Abstract

Using special linear combinations of finite energy sum rules which minimize the contribution of the unknown continuum spectral function, we compute the decay constants of the pseudoscalar mesons B and B_s . In the computation, we employ the recent three loop calculation of the pseudoscalar two-point function expanded in powers of the running bottom quark mass. The sum rules show remarkable stability over a wide range of the upper limit of the finite energy integration. We obtain the following results for the pseudoscalar decay constants: $f_B = 178 \pm 14 \text{ MeV}$ and $f_{B_s} = 200 \pm 14 \text{ MeV}$. The results are somewhat lower than recent predictions based on Borel transform, lattice computations or HQET. Our sum rule approach of exploiting QCD quark hadron duality differs significantly from the usual ones, and we believe that the errors due to theoretical uncertainties are smaller.

1 Introduction

The decay constant of a pseudoscalar meson B_q consisting of a heavy b -quark and a light quark q , with $q = u, d, s$, is defined through the matrix element of the pseudoscalar current:

$$\langle \Omega | (m_b + m_q) \bar{q} i \gamma_5 b(0) | B_q \rangle = f_{B_q} M_{B_q}^2.$$

These decay constants are of great phenomenological interest since they enter in the input to non-leptonic B -decays, in the hadronic matrix elements of $B - \bar{B}$ mixing and in the extraction of $|V_{cb}|$ from the leptonic decay widths of B -Mesons. Knowledge of the decay constants allows to estimate the so-called hadronic B parameter which is directly related to the deviation of the vacuum saturation hypothesis. The decay constants are therefore of central interest to the ongoing experiments carried out in B-factories. Unfortunately these matrix elements could not be measured directly so far, so that we have to rely on theoretical calculations. As the calculations must be non-perturbative there are essentially two approaches, QCD sum rules and lattice simulations.

The method of the sum rules has been successfully applied since the pioneering work of Shifman, Vainshtein and Zacharov [1] to calculate various low energy parameters in QCD. Particular sum rules are based on Borel, Hilbert transforms, positive moments or inverse moments. Sum rule calculations of the decay constants have been performed since the eighties using Borel transform techniques with results within the range $f_B = 160 - 210$ MeV and $f_{B_s}/f_B = 1.09 - 1.22$, [2, 4, 5, 7, 6, 8]. A more recent sum rule calculations using the new $O(\alpha_s^2)$ correlation function with one heavy and one light current [3] yields higher central values $f_B = 210 \pm 19$ MeV and $f_{B_s}/f_B = 1.16 \pm 0.04$. Lattice QCD determinations also give results in a wide range $f_B = 161 - 218$ MeV and $f_{B_s}/f_B = 1.11 - 1.16$ [11, 12] (for a review and a collection of the results, see [9]). A recent HQET calculation [10] yields $f_B = 206 \pm 20$ MeV. The large variation of the quoted values indicates that there is still room for improvement.

In general, the sum rule technique assumes duality. In our analysis duality means that weighted integrals over experimental measured amplitudes should agree with the same integrals evaluated in QCD perturbation theory.

We use a method based on finite energy sum rules (FESR) which equates positive moments of data and QCD theory to evaluate of the decay constants of the pseudoscalar bottom mesons (f_B and f_{B_s}). The method we propose here employs a particular combination of positive moments of FESR in order to optimize the effect of the available experimental information. On the theoretical

side it uses the asymptotic (large momentum expansion) of QCD, i.e. an expansion in m_b^2/s , where m_b is the mass of the bottom quark and s the square of the CM energy. Such an expansion makes sense as long as s is far enough from the continuum threshold. We will consider the perturbative expansion up to second order in the strong coupling constant and up to fourteen powers in the expansion of the b-mass over the energy, using the results of the reference [13]. On the phenomenological side of the sum rule we will consider the lowest lying pseudoscalar B_q -meson. In our method we circumvent the problem of the unknown continuum data by a judicious use of quark-hadron duality. We use a linear combination of finite energy sum rules of positive moments, designed in such a way that the contribution of the data in the region above the resonances turns out to be practically negligible [14].

The present paper differs from our earlier pilot work [15] in that $O(\alpha_s)^2$ corrections to the perturbative piece and the $O(\alpha_s)$ corrections to the leading non-perturbative term are included. In this way the stability of the prediction of f_B is improved and the errors are reduced. The stability analysis is also placed on more solid footing.

The plan of this note is the following: in the next section we briefly review the theoretical method proposed, in the third section we discuss the theoretical and experimental inputs used in the calculation and in the fourth one we write up the conclusions. Finally in the appendix we discuss briefly the main issues of the polynomials used in the finite energy sum rule.

2 The method

The two-point function relevant to our problem is:

$$\Pi(s = q^2) = i \int dx e^{iqx} \langle \Omega | T(j_5(x) j_5(0)) | \Omega \rangle,$$

where $\langle \Omega |$ is the physical vacuum and the current $j_5(x)$ is the divergence of the axial-vector current:

$$j_5(x) = (M_Q + m_q) : \bar{q}(x) i \gamma_5 Q(x) :$$

M_Q is the mass of the heavy bottom quark $Q(x)$, and m_q stands for the mass of the light quarks $q(x)$, up, down or strange. The starting point of our sum rules is Cauchy's theorem applied to the two-point correlation function $\Pi(s)$, weighted with a polynomial $P(s)$

$$\frac{1}{2\pi i} \oint_{\Gamma} P(s) \Pi(s) ds = 0. \quad (1)$$

The integration path extends over a circle of radius $|s| = s_0$, and along both sides of the physical cut $s \in [s_{\text{phys.}}, s_0]$ where $s_{\text{phys.}}$ is the physical threshold. Neither the polynomial $P(s)$ nor the power of the integration variable change

the analytical properties of $\Pi(s)$, so that we obtain the following sum rule:

$$\frac{1}{\pi} \int_{s_{\text{phys.}}}^{s_0} P(s) \text{Im} \Pi(s) = -\frac{1}{2\pi i} \oint_{|s|=s_0} P(s) \Pi(s) ds, \quad (2)$$

Duality now means that on the left hand side we can use experimental information starting from the physical threshold $s_{\text{phys.}}$ to s_0 , whereas on the right hand side, i. e. on a circle of radius s_0 , we can use the theoretical input given by QCD and the operator product expansion. The integration radius s_0 has to be chosen large enough so that the asymptotic expansion $\Pi^{\text{QCD}}(s)$ of QCD, which includes perturbative and non-perturbative terms, constitutes a good approximation to the two-point correlator on the circle.

On the left hand side of equation (2), we can parametrize the absorptive part of the two-point function by means of a single resonance B_q and the hadronic continuum of the $b\bar{q}$ channel from $s_{\text{cont.}}^{\text{phys.}}$ with $s_{\text{cont.}}^{\text{phys.}} \geq s_{\text{phys.}}$. Therefore, we write the representation of the hadronic experimental data in the form:

$$\frac{1}{\pi} \text{Im} \Pi(s) = \frac{1}{\pi} \text{Im} \Pi^{\text{res.}}(s) + \frac{1}{\pi} \text{Im} \Pi_{\text{phys.}}^{\text{cont.}} \theta(s - s_{\text{cont.}}^{\text{phys.}}), \quad (3)$$

where $s_{\text{cont.}}^{\text{phys.}}$ stands for the physical threshold of the continuum physical region, and therefore it is an input in our calculation. It is worth mentioning that it must not be confused with the duality parameter (s_0) that is determined by stability requirements in most versions of finite energy QCD sum rules.

On the right hand side of equation (2) the theoretical input necessary to write down the two-point function relevant to the integration over the circle of radius s_0 has both perturbative and non-perturbative contributions,

$$\Pi^{\text{QCD}}(s) = \Pi^{\text{pert.}}(s) + \Pi^{\text{nonpert.}}(s), \quad (4)$$

For the perturbative piece, we take the two-point correlation function $\Pi^{\text{pert.}}(s)$ which has been calculated in [13] for one massless and one heavy quark as an expansion up to second order (three loops) in the strong coupling constant α_s and as a power series in the pole mass of the heavy quark (M_b^2/s) up to the seventh order. We have checked that for the employed range of values of the radius s_0 of the integration contour, the power series converges well and does not introduce any appreciable error in the calculation. In the case of one and two loops the known complete analytic expressions of the two-point function could be used, but we also use the mass expansion in this case because the results of the integration can be given analytically. Numerically it makes no difference whether one uses the complete analytic expressions or the expansions.

The authors of [13] obtain the following compact expansion of the two-point function in terms of the pole mass M_b ,

$$\Pi^{\text{pert.}}(s) = \Pi^{(0)}(s) + \left(\frac{\alpha_s(M_b)}{\pi} \right) \Pi^{(1)}(s) + \left(\frac{\alpha_s(M_b)}{\pi} \right)^2 \Pi^{(2)}(s), \quad (5)$$

where the different terms of the expansion in α_s have the form:

$$\Pi^{(i)}(s) = (M_b + m_q)^2 M_b^2 \sum_{j=-1}^6 \sum_{k=0}^3 A_{j,k}^{(i)} \left(\ln \frac{-s}{M_b^2} \right)^k \left(\frac{M_b^2}{s} \right)^j \quad (i = 0, 1, 2). \quad (6)$$

and the coefficients $A_{j,k}^{(i)}$ of the QCD perturbative expansion are given in [13] to order $(M_b^2/s)^7$. For instance, the first term of the expansion is given by:

$$\begin{aligned} \Pi^{(0)}(s) = & \frac{3}{16\pi^2} (M_b + m_q)^2 s \left\{ 3 - 2 \ln \left(\frac{-s}{M_b^2} \right) + 4 \frac{M_b^2}{s} \ln \left(\frac{-s}{M_b^2} \right) + \right. \\ & \left[-3 - 2 \ln \left(\frac{-s}{M_b^2} \right) \right] \left(\frac{M_b^2}{s} \right)^2 + \frac{2}{3} \left(\frac{M_b^2}{s} \right)^3 + \frac{1}{6} \left(\frac{M_b^2}{s} \right)^4 + \frac{1}{15} \left(\frac{M_b^2}{s} \right)^5 + \\ & \left. \frac{1}{30} \left(\frac{M_b^2}{s} \right)^6 + \frac{2}{105} \left(\frac{M_b^2}{s} \right)^7 + \dots \right\} \end{aligned}$$

In the asymptotic expansion (4) there are also non-perturbative terms due to the quark and gluon condensates. In our calculations we will include these terms up to dimension six [2]:

$$\begin{aligned} \Pi^{\text{nonpert.}}(s) = & (M_b + m_q)^2 \left\{ M_b \langle \bar{q}q \rangle \left[\frac{1}{s - M_b^2} \left(1 + 2 \frac{\alpha_s}{\pi} \right) \right. \right. \\ & \left. \left. + 2 \frac{\alpha_s}{\pi} \ln \frac{M_b^2}{-s + M_b^2} \right] + O(m_q/M_b) \right. \\ & - \frac{1}{12} \frac{1}{s - M_b^2} \left\langle \frac{\alpha_s}{\pi} G^2 \right\rangle - \frac{1}{2} M_b \left[\frac{1}{(s - M_b^2)^2} + \frac{M_b^2}{(s - M_b^2)^3} \right] \langle \bar{q}\sigma Gq \rangle \\ & \left. - \frac{8}{27} \pi \left[\frac{2}{(s - M_b^2)^2} + \frac{M_b^2}{(s - M_b^2)^3} - \frac{M_b^4}{(s - M_b^2)^4} \right] \alpha_s \langle \bar{q}q \rangle^2 \right\} \quad (7) \end{aligned}$$

The α_s correction to the quark condensate [3] turns out to be small but non-negligible.

Before going on, a comment on the asymptotic expansion is in order. It is known that the convergence of the perturbative expansion of the two-point function, when written in terms of the pole mass, is rather poor. In fact, in many calculations involving heavy quarks, the first and second order loop contributions are typically of the same order of magnitude making difficult to achieved convergence in the results. On the other hand, the expansion in terms of the running mass converges much faster over a wide range of the renormalization scale. Henceforward, for calculational purposes, we will consider the relations among the pole and the running mass in the appropriate order in the coupling constant [16, 17, 18] in order to rewrite the perturbative piece of order $(\alpha_s)^i$ (6) in the form

$$\Pi^{(i)}(s) = m_b^2(\mu) (m_b(\mu) + m_q(\mu))^2 \sum_{j=-1}^6 \sum_{k=0}^3 \tilde{A}_{j,k}^{(i)} \left(\ln \frac{-s}{\mu^2} \right)^k \left(\frac{m_b^2(\mu)}{s} \right)^j \quad (i = 0, 1, 2). \quad (8)$$

and similarly for the non-perturbative piece. The coefficients $\tilde{A}_{j,k}^{(i)}$ depend on the mass logarithms $\ln(m_b^2/\mu^2)$ up to the third power. As $\Pi(s)$ is not known to all orders in α_s , the results of our analysis will depend to some extent on the choice of the renormalization point μ . In the sum rule considered here there are two obvious choices, $\mu = m_b$ and $\mu = s_0$, the radius of the integration contour. The former choice will sum up the mass logs of the form $\ln(m_b^2/\mu^2)$ and the latter choice the $\ln(-s/\mu^2)$ terms. We find that for the choice $\mu = m_b$ the convergence of the perturbative terms is significantly better, so we will adopt this value in the presentation here.

For the experimental side, we can split up the absorptive part into the established lowest lying pseudoscalar $b\bar{q}$ resonance B_q and an unknown hadronic continuum :

$$\frac{1}{\pi} \text{Im}\Pi(s) = M_{B_q}^4 f_{B_q}^2 \delta(s - M_{B_q}^2) + \frac{1}{\pi} \text{Im}\Pi_{\text{phys.}}^{\text{cont.}} \theta(s - s_{\text{cont.}}^{\text{phys.}}) \quad (9)$$

where M_{B_q} and f_{B_q} are, respectively, the mass and the decay constants of the pseudoscalar meson B_q .

Looking back to equation (2) and taking all the theoretical parameters including the mass of the B_q -meson as our inputs in the calculation, we see that the decay constant could be computed if we would have accurate information on the hadronic continuum contribution, which is, however, not the case.

To cope with this problem we make use of the freedom of choosing the polynomial in equation (2). We take for $P(s)$ a polynomial of the form:

$$P_n(s) = a_0 + a_1 s + a_2 s^2 + a_3 s^3 + \dots + a_n s^n, \quad (10)$$

where the coefficients are fixed by imposing a normalization condition at threshold

$$P_n(s_{\text{ph.}} = M_{B_q}^2) = 1, \quad (11)$$

and requiring that the polynomial $P_n(s)$ should minimize the contribution of the continuum in the range $[s_{\text{cont.}}^{\text{phys.}}, s_0]$ in a least square sense, i.e.,

$$\int_{s_{\text{cont.}}^{\text{phys.}}}^{s_0} s^k P_n(s) ds = 0 \text{ for } k = 0, \dots, n-1, \quad (12)$$

The polynomials obtained in this way are closely related to the Legendre polynomials. In the appendix the explicit form of the set of polynomials use in this work is given.

This way of introducing the polynomial weight in the sum rule makes negligible the integration of $\frac{1}{\pi} \text{Im}\Pi_{\text{phys.}}^{\text{cont.}} \theta(s - s_{\text{cont.}}^{\text{phys.}})$, so that in the phenomenological side of the sum rule only the contribution of the B_q resonance remains. On the other hand, as we will see in the results, it increases the value of the duality parameter s_0 and, therefore, the asymptotic expansion of QCD can be trusted safely in the integration contour.

To the extend that $\text{Im}\Pi_{\text{phys.}}^{\text{cont.}}$ can be approximated by an n degree polynomial these conditions lead to an exact cancellation of the continuum contribution

to the left hand side of equation (2). As a welcome side effect, this choice of polynomial will enhance the role of the B_q resonance. Notice however that increasing the degree of the polynomial $P_n(s)$, will require the knowledge of further terms in the mass expansion and in the non-perturbative series. Therefore the polynomial degree cannot be chosen arbitrarily high.

To check the consistency of the method, we have considered a second to fifth degree polynomials and the results are compatible within the range of the errors introduced by the inputs of the calculation. We also have checked explicitly that a smooth continuum contribution had no influence on the result.

The sum rule method above was previously used in the calculation of the charm mass from the $c\bar{c}$ experimental data. The continuum data in this case were known from the BES II collaboration [19] and were shown to have no influence on the predicted mass [21]. Employing the same technique, a very accurate prediction of the bottom quark mass was also obtained using the experimental information of the upsilon system [22].

After these considerations we proceed with the analytical calculation. The integrals that we have to evaluate on the right hand side of the sum rule, equation (2), are

$$J(p, k) = \frac{1}{2\pi i} \oint_{|s|=s_0} s^p \left(\ln \frac{-s}{\mu^2} \right)^k ds, \quad (13)$$

for $k = 0, 1, 2, 3$ and $p = -6, -5, \dots, n + 1$. These integrals can be found e.g. in reference [20]. After integration, equation (2) yields the sum rule

$$\begin{aligned} M_{B_q}^4 f_{B_q}^2 P(M_{B_q}^2) &= m_b^2(\mu)(m_b(\mu) + m_q(\mu))^2 \\ &\times \sum_{q=0}^n \sum_{i=0}^2 \sum_{j=-1}^6 \sum_{k=0}^3 a_q \left(\frac{\alpha_s(\mu)}{\pi} \right)^i \tilde{A}_{j,k}^{(i)} m_b^{2j}(\mu) J(q-j, k) \\ &+ \text{non-perturbative terms} \end{aligned} \quad (14)$$

where, for brevity, we have not written down the non-perturbative terms explicitly. The contribution of the continuum is neglected.

Plugging the theoretical and experimental inputs (physical threshold, quarks and meson masses, condensates and strong coupling constant) into the sum rule, we obtain the decay constant f_{B_q} for various values of the degree n of the polynomial and various values of s_0 . Given the correct QCD asymptotic correlator and the correct hadronic continuum, the calculation of the decay constant should, of course, not depend either on s_0 or on the degree n of the polynomial in the sum rule (2). Accordingly, for a given n we choose the flattest region in the curve $f_B(s_0)$ to extract our prediction for the decay constant. To be specific we choose the point of minimal slope. On the other hand, for different polynomials, the value of f_B , extracted in this way, could differ from each other as the cancellation of the continuum may be incomplete or the QCD expansion not accurate enough. We find, however, practically the same results for all our polynomials. This additional stability is truly remarkable as the coefficients of the polynomials of order $n = 2, 3, 4$ and 5 are completely different and the

respective predictions are based on completely different superpositions of finite energy moment sum rules. This extended consistency leads us to attach great confidence in our numbers and associated errors.

3 Results

We calculate the decay constants for the B and B_s heavy mesons. In the first case we take $m_q = 0$ everywhere. In the second case we retain $m_q = m_s \neq 0$ in the factor $(M_b + m_q)^2$ in front of the correlation function only. Further terms in the power series in m_s^2/s in (5) are completely negligible for the integration radii s_0 we use in the calculation.

The experimental and theoretical inputs are as follows. The physical threshold $s_{\text{ph.}}$ is the squared mass of the lowest lying resonance in the $b\bar{q}$ channel. For q being the light quark u , we have:

$$s_{\text{ph.}} = M_B^2 = 5.279^2 \text{ GeV}^2 = 27.87, \text{ GeV}^2 \quad (15)$$

whereas the continuum threshold $s_{\text{cont.}}^{\text{phys.}}$ is taken from the next intermediate state $B\pi\pi$ in an s-wave $I = \frac{1}{2}$, i. e.

$$s_{\text{cont.}}^{\text{phys.}} = (M_B + 2m_\pi)^2 = 30.90 \text{ GeV}^2.$$

For q being the strange quark we take:

$$s_{\text{ph.}} = M_{B_s}^2 = 5.369^2 \text{ GeV}^2 = 28.83, \text{ GeV}^2 \quad (16)$$

The continuum threshold starts in this case at the value:

$$s_{\text{cont.}}^{\text{phys.}} = (M_{B_s} + 2m_\pi)^2 = 31.92 \text{ GeV}^2.$$

In the theoretical side of the sum rule we take the following inputs. The strong coupling constant at the scale of the electroweak Z boson mass [24]

$$\alpha_s(M_Z) = 0.118 \pm 0.003 \quad (17)$$

is run down to the computation scale using the four loop formulas of reference [23]. For the quark and gluon condensates (see for example [3]) and the mass of the strange quark [25] we take:

$$\begin{aligned} \langle \bar{q}q \rangle (2 \text{ GeV}) &= (-267 \pm 17 \text{ MeV})^3, \\ \langle \frac{\alpha_s}{\pi} G G \rangle &= 0.024 \pm 0.012 \text{ GeV}^4, \\ \langle \bar{q}\sigma G q \rangle &= m_0^2 \langle \bar{q}q \rangle, \text{ with } m_0^2 = 0.8 \pm 0.2 \text{ GeV}, \\ m_s(2 \text{ GeV}) &= 120 \pm 50 \text{ MeV}, \\ \langle \bar{s}s \rangle &= (0.8 \pm 0.3) \langle \bar{q}q \rangle. \end{aligned} \quad (18)$$

As discussed, above we fix the renormalization scale μ in the theoretical side of the sum to be $\mu = m_b(m_b)$, as the perturbative series in α_s is well under control,

i.e. the first and second order terms are only a few percent of the dominant zero order one and the second order one is much smaller than the first order one. We use a reasonable variation of μ to estimate the corresponding error in our final result.

Finally, for the bottom quark, a value $m_b(m_b) \approx 4.20$ GeV is generally accepted. For consistency we take the result $m_b(m_b) = 4.19 \pm 0.05$ GeV of which has been obtained by us [22] with a similar sum rule method.

In order to calculate the decay constant for the pseudoscalar meson B , we proceed in the way described above. We compute f_B as a function of s_0 with the four different sum rules (2) corresponding to $n = 2, 3, 4, 5$. The results, plotted in Fig. 1 show remarkable stability properties. We define the optimal value of s_0 as the center of the stability region (represented by a cross in Fig.1) where the first and/or second derivative of $f_B(s_0)$ vanishes. At these values of s_0 we obtain the following consistent results:

$$\begin{aligned} f_B &= 175 \text{ MeV for } n = 2 \\ f_B &= 177 \text{ MeV for } n = 3 \\ f_B &= 178 \text{ MeV for } n = 4 \\ f_B &= 178 \text{ MeV for } n = 5 \end{aligned}$$

Notice from Fig. 1 that for the fourth degree polynomial ($n=4$) there is a stability region of about 50 GeV^2 around s_0 . In this region the decay constant changes by less than 1 percent. This stability region is pushed up to 100 GeV^2 in the case of $n = 5$. With these considerations we estimate a conservative error inherent to the method of $\pm 3 \text{ MeV}$.

Other sources of errors arising in the calculation of f_B are the quark condensates which affect the result by $\pm 3 \text{ MeV}$, and the bottom mass which, in the range given above, produces a variation in the decay constant of $-13, +10 \text{ MeV}$. This last one is the main source of uncertainty in the final result. Finally we have changed the renormalization scale in the range $\mu \in [3, 6] \text{ GeV}$. We estimate an error of $\pm 6 \text{ MeV}$ associated to this change in μ which is roughly related to the convergence of the asymptotic expansion

Other errors due to the QCD side of the sum rule (higher order terms in m_b^2/s and the error on $\alpha_s(m_Z)$) are negligible in comparison).

Adding quadratically all the errors, we finally quote the following result for the decay constant of the light meson B :

$$f_B = 178 \pm 14 (\text{inp.}) \pm 3 (\text{meth.}) \text{ MeV.} \quad (19)$$

The first error comes from the inputs of the computation and the truncated QCD theory whereas the second is due to the method itself.

Proceeding in the same fashion, but keeping the mass of the strange quark in the overall factor and the order m_s/m_b in the one loop contribution, we find the decay constant for the B_s meson (f_{B_s}),

$$f_{B_s} = 200 \pm 14 (\text{inp.}) \pm 3 (\text{meth.}) \text{ MeV.}$$

Figure 1: Decay constant f_B as a function of the integration radius s_0 for $m_b(m_b) = 4.19$ GeV. The lines represent the sum rule (2) for several choices of the polynomial $P_n(s)$.

(compare Fig. 2)

In the analysis of theoretical errors the only new ingredient is the uncertainty coming from the strange quark mass which turns out to be negligible.

The ratio of the decay constants f_{B_s} and f_B (which would be 1 in the chiral limit) is of special interest. We find:

$$\frac{f_{B_s}}{f_B} = 1.12 \pm 0.01 (\text{inp.}) \pm 0.03 (\text{meth.}). \quad (20)$$

In the calculation, the uncertainties due to the method and to the theoretical inputs (mainly to the bottom quark mass) are correlated, so that the final error is very small.

Finally we should mention that in the past the stability region was often determined in a rather ad hoc fashion by considering the intercept of sum rule predictions for moments differing by one power. We find that, suitably modified, this prescription also works in our sum rule method with similar results but larger errors.

Figure 2: Decay constant f_{B_s} as a function of the integration radius s_0 for $m_b(m_b) = 4.19$ GeV. The lines represent the sum rule (2) for several choices of the polynomial $P_n(s)$.

4 Conclusions

In this note we have computed the decay constant of B_q -mesons for q either the strange or the u or d massless quarks. We have employed a judicious combination of moments in QCD finite energy sum rules in order to minimize the shortcomings of the available experimental data. On the theoretical side of the pseudoscalar two-point function, we have used in the perturbative piece an expansion up to three loops in the strong coupling constant and up to order $(m_b^2/s)^7$ in the mass expansion and in the non-perturbative piece we considered condensates up to dimension six including the α_s correction in the leading term. Instead of the commonly adopted pole mass of the bottom quark, we use the running mass to get good convergence of the perturbative series. It turns out that for the renormalization point $\mu = m_b(m_b)$ the first and second order contribution in the strong coupling are term by term much smaller. This good convergence is due to the summing up of the mass logarithms.

In the sum rule, the contour integration of the asymptotic part is performed analytically. This particular fact differs from other computations based on sum

rules where the asymptotic QCD is integrated along a cut of the two-point function starting at the pole mass squared. The latter way to proceed is problematic when loop corrections are included and the complete analytical QCD expression along the cut is not known. In this approach QCD has to be extrapolated from low energy to high energy [3]. We also differ from many other sum rule calculation of f_B in that we do not require two largely unrelated sum rules to determine a stability point via an intercept of the curves $f_B(s_0)$.

Our results are very sensitive to the value of the running mass, giving most of the theoretical uncertainty. On the other hand they turn out to be very stable against the variations of the other parameters, in particular the renormalization scale and the integration radius s_0 .

Comparing with other results in the literature, our results agree within the error bars with the ones obtained using sum rule methods and with lattice computations. When compared with the most recent numbers [3, 11, 12, 10], however, our results are lower.

The interest in our method lies in the fact that it approaches the problem from a different angle and, in our opinion, is less prone to systematic errors.

Appendix

For convenience of the reader in this appendix we list the first few polynomials emerging from relations (11,12). From the second condition, namely (12), it is easy to realize that the set of polynomials $P_n(s)$ are n-degree orthogonal polynomials in the interval of the variable $s \in [s_{\text{cont.}}^{\text{phys.}}, s_0]$. Then, leaving aside the normalization condition (11) that we take, for convenience, in order to stress the contribution of the lowest lying resonance in the sum rule, they are related to the so-called Legendre polynomials ($\mathcal{P}_n(x)$) in the interval of the variable $x \in [-1, 1]$. After including this normalization condition, we can write more precisely:

$$P_n(s) = \frac{\mathcal{P}_n(x(s))}{\mathcal{P}_n(x(M_{B_q}^2))} \quad (21)$$

Where the variable $x(s)$ is:

$$x(s) = \frac{2s - (s_0 + s_{\text{cont.}}^{\text{phys.}})}{s_0 - s_{\text{cont.}}^{\text{phys.}}}$$

which ranges in the required interval when $s \in [s_{\text{cont.}}^{\text{phys.}}, s_0]$.

The explicit form of these polynomials is well known and can be found, for instance, in [26]. Nevertheless, for sake of completeness, we quote here the ones

Figure 3: Polynomials $P_n(s)$ obtained from conditions (11,12) taken at the stability values of s_0 in the calculation of f_B .

we have used in the calculation.

$$\begin{aligned}\mathcal{P}_2(x(s)) &= \frac{3}{2}(x^2 - 1), \\ \mathcal{P}_3(x(s)) &= \frac{1}{2}(5x^3 - 3x), \\ \mathcal{P}_4(x(s)) &= \frac{1}{8}(35x^4 - 30x^2 + 3), \\ \mathcal{P}_5(x(s)) &= \frac{1}{8}(63x^5 - 70x^3 + 15x).\end{aligned}$$

Finally, in Fig. 3, and in order to appreciate how the dumping of the experimental physical continuum in the sum rule is expected, we have plotted the form of the polynomials $P_n(s)$ for $n=2,3,4,5$ at the stability values of s_0 used in the calculation of f_B .
