E}_{\mathrm{o}}$ has been reported by Wilson and Dunning using $\operatorname{CCSD}(\mathrm{T})$ with the tight $d$-augmented sets. [119] They reported a CBS limit of $4.2 \mathrm{kcal} / \mathrm{mol}$, which is $1.2 \mathrm{kcal} / \mathrm{mol}$ lower than that estimated by Xantheas and Dunning and is $1.7 \mathrm{kcal} / \mathrm{mol}$ higher than that $(2.5 \mathrm{kcal} / \mathrm{mol})$ determined by Esseffar using $\operatorname{QCISD}(\mathrm{T}) / 6-311+\mathrm{G}(5 d 2 f, 2 p)$. [142] In contrasting these methods, DFT may not be an ideal choice of methodology due to the multi-reference character of HSO. However, the current results are comparable with a number of previous results using advanced ab initio methods. [119, 138, 142]

As discussed in Section 9.2, several extrapolation methods have been used to estimate Kohn-Sham limits for $\Delta \mathrm{E}_{0}$, and the results are listed in Table 9.6. For the standard correlation consistent basis sets, the KS limits are inconsistent, depending highly upon the extrapolation scheme chosen. When the tight $d$-augmented sets are used, the KS limits show much less dependence upon the extrapolation scheme. The largest deviation occurs for the $\mathrm{KS}_{\mathrm{DT}}$ extrapolation, which is to be expected. Similar KS limits are obtained whether the exponential $\mathrm{KS}_{\mathrm{DTQ} 5}$ or $\mathrm{KS}_{\mathrm{DTQ}}$ fits, or the two-point $\mathrm{KS}_{\mathrm{TQ}}$ fit are used. The KS limits from the $\mathrm{KS}_{\mathrm{Q} 5}$ fit are slightly ( $\sim 0.2-0.5 \mathrm{kcal} / \mathrm{mol}$ ) higher than those obtained using the $\mathrm{KS}_{\mathrm{DTQ}}, \mathrm{KS}_{\mathrm{DTQ}}$, and $\mathrm{KS}_{\mathrm{TQ}}$ extrapolation schemes. As compared with the CBS limits of 5.41 and $5.42 \mathrm{kcal} / \mathrm{mol}$ for CASSCF and CASSCF $+1+2$, respectively, reported by Xantheas and Dunning, the B3PW91 KS $\mathrm{Dtq}_{\mathrm{DTQ}}$, $\mathrm{KS}_{\mathrm{DTQ}}$, and $\mathrm{KS}_{\mathrm{TQ}}$ limits for aug-cc-pV(x+d)Z are in good agreement (5.54, 5.45, and 5.55 $\mathrm{kcal} / \mathrm{mol}$ ), while B3LYP underestimates ( $4.94,4.86$, and $4.97 \mathrm{kcal} / \mathrm{mol}$ ) them. The KS limits for PBE overestimate these previous results. However, all of the KS limits greatly overestimate the CBS limit of $4.2 \mathrm{kcal} / \mathrm{mol}$ predicted using $\operatorname{CCSD}(\mathrm{T})$.

In Figure 9.1, the calculated $\Delta \mathrm{E}_{\mathrm{o}}$ for B3PW91 with respect to cc-pV(x+d)Z and aug-cc$\mathrm{pV}(x+d) \mathrm{Z}$ basis sets is shown. Included in this figure are previous cc-pVxZ results from Denis and Ventura. [32] The tight $d$ functions greatly improved the convergence behavior with respect to increasing basis set as shown.

Table 9.5 Energy differences (with respect to HSO) of HSO and HOS. $\Delta \mathrm{E}_{\mathrm{e}}$ represents the energy difference without including the zero point correction while $\Delta \mathrm{E}_{0}$ represents the energy difference including the zero point correction. A positive value indicates that the HSO isomer is more stable.

Figure 9.1 Relative energies of the HSO and HOS isomers obtained from B3PW91 calculations with the cc-pV(x+d)Z and aug-cc-pV(x+d)Z basis sets. cc-pVxZ results from Denis and Ventura[32] (represented by the $\square$ - though the cc-pVDZ result is from the present study) have been included for comparison.

### 9.3.4 Enthalpy of Formation of HSO

For purposes of this study, our interest in examining the enthalpy of formation is in order to assess the potential impact of the tight $d$ functions upon calculated enthalpies of formation, rather than provide a recommended route or full discussion of possible means to determine the enthalpy of formation. We have simply selected a series of reactions used (and discussed fully) in previous work, most notably the work by Denis and Ventura using B3LYP and B3PW91 in combination with the cc-pVxZ basis sets, [32] as this provides us with a means for comparison for the tight $d$-augmented basis sets.

The seven reactions evaluated include the following:

$$
\begin{align*}
& \mathrm{H}_{2} \mathrm{~S}+\mathrm{SO} \rightarrow \mathrm{HSO}+\mathrm{HS}  \tag{1}\\
& \mathrm{H}+\mathrm{SO} \rightarrow \mathrm{HSO}  \tag{2}\\
& \mathrm{H}_{2}+2 \mathrm{SO} \rightarrow 2 \mathrm{HSO}  \tag{3}\\
& \mathrm{HS}+\mathrm{O} \rightarrow \mathrm{HSO}  \tag{4}\\
& 2 \mathrm{HS}+\mathrm{O}_{2} \rightarrow 2 \mathrm{HSO}  \tag{5}\\
& \mathrm{H}+\mathrm{S}+\mathrm{O} \rightarrow \mathrm{HSO}  \tag{6}\\
& \mathrm{H}_{2}+2 \mathrm{~S}+\mathrm{O}_{2} \rightarrow 2 \mathrm{HSO} \tag{7}
\end{align*}
$$

In Table 9.7, the HSO enthalpy of formation determined for each reaction, method, and basis set combination is reported, along with results from previous calculations. For each combination, the enthalpy of formation has been determined by combining enthalpies of reaction with accurately known enthalpies of formation.

Reactions [4] through [7] are more greatly impacted by the tight $d$-augmented basis sets than reactions [1] through [3]. For example, at the aug-cc-pVDZ level, the tight $d$ set results in an overall reduction of the enthalpies of formation of $5 \mathrm{kcal} / \mathrm{mol}$ (or greater), as well as a change
in sign of the enthalpy (in all cases but reaction [5]). In reaction [6] with B3LYP, tight $d$ functions result in reduction of the enthalpy of formation by $6.27,3.86,2.3$ and $0.51 \mathrm{kcal} / \mathrm{mol}$ energy at the aug-cc-pVDZ, cc-pVTZ, cc-pVQZ, and cc-pV5Z levels, respectively. Overall, at the quadruple-zeta level, for reactions [4] through [7], the tight $d$ set results in a reduction of $\sim 2$ $3 \mathrm{kcal} / \mathrm{mol}$ in the enthalpy. This marks a change in the value of cc-pVQZ relative to cc$\mathrm{pV}(\mathrm{Q}+d) \mathrm{Z}$ of $48 \%, 70 \%, 36 \%$, and $57 \%$ for reactions [4], [5], [6], and [7], respectively.

Reactions [1] through [3] are not impacted as significantly by the tight $d$ functions. At the B3LYP/aug-cc-pVDZ level, the tight $d$ drops the enthalpy of formation determined by reaction [1] by only $0.17 \mathrm{kcal} / \mathrm{mol}$. The changes for reactions [2] and [3] are slightly higher, with differences of 1.37 and $1.33 \mathrm{kcal} / \mathrm{mol}$, respectively. At the quadruple-zeta level, the impact of the tight $d$ function is reduced to $0.06,0.58$, and $0.54 \mathrm{kcal} / \mathrm{mol}$ for reactions [1], [2], and [3]. As compared with the cc-pV(Q+d)Z enthalpy of formation, this marks percentage differences of $1 \%$, $13 \%$, and $13 \%$ for the three reactions, indicating the smaller impact of the tight $d$ functions.

Though the tight $d$ functions do have an impact upon the overall convergence rate of the enthalpy of formation and also can have a dramatic impact upon the value of the enthalpy when lower level basis sets (through quadruple-zeta for reactions [4] through [7]) are used, at the quintuple-zeta level, the conclusions reached in the earlier study by Denis and Ventura regarding the magnitude of enthalpies of formation calculated via reactions [1] through [7] remain the same. The calculated enthalpies of formation overall result in two different ranges of values. From reactions [1], [4], and [6], B3LYP/aug-cc-pV $(5+d) \mathrm{Z}$ values of $-6.29,-6.36$, and -7.06 $\mathrm{kcal} / \mathrm{mol}$ emerge, while for reactions [2], [3], [5], and [7], values of $-4.83, \quad-4.42,-4.49$, and $4.73 \mathrm{kcal} / \mathrm{mol}$ result. For B3PW91, all predicted enthalpies of formation fall in three ranges, $\sim-4$
$\mathrm{kcal} / \mathrm{mol}$ for reaction [2] and [5], $\sim-6 \mathrm{kcal} / \mathrm{mol}$ for reaction [1], [3] and [7] and $\sim-7 \mathrm{kcal} / \mathrm{mol}$ for reaction [4] and [6]. Interestingly, the enthalpies of formation determined using PBE differ

Table 9.7 Estimated enthalpies of formation for HSO in $\mathrm{kcal} / \mathrm{mol}$.

substantially, based upon the reaction used in the determination. A very large enthalpy of formation ( $\sim-20 \mathrm{kcal} / \mathrm{mol}$ ) is obtained based upon reactions [4] and [6], while reactions [1] and [2] result in similar enthalpies as those determined by B3PW91. These values are not surprising, as PBE has been shown to perform poorly in predicting thermochemical data, including enthalpies of formation, for a large range of molecular systems. [164, 165] Xantheas and Dunning suggest a value of $-4.2 \mathrm{kcal} / \mathrm{mol}$ based upon their CASSCF results, which were obtained using the standard correlation consistent basis sets. [138] Esseffar also suggests a value of $-4.2 \mathrm{kcal} / \mathrm{mol}$, using $\operatorname{QCISD}(\mathrm{T})$. [142] Recently, Denis determined a value of $-5.2 \mathrm{kcal} / \mathrm{mol}$ using $\operatorname{CCSD}(\mathrm{T})$ with the aug-cc-pV $(x+d) \mathrm{Z}$ basis sets. [125] All above theoretical results are larger than a recently experimental enthalpy of formation $(-3.0 \mathrm{kcal} / \mathrm{mol})$ by Balucani. [148]

### 9.3.5 Reaction barrier to $\mathrm{HSO} \rightarrow \mathrm{HOS}$

In a previous study, $\mathrm{CASSCF}+1+2$ was used in combination with cc-pVTZ and cc-pVQZ to determine the reaction barrier for the HSO/HOS isomerization. [138] A substantial barrier was observed, which helps to explain why only HSO has been observed experimentally. In this study, DFT was used with the standard and tight $d$-augmented correlation consistent basis sets in order to assess the usefulness and impact of DFT and tight $d$ functions in determining the barrier to isomerization, which is reported in Table 9.8. Additionally, the structure and harmonic frequencies for the transition state are shown in Table 8, and are compared with previous CASSCF $+1+2$ calculations.

The tight $d$-augmented functions have an expected effect upon the barrier to isomerization - convergence in the barrier occurs more quickly than for the standard basis sets. For all three functionals, the barrier has nearly reached convergence at the quadruple-zeta level when the tight $d$-augmented sets are used, whereas this does not occur until the quintuple-zeta
level for the standard basis sets. The bond S-O and H-S bond distances determined for the transition state are slightly longer than those shown by CASSCF $+1+2 / \mathrm{cc}-\mathrm{pVQZ}$. The bond angle is $\sim 1-2^{\circ}$ larger using DFT.

Table 9.8 Structure of the transition state and the barrier for the $\mathrm{HSO} \rightarrow \mathrm{HOS}$ isomerization with respect to HSO.

### 9.3.6 Spectroscopic Constants for the HSO

Tables 9.9, 9.10, and 9.11 list calculated spectroscopic constants for HSO including rotational constants, anharmonicity constants, and rotational-vibrational coupling. The results were calculated using three density functionals in combination with cc-pVxZ, cc-pV(x+d)Z, and aug-cc-pV $(x+d)$ Z. Though experimental spectroscopic constants for HSO are not available to date, in this section, we aim to investigate the effect of tight $d$ sets on the calculated DFT spectroscopic constants.

As expected, tight $d$ sets have an impact on almost all of the spectroscopic constants. The impact is greatest at the double- and triple-zeta levels. For example, the B3PW91/cc-pVDZ and B3PW91/cc-pV(D+d)Z results for $A_{\mathrm{e}}$ differ by $0.13 \mathrm{~cm}^{-1}$. The difference decreases to $0.1 \mathrm{~cm}^{-1}$ at the triple zeta level, $0.05 \mathrm{~cm}^{-1}$ at the quadruple zeta level, and $0.02 \mathrm{~cm}^{-1}$ at the quintuple zeta level. Comparision of the results from cc-pV(x+d)Z and aug-cc-pV $(x+d) \mathrm{Z}$ shows that the addition of extra diffuse functions contributes little to the spectroscopic constants of HSO. As for the other properties described above, B3LYP and B3PW91 result in similar performance in
determining the spectroscopic constants of HSO. However, PBE results are quite different particularly for the anharmonicity constants, as compared with B3LYP and B3PW91.

Table 9.9 Calculated spectroscopic constants for HSO using B3LYP in combination with cc-pV $x \mathrm{Z}$, cc-pV( $x+d) \mathrm{Z}$, and aug-cc-pV( $x+d) \mathrm{Z}$.

### 9.4. Conclusions

The use of the cc-pV $(x+d) \mathrm{Z}$ and aug-cc-pV $(x+d) \mathrm{Z}$ basis sets in combination with B3LYP, B3PW91, and PBE for sulfur species such as HSO and HOS can be important, particularly for the lower level basis sets. For structures, the impact upon the bond lengths and angles of these structures is slight. However, the sets do enable a converged geometry to be ascertained using a lower level basis set. In terms of a description of the relative energies of the isomers, the tight $d$ functions enable the correct prediction that HSO is more stable than HOS to occur with simply a double-zeta level basis set and yield a relative energy of HSO and HOS that is in good agreement with previous MRCI calculations by Xantheas and Dunning. For the enthalpy of formation, the tight $d$-augmented basis sets can have a significant impact upon the enthalpies, even for a quadruple-zeta level basis set. The level of impact seems to be heavily based upon reaction used to determine the enthalpy. Overall, the use of the cc-pV(x+d)Z and aug-cc-pV(x+d)Z basis sets is important in the determination of energetics, including thermochemical properties such as enthalpies, and is recommended, particularly when lower level basis sets will be employed.
