Cooperative Monitoring Technologies Development Dept.

Sandia National Laboratories

Albuquerque, NM 87185

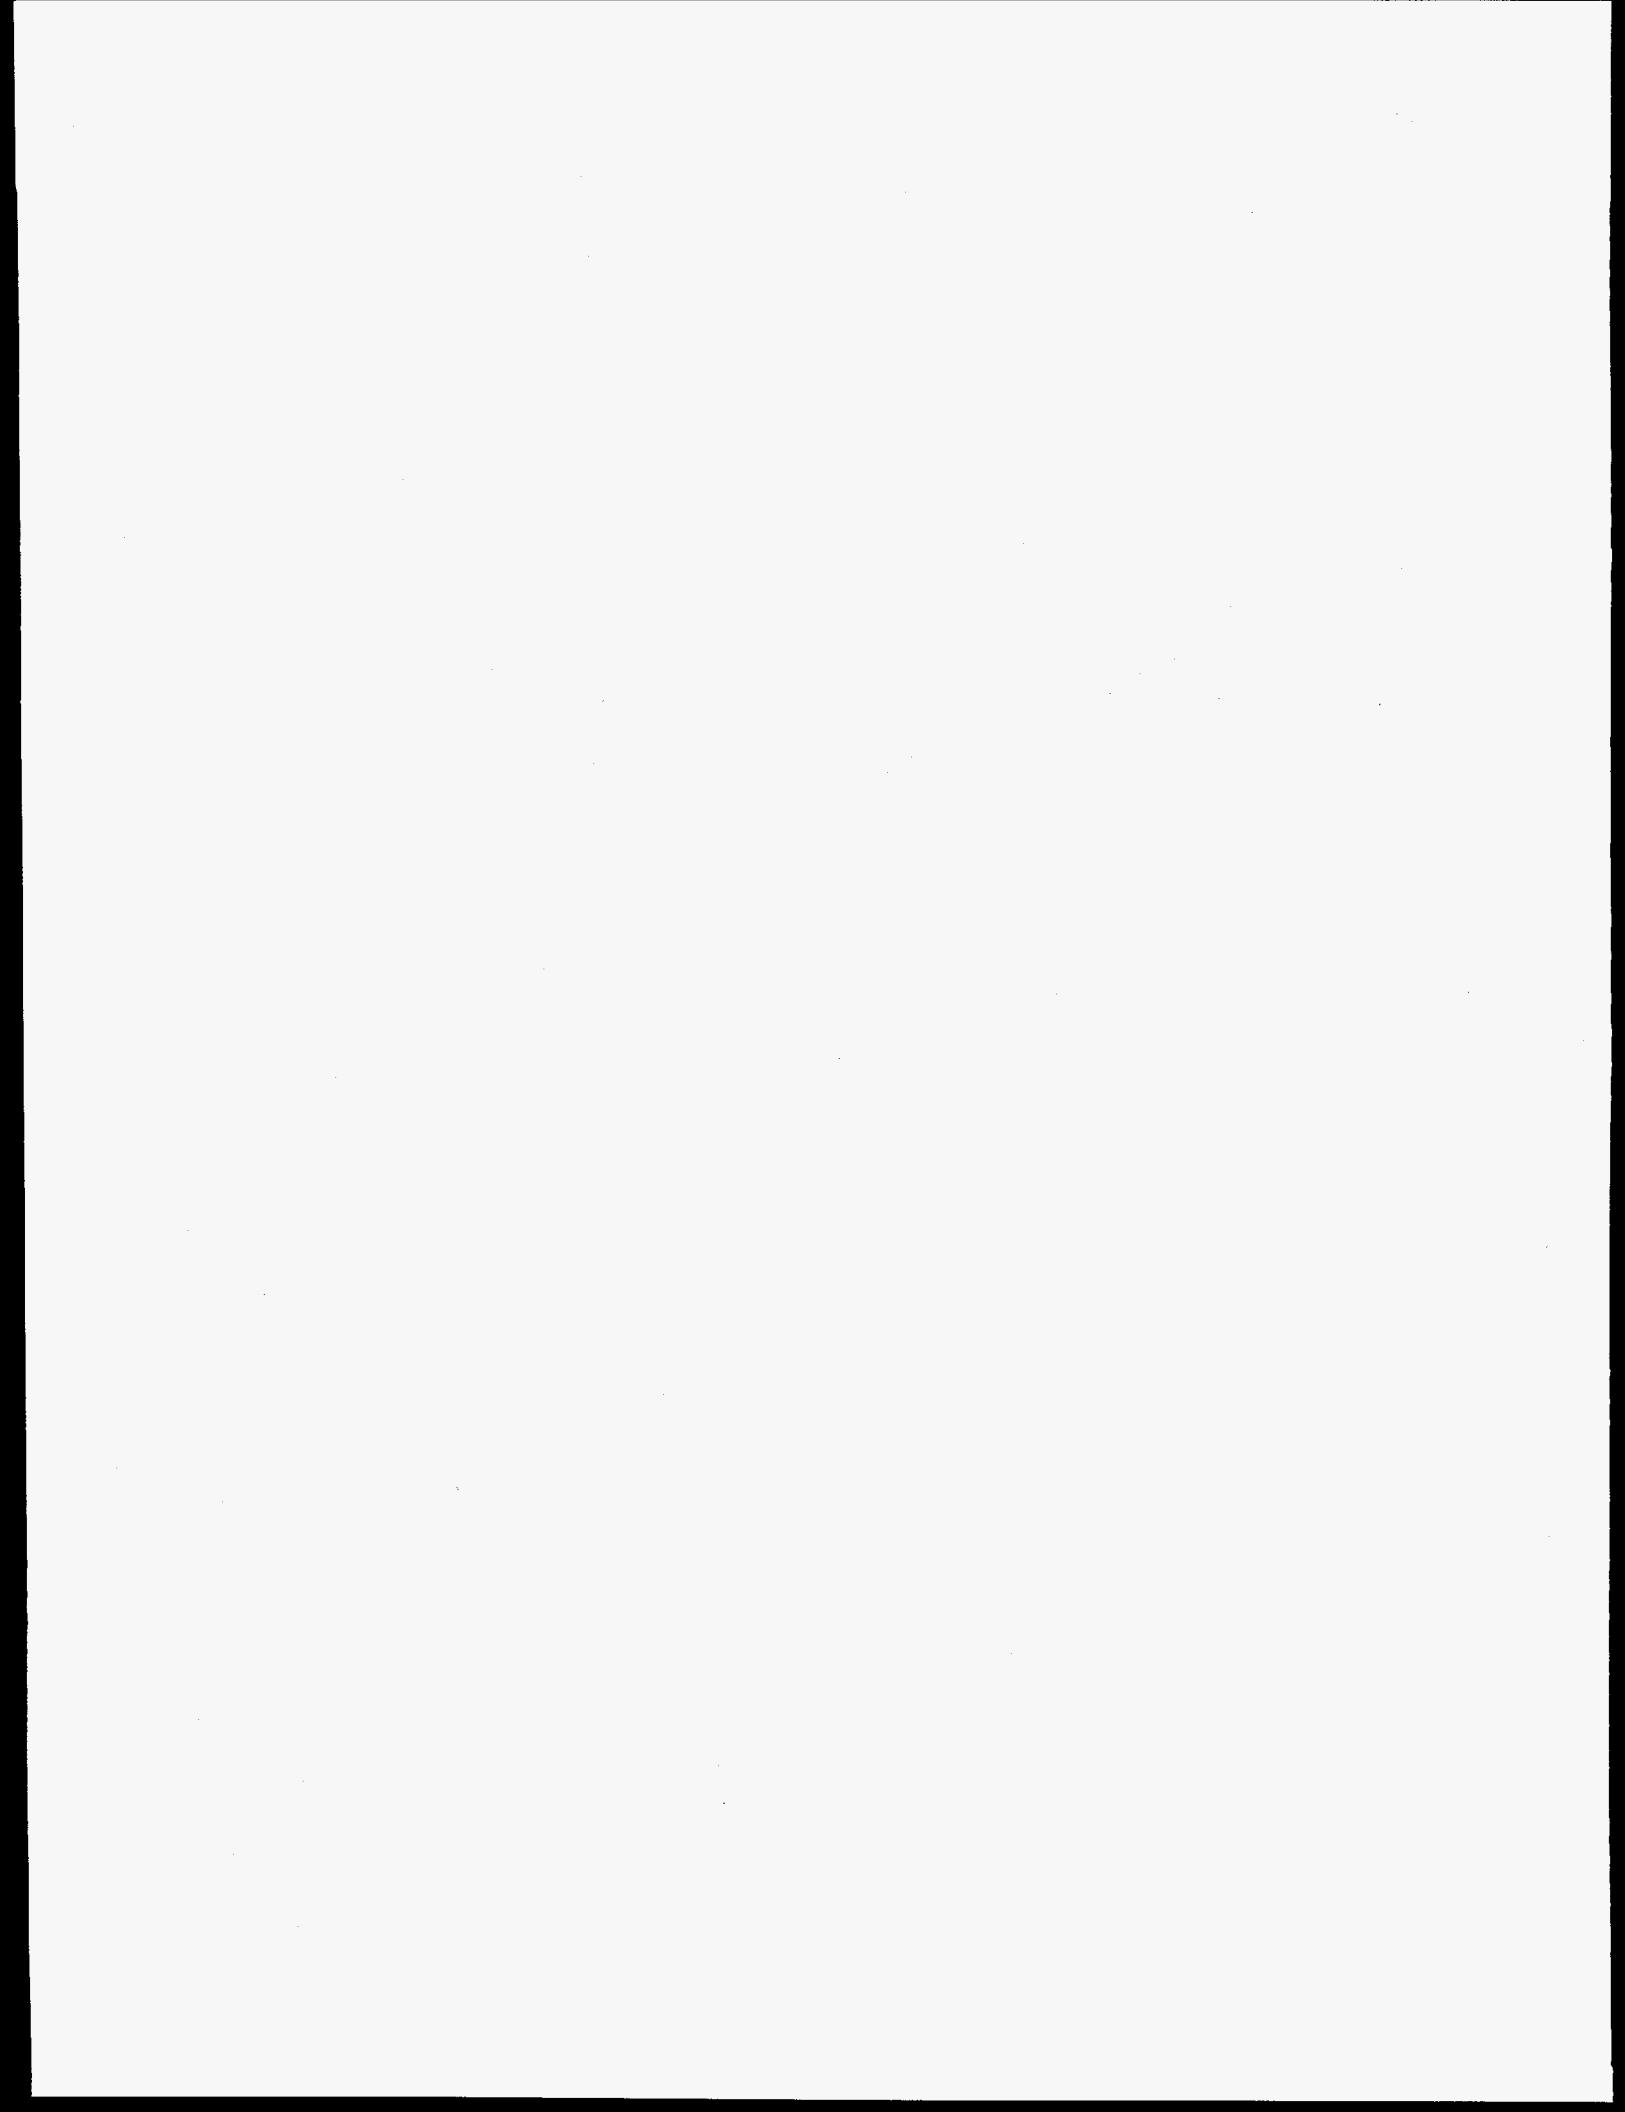

Abstract:

Over an extended period of time station noise spectra were collected from various sources for use in estimating the detection and location performance of global networks of seismic stations. As the database of noise spectra enlarged and duplicate entries became available, an effort was mounted to more carefully select station noise spectra while discarding others. This report discusses the methodology and criteria by which the noise spectra were selected. It also identifies and illustrates the station noise spectra which survived the selection process and which currently contribute to the modeling efforts. The resulting catalog of noise statistics not only benefits those who model network performance but also those who wish to select stations on the basis of their noise level as may occur in designing networks or in selecting seismological data for analysis on the basis of station noise level. In view of the various ways by which station noise were estimated by the different contributors, it is advisable that future efforts which predict network performance have available station noise data and spectral estimation methods which are compatible with the statistics underlying seismic noise. This appropriately requires 1) averaging noise over seasonal and/or diurnal cycles, 2) averaging noise over time intervals comparable to those employed by actual detectors, and 3) using logarithmic measures of the noise.

Acknowledgments

The authors wish to acknowledge and thank the many people who contributed noise spectra to this work. Jon Peterson of ASL/USGS provided the noise spectra for the GSN and USGS stations. This station noise database was extended by the analysis of noise data from the GEOSCOPE stations as provided by J. P. Montagner. Michel Morand of GEOSCOPE provided the software for reading their SEED formatted data. Additional noise spectra, primarily for the AFTAC and GSETT-3 stations, were provided by Keith McLaughlin of S-Cubed. D. R. Breding, D. B. Carr, E. P. Chael, and P. B. Herrington of Sandia National Laboratories provided helpful reviews of this work and report.

This work was performed at Sandia National Laboratories and supported by the U. S. Department of Energy under contract DE-AC04-94AL85000.

1.0 Introduction

Over an extended period of time station noise spectra were collected from various sources for use in estimating the detection and location performance of global networks of seismic stations. The goal of the underlying effort was to 1) evaluate global networks which have been proposed for monitoring a CTBT, 2) develop viable physical and theoretical bases for modeling network performance, and 3) develop a framework for understanding the performance of seismic networks. As the database of noise spectra enlarged and duplicate entries became available from various sources, an effort was mounted to more carefully select station noise spectra while discarding others. This report discusses the methodology and criteria by which the noise spectra were selected. It also identifies and illustrates the station noise spectra which survived the selection process and which currently contribute to the modeling efforts. The utility of this catalog of noise statistics not only benefits those who model network performance but also those who wish to select stations on the basis of their noise level as may occur in designing networks or in selecting seismological data for analysis on the basis of station noise level.

2.0 Approach

In order to systematically review a large set of noise files, a graphics program (QC_SPECTRA) was prepared to plot all the available noise spectra from various sources. The program was controlled by a master list of the station noise files. The program excluded noise files whose maximum frequency was less than 0.1 hertz. The program was flexible enough to read files containing or missing the noise standard deviation as a function of frequency. Some station noise spectra included estimates at frequencies lower than 0.001 Hz, but that portion of the spectrum was not illustrated in this report.

The spectra plotted by QC_SPECTRA for the same station were comparatively examined for consistency 1) across overlapping bands of frequencies, 2) between estimates from different sources (USGS, IRIS, CMR, AFTAC, SNL, etc.), and 3) within the constraints imposed by the Peterson high and low noise models¹. In cases where the noise spectra were available for the same seismographic station and the SNL estimates were among the choices, the SNL estimates were accepted because the estimates were based

on a procedure consistent with the statistics associated with seismic noise models in the detection algorithms.

Based on the span of frequencies associated with the station seismometers, the noise spectra were identified as high frequency (HF), very broad band (VBB), broad band (BB), short period (SP), long period (LP), or very long period (VLP) using a bandpass convention similar to that used by the Federation of Digital Seismographic Networks (FDSN). Except for the SP spectra, the spectra noise files which qualified for inclusion in the database were renamed incorporating these channel designations within their names, e.g., "xxx_ybb.noi". The SP files were identified with special names such as "xxx_day.noi" or "xxx_nig.noi" to reflect their daytime and nighttime noise characteristics, respectively. Here "xxx" designates the station code. For those stations having only a single SP spectral estimate, the spectrum was arbitrarily associated with the daytime condition.

Modifications were applied to some of the selected station noise spectra. A few of the spectra were smoothed using a 3 point moving average. This smoothing of the spectra avoided "singularities" as might be introduced by NetSim² as it interpolates or extrapolates noise spectra upon data entry. Other files had their last point(s) removed or replaced when the noise value(s) deviated drastically from the proceeding values. These large deviations are typically caused by the large uncertainties associated with compensating for the hard roll-off characteristic of the seismometer digital filter when translating the sensor output into ground motion.

The noise standard deviation as a function of frequency was not universally available for spectra produced by others. For these stations, a standard noise deviation of 0.3 magnitude units was assigned uniformly at each frequency. In a few cases the 5 and 95 percentile estimates together with the median noise level were available. From these latter estimates it was assumed that the median noise represented the mean noise level required by the detection model. The standard deviation of the noise was roughly estimated from the 5 and 95 percentile levels.

Finally some of the station names have been altered to be consistent with designations assigned by others in earlier efforts and maintained in our database. Table 1 identifies these changes and the one mentioned above.

3.0 Station Noise Spectra

The stations for which noise spectra were accepted after the consistency checks are listed in Table 2. This table primarily documents the station locations and lists the bands for which noise spectra are available. The station “mean” spectra together with the assigned or computed standard deviations are illustrated alphabetically by station code in Appendix A.

The reader should be aware that since most of the noise spectra came from outside sources, the actual quality of the estimates cannot be assured by the authors of this work. It is reasonable to assume that the spectral densities produced by others were accurately estimated using conventional and in some

cases advanced procedures. However, to establish the mean and standard deviation of the spectral estimates for use in network modeling requires careful sampling of the noise records throughout an entire annual or a diurnal cycle. The particular circumstances under which the noise was sampled by others is not known by the authors. Further, most of the spectra were not averaged on a logarithmic basis as required by the network models nor were the standard deviations in logarithmic noise estimated. Both the mean and standard deviation of logarithmic noise can significantly influence detection performance.

It can be stated that those daytime SP spectra estimated by the authors were carefully produced from noise records available over an entire calendar year within 2 hours of local noon to document the seasonal effects. The nighttime SP spectra, when available, were estimated from noise data recorded during the pre-dawn hours over a calendar year. These two periods of time are thought to represent the worst and best noise cases, respectively. The frequency dependent noise standard deviations, which are essential to network modeling, were included in the SNL estimates. This technique was applied to the NORESS, ARCESS, and GEOSCOPE station noise records.

4.0 Conclusions

Since station noise has a significant influence on the performance level of monitoring networks, it was extremely important to have available measures of actual station noise in estimating the performance of proposed monitoring networks. The authors were grateful to all who contributed noise spectra, in some cases from stations only recently installed. The duplicate measures of station noise from various sources provided an opportunity to build better confidence in some of the noise measures and, as a consequence, better confidence in the network predictions.

In view of the various ways by which station noise can be estimated, it is advisable that future efforts which predict network performance have available station noise data and spectral estimation methods which are compatible with the statistics underlying seismic noise. This appropriately requires 1) averaging noise over seasonal and/or diurnal cycles, 2) averaging noise over time intervals comparable to those employed by actual detectors, and 3) using logarithmic measures of the noise. For those estimates which were based on the mean spectral density, it can be stated that when the noise

standard deviation is small the log of the mean spectral density is approximately the mean of the log spectral density. For some stations, this is a good assumption, but not for all stations. For example, the standard deviations for the noisy stations are typically large and would not satisfy this criterion.

As additional station noise data become available for the primary and auxiliary stations proposed in monitoring a CTB treaty, these data should be analyzed to derive the noise statistics as required by NetSim. These additional spectra should then be used to upgrade the network performance estimates for the proposed networks. Where necessary, the station noise statistics in the existing database should be re-examined using log normal statistics as a basis for the spectral estimates. Coda noise models for other media are also required.
