Germany.**Abstract**

The growth of yeast cells in batches in glucose-based media is a standard condition in most yeast laboratories. Most gene expression experiments are done by taking this condition as a reference. Presumably, cells are in a stable physiological condition that can be easily reproduced in other laboratories. With this assumption, however, it is necessary to consider that the average amount of the mRNAs per cell for most genes does not change during exponential growth. That is to say, there is a steady-state condition for the transcriptome. However, this has not been rigorously demonstrated to date. In this work we take several cell samples during the exponential phase growth to perform a kinetic study using the genomic run-on (GRO) technique, which allows simultaneous measurement of the amount of mRNA and transcription rate variation at the genomic level. We show here that the steady-state condition is fulfilled for almost all the genes during most exponential growth in yeast extract–peptone–dextrose medium (YPD) and, therefore, that simultaneous measures of the transcription rates and the amounts of mRNA can be used for indirect mRNA stability calculations. With this kinetic approach, we were also able to determine the relative influence of the transcription rate and the mRNA stability changes for the mRNA variation for those genes that deviate from the steady state. Keywords: transcription rate; steady state; transcriptome; *Saccharomyces cerevisiae*; mRNA stability**1 Introduction**

2
3 Evaluation of the amount of mRNA (RA) for a
4 given gene by means of northern blot, qPCR or
5 other techniques is a routine in many molecu-
6 lar biology experimental protocols. Comparisons
7 between different physiological situations or be-
8 tween different cell types or mutants are habitu-
9 ally studied. As a significant number of mRNAs
10 can vary their concentrations, even upon subtle
11 changes in internal or external conditions, it is
12 crucial to sample cells in identical situations in
13 order to guarantee repetitiveness and comparativ-
14 eness between experiments. This is especially true
15 for batch cultures of free-living microorganisms

16 where the growth rate and environment are con-
17 tinuously changing. This problem can be solved by
18 using continuous culture conditions, but such con-
19 ditions are more technically demanding. Therefore,
20 most published experiments use batch conditions.
21 For most batch culture analyses, researchers select
22 exponential growth in a rich medium as the default
23 state for comparison, as it is usually thought to be a
24 physiologically constant condition in which most,
25 or all, mRNAs remain unchanged in a steady-state
26 condition. This can facilitate comparisons between
27 experiments done in different laboratories. How-
28 ever, because the emergence of genomic techniques
29 has raised the possibility of simultaneously quanti-
30 fying most cellular mRNAs at the same time, the

1 need for a rigorous demonstration of the steady-
2 state condition now extends to thousands of genes.

3 One of the most studied organisms in func-
4 tional genomics is the yeast *Saccharomyces cere-*
5 *visiae*. There are hundreds of experiments on
6 this yeast using cells growing on YPD (yeast
7 extract–peptone–dextrose) complete medium in
8 the ‘exponential growth condition’. It is known,
9 however, that many genes vary during exponen-
10 tial growth when cells approach the diauxic shift
11 (DeRisi *et al.*, 1997) or change in a growth rate-
12 dependent manner (Regenberg *et al.*, 2006). As
13 stated above, the use of chemostats has been
14 described as a more reliable way to avoid such vari-
15 ations because they keep culture conditions stable
16 (Daran-Lapujade *et al.*, 2009; Hayes *et al.*, 2002).
17 However, most yeast researchers have used, and
18 still use, the exponential growth condition in batch
19 cultures for their experiments.

20 Although the majority of studies focus only on
21 the determination of RA, it is becoming increas-
22 ingly clear that gene expression should be stud-
23 ied as a kinetic process in which the amount of
24 mRNA is controlled not only by transcription but
25 also by the influence of mRNA stability (RS, also
26 called mRNA half-life; Pérez-Ortín *et al.*, 2007). In
27 exponential growth a dynamic steady state can be
28 assumed for RA, i.e. the transcription and degrada-
29 tion rates (TR and DR, respectively) are equal. TR
30 follows a zero-order kinetics (does not depend on
31 RA), whereas DR follows first-order kinetics:

$$32 \quad DR = k_d RA$$

33
34 Therefore, in steady state:

$$35 \quad TR = DR = k_d RA$$

36
37 where k_d is the degradation constant, which is
38 inversely related to RS ($k_d = \ln 2/RS$). Thus, in this
39 situation, TR can be calculated from experimentally
40 determined RA and stability data (Holstege *et al.*,
41 1998); alternatively, DR can be calculated from RA
42 and TR data (García-Martínez *et al.*, 2004). Both
43 approaches are becoming increasingly popular for
44 TR or DR calculations, although it has not yet been
45 established whether the true steady-state condition
46 for gene expression actually applies (Pérez-Ortín,
47 2007). A steady state defined for RA does not
48 necessarily imply steady states for TR and DR. In
49 fact, it would be theoretically possible for TR and
50
51

52 DR to change simultaneously in parallel, keeping
53 RA constant.

54 In this paper we address the topic of assessing
55 the steady-state condition for mRNA amounts in
56 *S. cerevisiae* cells growing in YPD at the expo-
57 nential phase. First we performed an experiment
58 to determine whether the steady state applies for
59 yeast in which we simultaneously measure TR and
60 RA for all the genes. We also studied the kinetic
61 behaviour of any gene that seems to deviate from it.
62 In this way we have demonstrated that the steady-
63 state condition for RA is true for most of the genes
64 studied, but that there are small but significant
65 changes in some groups of genes, which change
66 either their TR or DR as the culture approaches
67 the diauxic shift. Because TR also remains almost
68 invariable, we can say that there is also a steady
69 state for TR and DR. Finally, we reanalysed pre-
70 viously published data (Radonjic *et al.*, 2005) to
71 expand the time window of our study and to deter-
72 mine how long the steady-state condition is main-
73 tained. We found that the RA steady state is ful-
74 filled over a long period within the exponential
75 phase.

76 77 78 **Materials and methods**

79 80 **Yeast strain and growth conditions**

81 Yeast strain BQS252 (*MATa, ura3-52*; derived by
82 sporulation from FY1679) was used. Cells were
83 grown in YPD (yeast extract 1%, peptone 2%, and
84 glucose 2%) with agitation (190 rpm) at 28 °C for
85 the repeated sampling of exponentially growing
86 yeast cells. Cell cultures were grown overnight
87 until they reached the desired OD₆₀₀. Five time
88 points were taken at 0, 10, 20, 30 and 40 min
89 after the initial sample, which corresponded to
90 OD₆₀₀ = 0.36 (8×10^6 cells/ml), 0.38, 0.41, 0.44
91 and 0.47, respectively. Three biological replicates
92 of the whole experiment were done.

93 94 95 **Genomic run-on (GRO)**

96 The GRO was done essentially as described in
97 García-Martínez *et al.* (2004). Briefly, two aliquots
98 of ca. 4×10^8 cells were harvested at each time
99 point. One aliquot was used directly for the GRO
100 protocol, in order to obtain TR data, while the
101 other one was frozen for subsequent total RNA
102 extraction. The cells of the GRO sample were

1 permeabilized with 0.5% Sarkosyl and incubated
2 for 20 min on ice. Then the cells were allowed to
3 extend the nascent RNA in the presence of [α - 33 P]-
4 UTP. Finally, the radioactively labelled RNA was
5 extracted and hybridized onto a nylon macroarray
6 (Alberola *et al.*, 2004). After TR determination, the
7 total RNA sample was labelled by cDNA synthesis
8 with random hexamers and hybridized in the same
9 arrays in order to determine the RA.

10 11 Image analysis and data normalization

12 Images were quantified using Array Vision soft-
13 ware, v. 7.0 (Imaging Research Inc.). The signal
14 intensity for each spot was the background sub-
15 tracted ARM (artifact removed median) density.
16 Only values that were 1.35 times over the cor-
17 responding background were taken as valid mea-
18 surements. The reproducibility of the replicates
19 was checked using Array Stat software (Imaging
20 Research Inc.). We considered the data to be inde-
21 pendent and used a minimum number of two valid
22 replicates in order to calculate the mean and stan-
23 dard deviation (SD) values for every gene. Nor-
24 malization between conditions was done using the
25 global median method.
26

27 28 Data analysis

29 We used the differential gene expression anal-
30 ysis program from the GEPAS suite (Montaner
31 *et al.*, 2006) to analyse whether there was any
32 significantly different slope from 0 for the varia-
33 tion of RA during exponential growth (Radonjic
34 *et al.*, 2005) with regard to a continuous indepen-
35 dent variable (time). Similar results were obtained
36 when the culture OD₆₀₀ was used as a continuous
37 independent variable instead of the time (data not
38 shown).
39

40 The detailed RA and TR data for exponential
41 growth between OD₆₀₀ 0.36 and 0.47 was cal-
42 culated as previously described (García-Martínez
43 *et al.*, 2004; for the whole dataset, see Support-
44 ing information, Table S1). Briefly, the intensity of
45 the mRNA or GRO hybridization was normalized
46 using a genomic DNA hybridization signal and the
47 U-richness (GRO) or C-richness (mRNA) correc-
48 tion. We computed the slope of RA and TR varia-
49 tions on a log₂ scale with regard to time by assum-
50 ing that the median TR and RA of the gene popula-
51 tion remained constant during the experiment (see

Supporting information, Table S2). Gene functional
52 analyses were done by analysing either individual
53 genes slopes (using FuncAssociate; Berriz *et al.*,
54 2003) or gene sets (using Fatiscan from the BABE-
55 LOMICS suite; Al-Shahrour *et al.*, 2006). To anal-
56 yse the changes in RS, we computed a theoreti-
57 cal RA variation dataset for all the genes, using
58 the RA amount data obtained for the first time
59 point and the experimentally obtained TR data
60 for the whole experiment. Using these data, it is
61 possible to calculate a theoretical RA for each
62 point by assuming that the RS calculated the first
63 time remains constant during the whole experiment
64 (Pérez-Ortín *et al.*, 2007). We compared the dif-
65 ferences between this theoretically computed RA
66 and the actual one, and assumed that the differ-
67 ences found would be due to stability changes
68 during the experiment (see Figure 1A). To obtain
69 a more robust RA variation, we performed a lin-
70 ear regression analysis of the actual and theoretical
71 RA data and computed the predicted RA varia-
72 tion for each gene during our experiment, using
73 all the time points. Finally, we computed the per-
74 centage of actual RA variation and the theoretical
75 one (TR-dependent RA variation) for each gene.
76 The difference between the actual and the theoret-
77 ical RA directly gives the stability-dependent RA
78 variation.
79

80 81 Accession numbers

82 The genomic data are stored in the Valencia
83 Yeast (VYdBase; <http://vydbase.uv.es/>) and GEO
84 databases. The GEO Accession No. for the set of
85 different hybridizations is GSE11521.
86

87 88 Results

89 90 Verification of the steady state for mRNA 91 on yeast cells using genomic run-on (GRO) 92 analyses

93 To determine whether the yeast transcriptome was
94 in a steady-state condition during the exponential
95 phase on the YPD medium, we measured the vari-
96 ation of mRNA at five time points during exponen-
97 tial growth. As most of the published experiments
98 start with a very low OD₆₀₀ after inoculation and
99 reach a middle exponential phase of 0.3–0.6 at 100
101 OD₆₀₀, we decided to monitor the mRNA varia-
102 tion under these conditions. We also used our GRO

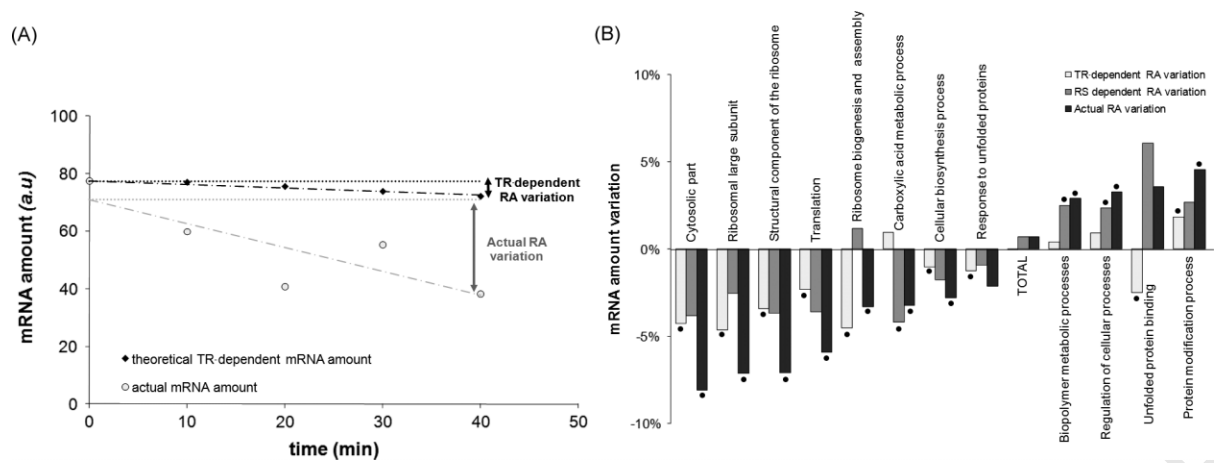

Figure 1. Relative contributions of the transcription rate (TR) and mRNA stability (RS) to the mRNA amount (RA) change. (A) Scheme of the protocol used to compute the mRNA variation, which is dependent in either TR or RS. The theoretical RA values in the experiment were computed for each gene by taking in account only the TR variations and by assuming a constant RS (in black). When comparing this theoretical TR-dependent RA change with the actual one (experimentally measured, in grey), it is possible to compute the percentage of RA variation for each gene, which is due to changes in either TR or RS. The data shown correspond to a sample gene (*YAL004W*) that has been chosen to show an important contribution of RS to RA variation. It is shown in natural scale to make the differences more evident. However its RA slope does not reach the significance cut-off for being statistically different from 0 (in either natural or \log_2 scale; FDR p value >0.8). (B) Relative contribution of TR (light grey) or RS (dark grey) to the total RA variation (black) for selected gene groups shown in Table 1. Bars represent the median value for the variation for all the genes in each group. The groups with significant differences from 0 (as shown in Tables 1 and S3) are marked with black dots

1 protocol, which allows the simultaneous determi-
 2 nation of TR and RA data. In this way, if the
 3 steady-state condition was verified, we could also
 4 calculate the mRNA stabilities from the RA and
 5 TR data (García-Martínez *et al.*, 2004).

6 We performed an experiment in triplicate for
 7 the five time points at OD_{600} 0.36–0.47 (span-
 8 ning 40 min, at 10 min intervals), using cultures
 9 inoculated 16 h beforehand. Under these condi-
 10 tions, the diauxic shift started several hours later
 11 at $OD_{600} \approx 2$ (V. Pelechano, unpublished observa-
 12 tion). All 15 samples were subjected to the GRO
 13 protocol for calculating RA and TR. The repeti-
 14 tiveness of the samples was very good (see Sup-
 15 porting information, Figure S1). Pearson's correla-
 16 tion was, on average, 0.934 for the TR data and 0.936
 17 for the RA data between the biological replicates. The
 18 correlation for the data points for a single growth
 19 curve was even better: 0.965 for TR and 0.964
 20 for RA. This suggests that there is more biolog-
 21 ical variation between growth curves in different
 22 experiments than within the time points of a single
 23 exponential phase curve. However, as we fused
 24 the different replicates, only the time-dependent
 25

variations (common for all three experiments) were
 taken into account.

We reasoned that the slight changes occurring
 during growth in the culture composition would
 affect the cells' physiology, leading to a continuous
 change in RA or TR, which would be visible as
 positive or negative slopes in their respective plots.
 In this way, artifactual or random changes would
 not be accounted for. However, when we analysed
 these data using the GEPAS suite (a differential
 expression analysis tool; Montaner *et al.*, 2006),
 no individual slope of any gene differed signifi-
 cantly from zero (FDR >0.6). This result confirms
 that the steady-state condition applies for all (at
 least most of) the yeast genes. Therefore, no im-
 portant error is associated when taking samples for
 mRNA quantification from cells growing in the
 early exponential phase. Thus, either TR or RS
 can be calculated in these growth conditions from
 the RA experimental data and either from the
 respective RS data, measured by conventional
 methods (Grigull *et al.*, 2004), or from the TR
 data, measured by GRO by means of mathematical
 calculations (Pérez-Ortín, 2007).

1 However, the behaviour of genes can be too
2 subtle to be discovered from studying single genes
3 tendencies only. Therefore, in order to analyse
4 this result in more depth, we used a tool from
5 the BABELOMICS suite (Fatiscan algorithm; Al-
6 Shahrour *et al.*, 2006), which scans the whole set
7 of gene data to discover any common trends in
8 the GO categories. Specifically, this algorithm does
9 a segmentation test that checks whether there are
10 any significant asymmetries in the distribution of
11 each GO. In this way, minor changes that are often
12 too minor to be significant for individual genes
13 can be statistically stressed by the common GO
14 group behaviour. We scanned all the GO categories
15 at all the possible levels. With this analysis, we
16 found that some groups significantly increased
17 or decreased during the experiment (Table 1A).
18 Moreover, as we simultaneously measured RA
19 and TR, we were able to distinguish between the
20 different regulatory strategies.

21 Some group changes were detected in both TR
22 and RA, but others were observed in only one
23 of them. For instance, the translation-related cat-
24 egories were seen to lower RA and TR, which is
25 in agreement with the decrease noted in the cell

duplication rate that the culture would undergo sev- 26
eral hours afterwards. Moreover, the differences 27
between RA and TR behaviours illustrate the possi- 28
bility of detecting the regulatory strategies followed 29
for the mRNA changes: are the changes in RA 30
due to changes in transcription or to changes in 31
mRNA stability? If we assume that the steady- 32
state condition applied for this experiment, then 33
we could calculate the respective influence of TR 34
and RS on the RA change (for a detailed expla- 35
nation, see Figure 1A and Materials and methods). 36
With this protocol, we were able to calculate their 37
relative influence on the changes noted in each 38
GO category, as seen in Table 1 and Figure 1B. 39
We analysed the slope of the RA variation that 40
could be explained by RS changes using Fatiscan. 41
Then we selected the groups with either a sig- 42
nificant positive contribution (meaning increased 43
stability) or a significant negative one (meaning 44
decreased stability) (Table 1B). The fact that the 45
number of statistical significant groups found for 46
the RS changes is smaller than the ones found in 47
the direct measures could be explained mainly by 48
two factors; because it only takes into account the 49
part of the variation for the RA, due to stability 50

Table 1. Functional groups with a significant deviation from the steady state during exponential growth

(A) Direct measures			
Groups in which Transcription Rate (TR) increases		Groups in which mRNA amount (RA) increases	
Adjusted <i>p</i> value	Functional group	Adjusted <i>p</i> value	Functional group
$6.35 \cdot 10^{-3}$	Protein modification	$3.36 \cdot 10^{-4}$	Biopolymer metabolic process
$7.26 \cdot 10^{-3}$	Post-translational protein modification	$5.71 \cdot 10^{-4}$	Regulation of cellular process
$1.66 \cdot 10^{-2}$	Cation transporter activity	$1.27 \cdot 10^{-2}$	Regulation of transcription
$2.53 \cdot 10^{-2}$	Meiosis I		
$3.39 \cdot 10^{-2}$	Oxidoreductase activity, oxidizing metal ions		
Groups in which transcription rate (TR) decreases		Groups in which mRNA amount (RA) decreases	
Adjusted <i>p</i> value	Functional group	Adjusted <i>p</i> value	Functional group
$2.82 \cdot 10^{-10}$	Cytosolic part	$2.52 \cdot 10^{-8}$	Structural constituent of ribosome
$1.33 \cdot 10^{-6}$	Ribosome	$2.78 \cdot 10^{-7}$	Ribosome
$8.91 \cdot 10^{-5}$	Ribosome biogenesis and assembly	$4.00 \cdot 10^{-6}$	Cytosolic part
$2.32 \cdot 10^{-4}$	Structural constituent of ribosome	$7.23 \cdot 10^{-5}$	Large ribosomal subunit
$6.35 \cdot 10^{-3}$	Translation	$1.09 \cdot 10^{-4}$	Translation
$6.35 \cdot 10^{-3}$	Cellular biosynthetic process	$5.29 \cdot 10^{-3}$	Ribosome biogenesis and assembly
$1.18 \cdot 10^{-2}$	Cytoplasmic exosome (RNase complex)	$4.16 \cdot 10^{-2}$	Monocarboxylic acid metabolic process
$2.15 \cdot 10^{-2}$	Histidine biosynthetic process		
$2.15 \cdot 10^{-2}$	Riboflavin metabolic process		
$3.39 \cdot 10^{-2}$	Response to unfolded protein		
$3.39 \cdot 10^{-2}$	Response to protein stimulus		

Table I. Continued

(B) Indirect measures			
Groups in which mRNA stability (RS) increases		Groups in which mRNA stability (RS) decreases	
Adjusted <i>p</i> value	Functional group	Adjusted <i>p</i> value	Functional group
$1.07 \cdot 10^{-5}$	Biopolymer metabolic process	$2.06 \cdot 10^{-3}$	Organic acid metabolic process
$2.06 \cdot 10^{-3}$	Regulation of biological process	$2.06 \cdot 10^{-3}$	Carboxylic acid metabolic process
$2.86 \cdot 10^{-3}$	Regulation of cellular process		

(A) Functional groups with significant slopes for experimentally determined (direct measures) TR or RA along the five time points analysed during early exponential growth. (B) Functional groups with a significantly high contribution of RS to the RA increase or decrease (mRNA stabilization or destabilization, respectively). The RS-dependent RA slope was mathematically computed (indirect measures), as explained in Figure 1A, and used for the functional analysis. Only some representative GO are shown (for the complete list, see Supporting information, Table S3). All the analyses were done using the Fatscan algorithm from BABELOMICS (Al Shahrour *et al.*, 2006); the FDR-adjusted *p* values are shown.

1 changes, and because it is an indirect measure.
 2 The fact of being an indirect measure depending
 3 on the TR and RA data makes it more noisy (in
 4 fact the SD for the RS-dependent RA slopes is
 5 larger (0.0074) than that from TR or RA direct
 6 measures (0.0058 and 0.0057, respectively). It can
 7 be seen that both TR and RS cooperate to either
 8 lower or increase RA for most categories; that is to
 9 say, homodirectional changes occurred, although in
 10 variable proportions. In some groups, however, the
 11 changes observed operated in opposite senses. RiBi
 12 genes had a decreased RA, due to a large effect
 13 on TR that compensated slight mRNA stabiliza-
 14 tion, whereas unfolded protein response mRNAs
 15 increased because of strong mRNA stabilization,
 16 despite a certain decrease in TR. It is important to
 17 note that all these changes were very subtle, and
 18 could be taken in account only for those GOs in
 19 which significant changes for the kinetic param-
 20 eters had been previously detected. These results
 21 illustrate the variable methods used by the yeast
 22 cell to change the mRNA level (Pérez-Ortín *et al.*,
 23 2007).

24 25 Determination of the time window 26 when assuming the steady state for mRNAs 27 in yeast cells growing in the exponential phase 28

29 As our experiment covered only a relatively small
 30 time window of exponential phase growth in yeast
 31 ($OD_{600} = 0.3-0.5$), we decided to assess whether
 32 this steady state for the transcriptome is maintained
 33 in later phases of exponential growth. To deter-
 34 mine this, we reanalysed the data from the com-
 35 prehensive study of Radonjic *et al.* (2005). In their

experiment, the authors analysed the transcriptome 36
 of wild-type yeast (S288c background) growing in 37
 a batch culture in YPD since the inoculation on 38
 fresh medium to the late stationary phase. They use 39
 $OD_{600} = 0.5$ as the starting condition, which pre- 40
 cludes a direct comparison with our conditions. The 41
 growth curve included nine experimental points in 42
 the exponential phase in the range 3.9–9 h after 43
 inoculation (see Figure 1A from Radonjic *et al.*, 44
 2005). This study measured only the RA changes, 45
 but this is enough to check the steady-state condi- 46
 tion. First, we analysed this data using the GEPAS 47
 suite (a differential expression analysis tool; Mon- 48
 taner *et al.*, 2006). Probably because the analysed 49
 time window in this experiment is longer, covering 50
 more physiological variations, the number of genes 51
 with a slope different from zero ($FDR < 0.01$) was 52
 higher. We obtained 304 genes showing a posi- 53
 tive slope, and 271 showing a negative slope when 54
 their \log_2 RA data were plotted against the time 55
 course (Figure 2A). They were enriched in some 56
 GO categories. Specifically, the mRNA levels of 57
 those categories related with respiration and pro- 58
 tein catabolism increased, unlike the mRNA levels 59
 of those categories related to ribosome biogenesis, 60
 which decreased (Figure 2B). Both results fitted the 61
 expected changes in cell metabolism, which would 62
 take place when entering the diauxic shift some 63
 hours later (DeRisi *et al.*, 1997; Radonjic *et al.*, 64
 2005), and they are in agreement with the slight 65
 changes detected in our previous experiment. A 66
 close inspection of the results, however, showed 67
 that most of the changes noted in relation to the 68
 initial exponential phase at 3.9 h in those genes 69
 took place at the last two time points analysed, 70

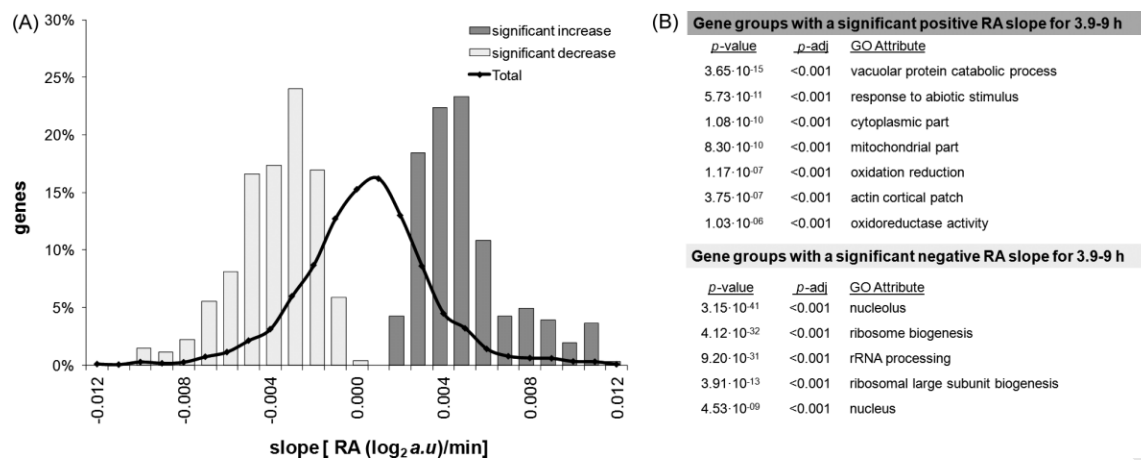

Figure 2. mRNA amount variation during exponential growth. (A) Histogram of slopes for the mRNA amount (RA) variation (in log₂ scale for arbitrary units) as a function of time (min) for the 3.9–9 h interval, according to Radonjic *et al.* (2005). The distribution of all the gene slopes is shown as a black line. Bars represent the genes with slopes that significantly differ (positively in dark grey and negatively in light grey) from 0 (FDR < 0.01). The y axis represents the percentage of genes, with regard to the total number analysed, belonging to each class. (B) The gene groups that are significantly enriched in genes that increase or decrease RA. Significance was calculated using FuncAssociate (Berriz *et al.*, 2003) Only the most representative GO categories are shown

Table 2. Change in the mRNA amount slope during exponential growth

Functional group	3.9–4.75 h	4–5.25 h	4.25–5.75 h	4.75–6.5 h	5.25–7.25 h	5.75–9 h
Cytoplasm	↑ 2.29 · 10⁻⁸	↑ 9.53 · 10⁻⁸	↑ 2.76 · 10⁻⁵	↑ 2.05 · 10⁻⁷	↑ 3.35 · 10⁻¹⁶	↑ 1.14 · 10⁻⁶

Gene-set enrichment analysis using Fatican (Al Shahrour *et al.*, 2006) according to the RA slopes at different intervals during exponential growth (Radonjic *et al.*, 2005). The categories which increase RA (↑, enriched in the positive slopes) are shown in bold type, and the categories which decrease RA (↓, enriched in the negative slopes) are depicted in normal type. All the slopes were computed using four time points. Only some representative functional groups are shown.

1 i.e. at 7.25 and 9 h after inoculation. When we
 2 considered only the first seven time points, from
 3 3.9 to 6.5 h, no gene's slope significantly differed
 4 from zero when we used the same criteria. This
 5 result confirms that the time window in which a
 6 steady state for the transcriptome can be widely
 7 assumed is extended to up a couple of hours before
 8 the diauxic shift.

In order to confirm the small deviations from 9
 the steady state that we were able to calculate 10
 in our previous experiment, we used the same 11
 gene set enrichment analysis (Fatican algorithm; 12
 Al-Shahrour *et al.*, 2006) to detect the groups of 13
 the related genes showing slight but significant 14
 changes in their RA in the Radonjic *et al.* (2005) 15
 data. Table 2 shows how the RA of some GO 16

1 categories tended to increase (\uparrow , bold numbers) or
 2 decrease (\downarrow) along the growth curve. As expected,
 3 the respiration and stress response categories were
 4 significantly represented in the RA increase, while
 5 the translation categories were significantly repre-
 6 sented in the RA decrease.

7 Therefore, although we conducted a kinetically
 8 detailed study of the transcriptome only during
 9 mid-exponential growth, these results confirm that
 10 our conclusions can be extrapolated to most of the
 11 exponential growth phase.

14 Discussion

15
 16 It is commonly assumed that mRNAs are approxi-
 17 mately in a steady state during exponential growth
 18 in a free-living microorganism. For instance, we
 19 have used this assumption in order to calculate
 20 the mRNA stabilities in the yeast *S. cerevisiae*
 21 by means of GRO experiments (García-Martínez
 22 *et al.*, 2004). However, an experimental demonstra-
 23 tion is currently lacking.

24 Here we report a detailed study of the gene
 25 expression in yeast during exponential growth. In
 26 this experiment we simultaneously checked both
 27 RAs and TRs. The general conclusion is that a
 28 steady state for the transcriptome and transcription
 29 rates can be assumed, and that small deviations
 30 from it can be detected, but only when looking
 31 at all the genes from a given GO at the same
 32 time. This last analysis procedure is much more
 33 sensitive because it detects common tendencies
 34 for a group of related genes. However, when we
 35 analysed them individually, each yeast gene was
 36 within the steady-state condition for its mRNA.
 37 In addition, our kinetically orientated approach
 38 enables us to determine the respective contributions
 39 of TR and RS to the putative changes in RA.
 40 For most cases, both changes work in the same
 41 direction. However, certain exceptions indicate
 42 how the cell uses mRNA stability as an additional
 43 controller of the gene expression. Moreover, the
 44 demonstration of steady state for TR allows the
 45 conclusion that the cells keep the RA values
 46 constant by also maintaining constant turnover, not
 47 by coordinately changing TR and DR — a more
 48 complicated option but theoretically possible.

49 To extend our results and to determine how
 50 long the steady state for the transcriptome can
 51 be assumed during exponential growth, we used

52 data from a comprehensive microarray study by 52
 Radonjic *et al.* (2005), which is representative for 53
 many others. Using these data, we verified that the 54
 steady-state condition is met by a sample series 55
 over a long period (for at least 3 h and up to 2 h 56
 before the diauxic shift). There is nevertheless a 57
 significant tendency of the mRNAs related with 58
 the growth rate (translation) to decrease and the 59
 genes related to the diauxic shift (mitochondria) 60
 to increase. This probably reflects the cell's early 61
 response to the forthcoming changes to take place 62
 in metabolism, and corroborates the suggestion that 63
 yeast cells use a feed-forward strategy, anticipating 64
 growth changes with gene expression changes 65
 (Levy and Barkai, 2009). 66

67 Having established that the steady-state condi- 67
 tion during exponential growth had been fulfilled, 68
 we can say that our protocol to calculate mRNA 69
 half-lives indirectly, as well as that used by other 70
 authors to calculate TR from the RA and RS data, 71
 have been verified. The correlations for direct and 72
 indirect computed TRs are about 0.5 (Pérez-Ortín, 73
 2007). This is a significant correlation but is not as 74
 high as expected. There may be several reasons for 75
 this: first, the mathematical error associated with 76
 indirect calculations; second, the error associated 77
 with the direct measurement of the mRNA half- 78
 life (see below). Both problems are unavoidable 79
 and will mostly introduce random noise into the 80
 indirect data and, therefore, decreased correlation. 81
 Another reason for the low correlation obtained 82
 could be that indirect TR measures the appear- 83
 ance of mature mRNA in the cytoplasm, whereas 84
 GRO (or other methods to estimate the TR, such 85
 as RPCC (Pelechano *et al.*, 2009), measures the 86
 density of RNA polymerases. Density can only be 87
 converted into TR by assuming a constant RNA 88
pol-II speed (Hirayoshi and Lis, 1999). Direct 89
 methods measure 'nascent TR', which can differ 90
 from 'mature TR' (increase of mature, cytoplasmic 91
 mRNAs over time) if the proportion of produc- 92
 tive transcription (finished mRNAs) is not the same 93
 for all the genes, or if the transport of mRNAs is 94
 not equally efficient for them all. This discrepancy, 95
 however, is potentially interesting because it opens 96
 a way to determine the differences in transcription 97
 elongation or mRNA processing between different 98
 groups of genes. 99

100 The calculation of the RS data indirectly from 100
 the RA and TR data can also be compared with 101
 those calculated by direct methods. In this case, 102

1 no correlation exists (see Pérez-Ortín, 2007). This
 2 result is surprising and suggests potential con-
 3 fusing influences when mathematically operating
 4 with variables that have already been correlated.
 5 For instance, TR and RA correlate positively, and
 6 both correlate negatively with RS (García-Martínez
 7 *et al.*, 2007). Thus, when computing TR with the
 8 RA and RS data (TR \propto RA/RS), we obtain a new
 9 dataset by dividing one dataset that correlates pos-
 10 itively with the TR by one that is inversely cor-
 11 related. The result is, therefore, a new dataset that
 12 should mathematically correlate positively with the
 13 TR, as is in fact the case. However, when we
 14 attempted to compute RS using the TR and RA
 15 data (RS \propto RA/TR), we divided two datasets that
 16 negatively correlated to RS. Thus, this negative
 17 correlation in the new dataset decreased, due to a
 18 confusing effect of the different variables. Another
 19 source of discrepancy is the dilution effect caused
 20 by the continuous growth of the culture when cal-
 21 culating indirect RS that contributes to mRNA
 22 concentration reduction besides the mRNA degra-
 23 dation itself (Alon, 2006), whereas it does not affect
 24 indirect methods because the growth of the culture
 25 is stopped due to the transcription stop. Additional
 26 limitations in the calculations are related to the
 27 use of nascent TR (see above) and the well-known
 28 problems brought about by the stressing situation
 29 caused to cells because of the transcription stop
 30 that they require (Grigull *et al.*, 2004; Pérez-Ortín
 31 *et al.*, 2007).

32 Finally, the confirmation of a transcriptional
 33 steady state during the exponential phase means
 34 that the functional analyses of gene expression
 35 done in yeast to date are reliable, as this steady state
 36 confirms that the different time points within that
 37 phase can be considered as identical with regard to
 38 all mRNA levels.

40 Acknowledgements

41 We wish to thank Dr S. Chávez and Albert Sorribas for
 42 critically reading the manuscript, and all the members of
 43 the Yeast Functional Genomics Group for discussions. We
 44 are especially grateful to José García-Martínez (DNA-chip
 45 service at the SCSIE) for performing the DNA macroarrays.
 46 V.P. was partially funded by a FPI fellowship from the
 47 Generalitat Valenciana (Valencian Regional Government).
