Executive Summary

This report describes the methodology for calculating combustible waste fractions in Hanford Single Shell Tanks. Two sets of combustible waste fractions are calculated; Dry combustible waste represents the fraction of waste that would be combustible if the tanks were allowed to completely dry out and current combustible waste represents the fraction of waste that is combustible under current conditions. Combustible waste estimates are calculated for 138 of the 149 single shell tanks at Hanford. Eleven tanks have been excluded from the analysis because the waste they contain is thought to be atypical.

The estimates are calculated from total organic carbon and moisture measurements made on waste sampled from the tanks. Not all tanks have been sampled, but this methodology is capable of estimating combustible waste fractions for unsampled tanks by extrapolating information from sampled tanks to the unsampled tanks.

This report also lists all the tank characterization measurements that have been used to construct the combustible waste estimates. The data and estimates are organized on a tank-by-tank basis in Appendix A, so that results can easily be compared to raw data.

Contents

List of Tables

List of Figures

Glossary

ANOVA ANalysis Of VAriance: A statistical procedure for estimating different sources of variation (both deterministic and random) in data.

Combustion Threshold : This is the amount of TOC that must be present in dry waste to support combustion. This threshold is presently set at 4.5%. This threshold assumes that no moisture is present in the waste and the waste is oxidant-rich.

CDF Cumulative Distribution Function: The CDF of a random variable X describes the probability that $X \leq t$ for any value t.

CWF Combustible Waste Fraction: The fraction of waste in a tank that is capable of burning when exposed to a source of ignition. For this analysis, a unit of dry waste is combustible if TOC>4.5%, so CWF is equivalent to the proportion of waste with TOC>r.5%.

DOF Degrees of Freedom: A parameter associated with an ANOVA variance estimate that describes how much data was available to estimate the parameter.

H_2O Water in the waste, measured in weight percent.

NA Not Available: This term is used in tables to identify data that is not available.

PDF Probability Density Function: The PDF of a random variable is the derivative of its CDF.

REML REstricted Maximum Likelihood: A statistical procedure for determining parameter estimates for regression and ANOVA models.

RSD Relative Standard Deviation: The relative standard deviation of a random variable is its standard deviation divided by its mean.

Safety Screening Threshold: This is the amount of combustible waste allowed in the tank. This threshold is set to 5%.

TCD Tank Characterization Database: This data-base is the electronic repository for all Hanford tank sampling data.

TGA Thermo-Gravimetric Analysis: A method for measuring moisture in a waste sample.

TOC Total Organic Carbon: All organic carbon present in the waste, measured in weight percent.

1 Introduction

This report describes how in-tank measurements of moisture (H_2O) and total organic carbon (TOC) are used to calculate combustible waste fractions (CWF) for 138 of the 149 Hanford single shell tanks. The combustible waste fraction of a tank is defined as that proportion of waste that is capable of burning when exposed to an ignition source. These CWF estimates are used to screen tanks for the organics complexant safety issue. Tanks with a suitably low fraction of combustible waste are classified as safe.

The calculations in this report determine the combustible waste fractions in tanks under two different moisture conditions: under current moisture conditions, and after complete dry out. The first fraction is called the **wet combustible waste fraction** (wet CWF) and the second is called the **dry combustible waste fraction** (dry CWF). These two fractions are used to screen tanks into three categories: if the wet CWF is too high (above 5%), the tank is categorized as unsafe; if the wet CWF is low but the dry CWF is too high (again, above 5%), the tank is categorized as conditionally safe; Finally, if both the wet and dry CWF are low, the tank is categorized as safe.

This screening operation is only the first step in the complete tank assessment strategy. Other information may change the initial categorization of a tank. For example, additional measurements might find that the TOC in the tank is degraded, or that the tank can never completely dry out, or that the waste is oxidizer poor.

Although the CWF can be calculated for any tank, the screening operation has not been applied to all 149 single-shell tanks. A set of 11 tanks were classified as "special" tanks, with waste streams that are considered much more unpredictable than the other tanks and these special tanks were excluded from the analysis (see Appendix F of [14] for a more complete discussion of special tanks). Thus this analysis estimates combustible waste fractions for 138 tanks.

An important feature of this methodology is that it provides CWF estimates for all chosen tanks – even those without any TOC or H_2O measurements. The methodology also produces uncertainties for the estimates, which are utilized in the screening operation to produce conservative classifications.

Section 2 describes the data that was required for these calculations. Sections 3 and 4 describe the statistical model and resulting fit for dry combustible waste fractions. Sections 5 and 6 present the statistical model used to estimate wet CWF and the resulting fit. Section 7 describes two tests that were performed on the dry combustible waste fraction ANOVA model to validate it. Finally, Section 8 presents concluding remarks.

Two Appendices present results on a tank-by-tank basis. The first Appendix lists input data for each tank, along with ANOVA model results, and the final CWF estimates. The second Appendix plots dry CWF uncertainty distributions for each tank.

2 Description of the Data

This section describes the data collection and transformations required to produce a database for the combustible waste fraction calculations. The basic data consists of H_2O and TOC measurements from tank waste at identified locations in the tank. Other information required includes sampling and location codes, as well as the fraction of solid and liquid mass recovered from each sample location. The solid and liquid masses are used to form proper weights for combining the H_2O and TOC measurements associated with the solid and liquid phases.

2.1 Sampling Methodology

Hanford single shell tanks contain radioactive process waste produced by Plutonium production operations over the past 50 years. The tanks are buried underground, with access through pipes, called risers, that penetrate the tank domes. All waste samples are taken through these tank risers. Since the location of risers in a typical tank is limited, and risers may be used by other instrumentation, it is possible that the sampled waste is not necessarily representative of the waste in the tank.

Tanks are typically 75 feet in diameter and the largest can contain a million gallons of waste. Tank sizes range from million gallon, to 50,000 gallon tanks. Almost all tanks are only partially filled with waste – many contain less than a quarter of their rated capacity.

The waste was initially liquid when first transfered to the tanks. However, to make room for more waste in the tanks, the water was removed and most tanks are now filled with a waste that is largely solid. The waste in a typical tank has gone through several operations (i.e. evaporation, precipitation, and transfer between tanks), consequently the waste in the tanks is quite inhomogeneous.

Sampling is carried out to "characterize" the waste (i.e. measure the chemical and physical characteristics of the waste in the tanks). Normally, tank wastes are accessed from two different risers, one near the center of the tank, the other near the tank perimeter. To retrieve the tank waste, a sampling device is selected based upon the type of waste in each individual tank. Three types of sampling devices are used: core samplers, grab samplers, and auger samplers. Core samplers are used to retrieve a thin cylinder of waste for analysis, grab samplers are used to retrieve liquid waste, and auger samplers are used to retrieve solid surface waste.

In core sampling, a cylindrical cross section of the tank contents below the riser is obtained by pushing or rotating a 2.5 cm x 48 cm (1 in x 19 in) stainless steel sampler bit into the waste. Each 19-inch vertical length represents one segment, with segment number 1 being nearest the surface. The usable volume of the sampler segment is about 187 ml. The samples collected for each segment are extruded in a hot cell and the mass of the solid sample is determined. The drainable liquid is recovered from the extrusion for each segment. The percent mass recovered for each segment can vary from 0 to 100%.

Waste material from individual segments are also mixed together to produce a "core composite sample" which represents an average of an entire vertical profile of the waste.

Grab sampling collects liquid samples using a sampling bottle that is contained in a cage and lowered into liquid waste. Auger samplers collect solid surface waste and is used in safety screening of sludge or saltcake waste. If auger sampling is performed on waste that contains a great deal of liquid, the liquid portion of the waste may run out of the sampler and a non-representative sample will result. Consequently, drainable liquid is generally not present in auger samples. Auger sampling collects the first 20 to 30 cm (7.9 to 12 in) from the surface.

The sampling carried out to retrieve tank waste for characterization provides the means to associate the measurement results with the location of the sample (tank, riser, segment). Tank and riser id's provide the horizontal location, while the segment numbers provide the vertical distance from the surface of the waste. Several measurements are typically present for a single location. Duplicate TOC and H_2O measurements will be taken, and if both drainable liquid and solid phases are present, separate TOC and H_2O measurements will exist for them too. It is also possible that the segment has been subdivided into subsegments, resulting in measurements for each subsegment.

All these measurements are averaged together, resulting in one TOC and one H_20 measurement per location. Averaging of drainable liquid and solid phase measurements is weighted by each phase's mass.

The sampling method used to retrieve tank waste for characterization provides the means for associating the measurement with one of three waste layers, the surface layer, the sub-surface layer, and the supernate layer. All auger samples are designated as surface measurements. All solid-phase segment 1 core measurements are also designated as surface measurements. Finally, grab samples are designated as supernate layer measurements.

Samples associated with the sub-surface layer include all core samples from segment 2 or greater. The sub-surface measurements comprise the majority of data collected for TOC/H_2O data, as shown below in Table 1

Table 1: Description of TOC/H_2O Data According to Sample Layer

	No. of Measurements	
Tank Layer	TOC	H_2O
Supernate	68	158
Surface	278	598
Sub-surface	1871	2870

The "supernate layer" represents a liquid layer of waste above the solid layers of waste, or pools of liquid waste on the solid waste surface. Supernate does not normally exist in pumped or stabilized tanks and therefore measurements from this layer are not included in the combustible waste calculations. However, supernate measurements are kept for reference in the raw dataset. The other two layers (surface and sub-surface) are explicitly included in the ANOVA's used to estimate CWF. The tank waste was divided into surface and sub-surface regions to reduce potential bias; It was thought that TOC and H_2O concentrations

of surface waste should be much different from subsurface waste.

Division of the waste in these three "layers" is undoubtedly a simplification of the true state of the waste in the tanks. The use of the term "layer" is not meant to imply that the waste is segregated into three horizontally uniform layers. It might be more accurate to call these three layers sampling strata.

2.2 Collection of the H_2O and TOC Data

Nearly 7000 H_2O and TOC measurements have been collected from the Tank Characterization Database (TCD,[9]), an electronic database that contains almost all of the recent Hanford sampling measurements, and various laboratory reports. However, not all collected measurements are relevant for the estimation of the CWF. Further, this initial set of data requires transformations before it is useful for CWF estimation. The solid and drainable liquid measurements for H_2O and TOC at each location must be combined. In addition, the measurements must be converted to consistent units, (wet weight percent), and laboratory replicates must be averaged together. The resulting "transformations" produce a single (H_2O, TOC) estimate for each discrete sample location. After transformations and averages are complete, (H_2O, TOC) data are produced for approximately 519 tank waste locations.

Table 2: Summary of TOC/H_2O Data

Description	Quantity
Number of Tanks Sampled for H_2O or TOC	112
Number of Tanks Sampled for H_2O and TOC	88
Number of Tanks Sampled for H_2O	107
Number of Tanks Sampled for TOC	93
Number of H_2O Measurements Collected	4212
Number of TOC Measurements Collected	2620
Number of Locations Sampled for H_2O or TOC	1004
Number of Locations Sampled for H_2O and TOC	519
Number of Locations Sampled for H_2O	865
Number of Locations Sampled for TOC	658

Most of the data, (i.e. 70%) has been extracted from the TCD. The additional records not from TCD include data from process aids reports, and data measured in 1998 that has not yet been entered to the TCD. These samples have been reviewed to verify that the sample measurements represent the current tank waste. If sample measurements were deemed not representative, they were not used in the screening calculations.

Table 2 summarizes the amount of (H_2O, TOC) data available for the calculations. As one can see, approximately 70% of the 149 single shell tanks have been sampled for H_2O while about 60% have been sampled for TOC. This sampling data allows us to produce H_2O or TOC estimates for 1004 discrete locations within the tank wastes. A total of 519 of

the 1004 locations sampled have both H_2O and TOC measurements associated with them, while 865 locations have only H_2O measurements. TOC measurements are missing at several sampled locations because the sampling protocol did not require TOC measurements to be taken on every sample. About ninety percent of the TOC/H_2O measurements were based on the core samples. The sampling methods are summarized in Table 3.

Table 3: Description of TOC/H_2O Data According to Sampling Device

	No. of Samples			
Device Type	TOC (solid)	TOC (liquid)	H_2O (solid)	H_2O (liquid)
Core Sampler	1976	373	3220	486
Grab Sampler	29	20	82	74
Auger Sampler	68	2	249	2
Not Reported	137	15	75	24
Subtotal	2210	410	3626	586

Total TOC = 2210 + 410 = 2620

Total H_2O = 3626 + 586 = 4212

Approximately 4200 measurements were collected for H_2O and approximately 2600 measurements for TOC. Part of the reason the number of measurements is not the same for the two analytes is because the characterization scheme was not required to analyze every tank for TOC or moisture. In some cases, the characterization scheme followed a path of first testing for waste energetics with a differential scanning calorimeter (DSC). Only those tanks with positive DSC results had TOC measurements taken on the waste samples. The following 26 tank wastes were analyzed for DSC energetics but the values were not high enough to trigger a TOC analysis: AX-104, B-104, B-107, B-108, B-112, B-201, B-204, BX-101, BX-108, BX-110, C-201, C-202, C-203, SX-104, SX-113, T-103, T-106, T-108, T-109, T-112, TX-107, U-101, U-112, U-201, U-202, and U-203.

2.3 TOC Analytical Methods, Persulfate and Combustion Oxidation

The potential for TOC and H_2O measurements to vary depends upon the analytical methods employed including the laboratory method, limits of detection (dilutions), sample heterogeneity, and assumptions made in the sample calculations. Analysis of TOC requires oxidation of the organic carbon using either persulfate or combustion. The written procedures for analyzing TOC are listed in Table 4.

The observed variation of TOC with either the persulfate oxidation or furnace oxidation was investigated on both simulants and in actual tank waste. Baldwin, [4] investigated the effect of the TOC methods for waste stimulants. Because organic carbon in tank waste includes a broad range of compounds, percent recoveries were measured for various compound types. Organic salt and complexant recoveries ranged from 83% to 120%.

Table 4: TOC Methods

Method id	Method	Laboratory
LA-344-105	Furnace Oxidation	222-S
LA-342-100	Persulfate Oxidation	222-S
LA-344-105	Furnace Oxidation	222-S
PNL-ALO-380	TOC/TIC/TC by Hot Persulfate	325
PNL-ALO-381	TOC/TIC/TC by Furnace Combustion	325
PNL-ALO-382	TOC/TIC/TC by UV-Catalyzed Persulfate	325

Observed TOC variation from using either the persulfate oxidation or furnace oxidation of actual waste has been examined in double shell tank SY-101 (Herting, [11]). The study indicates that the persulfate method yielded results that varied from 62% to 91% of the furnace assay results.

Sample heterogeneity contributes to assay variation, and this effect can be examined from the TOC results on the waste in single-shell tank U-106, a tank known to contain organic-complexants. The TOC segment results of shown in Table 5 for the hot persulfate analytical method indicate that the segment level primary results varied from 91% to 128% of the duplicate results.

Table 5: Selected TOC Data from Tank U-106

State	Location	Lab sample id	Primary TOC (%)	Duplicate TOC (%)	Primary Dupl. ratio
solid	u106 19 2	s96t003065	2.63	2.67	0.98
solid	u106 19 3	s96t003066	2.65	2.61	1.01
solid	u106 19 3	s96t003070	1.92	1.5	1.28
solid	u106 19 4	s96t003067	2.59	2.57	1.01
solid	u106 19 4	s96t003068	2.44	2.58	0.94
solid	u106 19 5	s96t003069	1.63	1.46	1.11
solid	u106 19 5	s96t003071	0.87	0.939	0.93
solid	u106 2 2	s96t003010	2.36	2.29	1.03
solid	u106 2 2	s96t003011	2.54	2.45	1.04

solid	u106 2 5	s96t003017	0.893	0.895	1.00

2.4 H_2O Analytical Methods, Thermogravimetric and Gravimetric Analyses

To measure moisture in a sample using thermal gravimetric analysis (TGA), the mass of a sample is measured while it is heated at a constant rate. The mass of the original sample is approximately 10 mg. A gas, such as nitrogen or air, is passed over the sample during the heating to remove any sample off-gases. Any decrease in the mass of the sample represents a loss of gases from the sample through evaporation or through a reaction that forms gas phase products. Mass loss versus sample temperature is recorded on a graph. Mass loss from ambient temperature to approximately 150°C (302°F) is assumed to be water unless the responsible chemist evaluates the graphed data and finds an exception to this rule. The weight percent water by TGA was performed using procedures LA-560-112, Revision B-1 (Mettler) equipment and LA-514-114 (Perkin Elmer Equipment).

To measure moisture in a sample using gravimetric analysis, the mass of a sample is measured after being heated at a constant temperature of 110°C (230°F) for 18 hours. Any decrease in the mass of the sample represents a loss of gases from the sample through evaporation or reaction, and is assumed to be water.

The assay errors resulting from using either the TGA and gravimetric methods were evaluated on the grab sample sludges and are reported in the C-106 Tank Characterization Report [17]. Samples of the supernate, centrifuged solids, and filtered centrifuged solids were analyzed and the results are shown in Table 6. For the solids samples, the percent water for gravimetric analysis are greater than the TGA method. This is expected because the gravimetric method uses larger samples and a constant drying temperature of 110°C for 18 hours could potentially drive off more water.

2.5 Collection of Tank Data

Miscellaneous information concerning each tank is required for the combustible waste calculation. The data include diameter of each single-shell tank and volume of sludge and saltcake. Using published data, each single-shell tank was grouped according to the quantity of organic complexant waste admitted to each tank, the surface condition of the waste, and the predominant waste phase. This grouping was also utilized by the calculations.

2.6 Database Description

Although all indications are that good laboratory and quality control procedures were in place for sample analysis and evaluation, some reported laboratory results are worth mentioning as an indication of possible problems. For example, some samples present in the database were described as liquids with less than 30 percent water. Liquid waste measurements for tanks SX-106, S-102, C-106, and BY-108 were found to be below 30% water, as shown in Table 7. One reason for the reported low percent water values for liquids is the high heat content of the waste in some tanks, resulting in the liquid containing low water (super-saturated solution). Two tanks where high heat can explain the low percent water

Table 6: Comparison of Percent Water by Thermogravimetric and Gravimetric Analyses in Tank C-106

Laboratory Number	Sample Number	TGA	Gravimetric Analysis
Supernate			
S96T000538	6C-96-5	80.88	81.4
S96T001023	6C-96-12	79.27	79.0
Filtered Centrifuged Solids			
S96T001537/ S96T001539	6C-96-4	24.10	25.1
S96T000567/ S96T000569	6C-96-7	25.74	26.8
S96T000551/ S96T000553	6C-96-10	12.78	19.05
S96T001685/ S96T001687	6C-96-11	31.92	34.1
S96T001559/ S96T001561	6C-96-13	23.7	26.3
Centrifuged Solids			
S96T001527	6C-96-4	3.58	5.75
S96T000542	6C-96-7	8.28	9.9
S96T000558	6C-96-10	12.86	17.1
S96T001674	6C-96-11	9.03	11.65
S96T001030	6C-96-13	9.36	20.85

measurements are SX-106 and C-106. However, no reason is evident for the low percent water found in wastes from tanks S-102 and BY-108.

Table 7: Liquid Measurements Reported with Less Than 30% Water

Tank	Lab sample id	Riser (event)	Segment	Layer	H_2O	Date	State
SX-106	s97T002179	223	1	supernate	22.37	980430	liquid
SX-106	s97T002179	223	1	supernate	19.34	980430	liquid
S-102	s96t000634	11	11	sub-surface	29.47	960113	liquid
C-106	s96t001679	7	1	supernate	28.37	960301	liquid
BY-108	s95t001427	12a	2	sub-surface	27.11	950727	liquid
BY-108	s95t001427	12a	2	sub-surface	25.03	950727	liquid

In addition to these liquid measurements with low water, 49 solid waste measurements presented in the dataset report less than 2 percent water. Of these, 32 measurements were used in the calculation of combustible waste fraction. Some samples reported a complete absence of water that has not been explained. For example, TGA plots for tank C-111 show very little weight loss until $\sim 225^oC$. Twenty one sample results reporting less than 1 percent water were replaced with a value of 1% water for purposes of the CWF calculation. The distributional model employed to describe moisture requires a value above 0%, but more importantly, waste physics (see [18]) also requires moisture to be greater than 0%.

2.7 Data Editing and Transformations

All analytical results for liquid samples have been converted from a volume basis (as reported by the analytical laboratory) to a weight basis, so that liquid and solid phase measurements can be combined. The conversion of data from a volume to weight basis required knowledge of the sample density. In cases where the density of the sample was not reported, a density of 1.3 gm/ml was used for liquid samples, and a density of 1.5 gm/ml was used for solid samples. For comparison, Willingham (1994) modeled density and density variation in Hanford tank waste samples. The density of supernatants was reported as 1.26 gm/ml with a standard deviation of 0.13 gm/ml. The density of sludge was reported to be 1.54 gm/ml with a standard deviation of 0.23 gm/ml.

The following data were excluded from the ANOVA calculations as incorrect measurements:

1. H_2O or TOC values reported that are not consistent with other values from this sample or possibly surrounding samples.

2. Reported values which the responsible chemist has indicated do not represent the waste in the tank due to out-of-specification conditioning or heating of the waste sample after retrieval from the tank.

3. Reported values from samples that were contaminated with lithium bromide used in the sampling process.

4. Reported values from secondary or tertiary sources of data and cannot be verified. This is especially true for pre-1989 data.

Nearly 1400 measurements related to solid fraction or liquid fraction were collected from the TCD. The initial set of constituent data collected from the TCD was associated with unique locations, similar to the location identification system developed for the TOC/H_2O dataset. However, the solid fraction and liquid fraction data required transformation before they could be combined. The measurements used to develop the solid and liquid fraction data are:

1. solid weight and drainable liquid weight

2. solid volume and drainable liquid volume

3. weight percent solids and volume percent solids

It was necessary to transform the constituent data to solid fraction and liquid fraction data on a weight basis. The transformed constituent data and resulting liquid fractions for each location are presented in the Appendix A. Solid weight and drainable liquid weight offer the most direct calculation of the fraction of solid and liquid by weight. Solid volume and drainable liquid volume were also used to calculate solid and liquid fractions by assuming an appropriate density. In this case, 1.5 g/ml was used as the density for solid and 1.3 g/ml was used as the density for liquid as described above. In the absence of the first two categories of data listed above, values for the weight percent solids and then the volume percent solids were used to calculate solid and liquid fractions.

The (H_2O, TOC) solid measurements were averaged to obtain a single mean value for each discrete sample location. Similarly, drainable liquid measurements were averaged to obtain a single mean value for each discrete sample location, if drainable liquid was present in the sampler. As previously stated, supernate samples were not used in the combustible waste calculation. In most cases, only a solid sample was recovered in the surface and sub-surface layers; no drainable liquid was recovered. Where TOC or H_2O measurements were present in both solid and liquid phases, the solid average and the liquid average were combined by a weighted average to form a single mean value for the location, using weights proportional to the solid and liquid fractions. Where TOC or H_2O measurements were present in the solid phase but absent in the liquid phase, it is assumed that liquid was not recovered. Where TOC or H_2O measurements were present in both solid phase and liquid phase, but the fraction information is missing, the solid average was used to represent the mean for the location. Where TOC or H_2O measurements were present in liquid phase but absent in the solid phase, the measurement was not used unless the liquid fraction was larger than 90%, in which case, the liquid average was used to represent the mean value at the location.

3 Estimation Methodology for Dry CWF

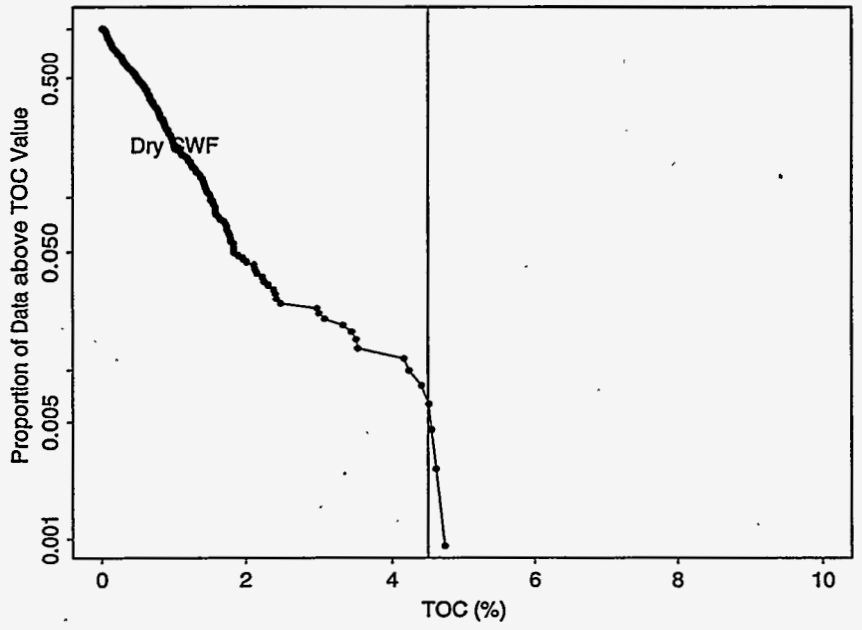
This section describes the statistical calculations that produce the dry CWF's from (H_2O,TOC) sampling data. The calculation actually produces more than a single point estimate for combustible waste fractions. A Bayesian "uncertainty distribution" is produced, which describes how close the estimate is to the true dry CWF.

3.1 Quantities to be Estimated

Dry combustible waste is currently defined as waste with a dry-TOC concentration greater than 4.5% (see [14] for a justification of this definition). According to this definition, dry CWF is then the fraction of waste in a tank that exceeds this combustion threshold.

The basic features of this estimation strategy can be illustrated with tank data. Figure 1 presents all the dry-TOC values that can be computed from (H_2O,TOC) data (519 points). If this data represented a random sample from the tank farm, this plot would estimate the actual site-wide dry-TOC distribution. One could therefore estimate the site-wide combustible waste fraction by counting the number of points that fall above the 4.5% threshold. In this example, 4 points are above the threshold, so we would estimate the dry CWF at 4/519=0.8%.

Figure 1: Illustration of Dry Combustible Waste Estimate from Tank Data



This illustrative estimate has several deficiencies: It produces site-wide estimates, when tank-specific estimates are needed; It may be biased high because the tanks chosen for sampling are the "problem" TOC tanks; Finally, it requires a great deal of data to produce

accurate estimates. The methodology developed for tank screening attempts to deal with these difficulties, but it still utilizes the same simple strategy as illustrated.

To use the available data to estimate the distribution of dry-TOC for each tank, and to reduce biases in the data as mentioned above, statistical procedures suited to the structure of the available data have been chosen. A dry-TOC distribution describes what proportion of the waste has a dry-TOC concentration above any specified threshold, in particular the threshold that defines the dry combustible waste. Historical information was used to group tanks with similar TOC and moisture content into 5 TOC groups and 4 moisture groups (see [14] for more details). Then, a random-effects analysis of variance (ANOVA) model was used together with the tank groupings to estimate the dry-TOC distribution for each tank.

In the random-effects ANOVA model, the dry-TOC concentration was assumed to have a logistic-normal distribution and the two unknown parameters that define such a distribution (i.e., logistic mean and logistic standard deviation) were estimated using the ANOVA procedures. A simple parametric form was chosen for the distribution because sufficient data does not exist to estimate the distribution empirically for each tank. Although the assumption of logistic-normality is undoubtedly an approximation to reality, the residual plots presented in Section 4 demonstrate that the assumption is reasonable. (Further discussion about this can be found in Section 4.)

We want to utilize all the relevant TOC data available. This means that for each tank location where TOC data exists, we would like to have a dry-TOC value and this requires both TOC and moisture measurements. Although logically every TOC measurement required a moisture measurement to convert from a dry to wet basis before it was entered into TCD, such a correspondence between TOC and moisture measurements is not observed. In the observed data, about 19% of the tank locations with TOC measurements are missing corresponding moisture measurements. For those tank locations, we have used the H_2O ANOVA best estimate to fill in the missing moisture value. Details of the H_2O ANOVA are discussed in Sections 5 and 6.

From the H_2O and TOC measurements for a given tank location, the dry-TOC can be easily calculated. We considered a dry-out scenario in which the moisture was reduced from its original concentration of $X_{h2o}(wet)$ to the value $X_{h2o}(dry)$. If $X_{toc}(wet)$ represents the TOC currently in a unit of waste, then after dry-out the result is:

$$X_{toc}(dry) = \frac{1 - X_{h2o}(dry)}{1 - X_{h2o}(wet)} X_{toc}(wet) \tag{1}$$

In our analysis, the above formula was applied by making the most pessimistic assumption for dry-out, that is $X_{h2o}(dry) = 0$, or all water is eliminated. Studies have shown that a typical single shell tank would achieve equilibrium at 5% to 25% moisture (see [18]), so if best estimates for dry-out were used in the screening calculation, more optimistic results might be obtained.

For each tank, the ANOVA produced an estimated dry-TOC distribution that describes the spatial variability of the waste in terms of dry-TOC. As mentioned earlier, we used a logistic-normal distribution to describe this spatial variability. If we denote the ANOVA estimate of the logistic-mean and logistic-standard deviation by $\hat{\mu}$ and $\hat{\sigma}$, we can calculate

the dry CWF, i.e., the fraction of waste with dry-TOC above the 4.5% threshold, by:

$$R_{dry} = \Phi\left(\frac{\hat{\mu} - \text{logistic}(4.5\%)}{\hat{\sigma}}\right) \tag{2}$$

where $\Phi(\cdot)$ is the CDF for standard normal distribution.

As can be seen, this fraction R_{dry} depends on the estimated values $\hat{\mu}$ and $\hat{\sigma}$, and the true μ and σ are unknown. We use a Bayesian "uncertainty distribution" to assess how close the estimated fraction is to the true one.

The calculations can be summarized in five steps:

1. Fill in missing H_2O values at tank locations where there are TOC measurements by using the result of a separate ANOVA model on H_2O, which is discussed in details in Sections 5 and 6.

2. Transform the (H_2O,TOC) data, which describes waste in its present state, to account for dry-out. The result is a dry-TOC measurement.

3. Perform an ANOVA analysis on dry-TOC measurements to determine the dry-TOC distribution in each tank.

4. Transform the dry-TOC distribution into a dry CWF for each tank.

5. Calculate Bayesian "uncertainty distributions" for each tank.

The 95% upper quantiles from the dry CWF distribution are compared to the 5% safety screening threshold to determine whether or not each tank passed the screening test.

3.2 Tank Grouping

Tank groups were introduced into the ANOVA modeling to allow prediction of TOC in unmeasured tanks. Tanks were arranged into 5 waste groups to represent the concentration of complexant TOC that one would expect on the basis of the tank's waste transfer history (this is described in detail in [14]).

Five categorizations cannot predict TOC perfectly. For example, a "non-complexant" tank may still contain TOC because secondary waste streams contain TOC, the TOC may be from solvents or extractants, or because of errors in the historical records. Splitting the tanks into more categories might decrease the within-group variations, but this would also decrease the amount of data available to estimate TOC for each group.

Given this constraint (i.e., sufficient data must exist to describe TOC in each group), we decided to limit the TOC categories to the following five:

High Tanks receiving high complexant waste streams.

Medium Tanks receiving indirect transfers of complexant waste.

Low Tanks receiving very little complexant waste.

Non-TOC Tanks that should have received no complexant waste.

Special Tanks with unique or unusual waste transfer histories, which were excluded from the screening.

3.3 ANOVA Model

The dry-TOC distribution was assumed to have a logistic-normal distribution. This distribution is created by applying a logistic transformation to the dry-TOC values and assuming that the result is normally distributed. If X_{min} and X_{max} represent the minimum and maximum bounds on a dry-TOC measurement, then the logistic transformation of the dry-TOC value $X_{dry.toc}$ is defined by:

$$Y = \log\left(\frac{X_{dry.toc} - X_{min}}{X_{max} - X_{dry.toc}}\right) = \text{logistic}(X_{dry.toc}) \tag{3}$$

The transformed value Y is assumed to be normally distributed with a mean of μ and a standard deviation of σ. This distribution is called the logistic-normal distribution and is often utilized in binomial regression modeling.

This distribution was chosen because it obeys the natural constraints on the TOC measurement (TOC concentration cannot be negative or greater than 20%). Also, the distribution produces a standard deviation that is roughly proportional to the mean, at least for small values. TOC concentration has been observed to obey such a relationship between mean and standard deviation. In previous reports, the TOC and H_2O distributions were assumed to be log-normal. When concentrations are low (as is generally the case for TOC), there is virtually no difference between the log-normal and logistic-normal distributions. However, the log-normal distribution does not have an upper bound, so the distributions differ markedly when concentrations are high (as is frequently the case for H_2O). The logistic-normal distribution was selected over the log-normal for its capability to model the right-hand tail of these distributions correctly.

For the screening analysis, the minimum bound on dry-TOC was set at $X_{min} = 0$ and the maximum bound was set to $X_{max} = 20\%$. The maximum bound was set to 20%, a value much lower than 100%, because the waste cannot consist of 100% *combustible* organic carbon. Oxidizer must be present in the waste and the organic carbon must be chemically combined with hydrogen, oxygen, and/or nitrogen. These constraints result in a practical upper bound on TOC of 20%.

To "fit" a logistic-normal distribution to TOC data, one really needs to estimate the two parameters, the mean, μ and the standard deviation, σ, of the logistic-transformed data. There are several ways to do this, and the best way depends on the amount of data available as well as on any relationships that might exist between tanks. An ANOVA model was employed to estimate these two parameters for each tank.

The ANOVA model assumes that (1) the σ parameter is the same for all tanks, and that (2) the means μ are described by a certain random-effects ANOVA formula. Because of these assumptions, the ANOVA model can produce estimates from modest amounts of data, and can in fact produce dry-TOC distributions for tanks that have no data.

Let us identify the logistic transformed dry-TOC data by $Y_{ijk\ell}$, where the indices describe the sampling conditions. These conditions are defined as:

i: Describes the waste layer (surface layer, sub-surface layer) the sample was taken from. The model divides the tank into a surface layer (the top 19 inches of waste), and the sub-surface layer (the remaining portion of the waste).

j: Identifies a tank group. There are four tank groups (High TOC, Medium TOC, Low TOC, and Non-TOC).

k: Represents the particular tank associated with the sample.

ℓ: Identifies the "replicate" measurements that occur within a layer in a particular tank.

This notation can be used to identify the distribution parameters μ and σ, which must be estimated for the surface and sub-surface layers of every tank. Thus layer i in tank jk has parameters μ_{ijk} and σ_{ijk} associated with it.

ANOVA estimates are produced by fitting an ANOVA model of the form:

$$Y_{ijk\ell} = \mu + D_i + G_j + DG_{ij} + T_{jk} + DT_{ijk} + e_{ijk\ell} \tag{4}$$

The terms D_i, G_j, DG_{ij}, T_{jk}, DT_{ijk}, and $e_{ijk\ell}$ are assumed to be independently and normally distributed random variables with zero means and standard deviations σ_D, σ_G, σ_{DG}, σ_T, σ_{DT}, and σ_e, respectively. The model terms (parameters) actually describe the following quantities (on the logistic scale):

μ: logistic-mean TOC for the site.

D_i: Deviation of layer i from the mean μ.

G_j: Deviation of tank group j from the mean μ.

DG_{ij}: Deviation of layer i from group average.

T_{jk}: Deviation of Tank k from the group average.

DT_{ijk}: Deviation of layer i in tank k from the tank's average.

$e_{ijk\ell}$: Spatial deviations within any layer (i, j, k).

σ_T^2: $Var(T_{jk})$, tank-to-tank variability.

σ_{DT}^2: $Var(DT_{ijk})$, layer-to-layer variability.

σ_e^2: $Var(e_{ijk\ell})$, within-layer variability.

This model includes the tank group effects as the terms G_j and DG_{ij}, which are important in determining estimates of TOC for tanks without any data. The waste within the tanks was divided into two layers because the surface of the waste was thought to be different from the sub-surface. Ideally, one would like to include more layers than this in the model (perhaps a layer for every segment taken) but not enough data is available.

The ANOVA fitting procedure produces estimates for all the unknown terms in the above equation. Since all terms in the model are considered to be random variables (with the exception of μ), it also calculates their variances (such as $Var(e_{ijk\ell}) = \sigma_e^2$, $Var(T_{jk}) = \sigma_T^2$, etc.). These variances are then used in the ANOVA procedure to calculate uncertainties in the TOC estimates.

This model produces estimates for all random effects by conditioning on the observed data ($Y_{ijk\ell}$). We explain how this is done by re-specifying the model (see [8] and [15]) in Equation (4) in matrix form as:

$$Y = X\beta + E \tag{5}$$

where Y is an $n \times 1$ response vector, X is the design matrix from the over-parameterized model comprised of zeros and ones denoting absence or presence of effects for a particular response. β is a vector comprised of μ and all of the random effects in the model, and E is the error vector of $e_{ijk\ell}$. Therefore,

$$\beta \sim N(0, \Sigma) \tag{6}$$

$$E \sim N(0, \sigma_e^2 I) \tag{7}$$

where Σ is a diagonal matrix with the variances of the model effects on the diagonal (i.e., $\Sigma = diag\{\infty, \sigma_D^2, \sigma_D^2, \sigma_G^2, \sigma_G^2, \cdots\}$). The first diagonal element corresponds to μ, which is fixed; it is mathematically equivalent to consider μ as a random term with infinite variance (see [8]). The joint distribution of the random variables Y and β can be written as

$$\begin{bmatrix} Y \\ \beta \end{bmatrix} \sim N\left(\begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} X\Sigma X^T + \sigma_e^2 I & X\Sigma \\ \Sigma X^T & \Sigma \end{bmatrix} \right). \tag{8}$$

If Y is observed, then the conditional distribution of β given Y is a multivariate normal with

$$E(\beta|Y) = (X^T X + \sigma_e^2 \Sigma^{-1})^{-1} X^T Y \text{ and} \tag{9}$$

$$Cov(\beta|Y) = \sigma_e^2 (X^T X + \sigma_e^2 \Sigma^{-1})^{-1}. \tag{10}$$

and the Σ inverse matrix has the form

$$\Sigma^{-1} = diag\left\{0, \frac{1}{\sigma_D^2}, \frac{1}{\sigma_D^2}, \frac{1}{\sigma_G^2}, \frac{1}{\sigma_G^2}, \cdots\right\}. \tag{11}$$

$E(\beta|Y)$ is the "best estimate" for the random effect vector β and $Cov(\beta|Y)$ represents its associated uncertainty.

The ANOVA model presented in Equation (5) was fit to the data using the Restricted Maximum Likelihood (REML) algorithm present in Splus^{TM} (see [6], [7], [15], and [8] for

details). The fitting procedure uses the above formulas to determine all unknown model parameters in an iterative fashion. Given estimates for Σ, an estimate for the random effects parameter β is determined. Given β, the variances in Σ can be determined using sum of squares formulas.

In matrix form, the best estimate for a specific layer (identified by indices (i, j, k)) is given by:

$$\hat{\mu}_{ijk} = V^T E(\beta|Y) \text{ or} \tag{12}$$

$$= \hat{\mu} + \hat{D}_i + \hat{G}_j + \hat{DG}_{ij} + \hat{T}_{jk} + \hat{DT}_{ijk} \tag{13}$$

where the hat over the parameter signifies its estimated value and V represents a vector of zeros and ones chosen to select the 6 terms listed in equation 13. The uncertainty of this estimate is given by:

$$Var(\hat{\mu}_{ijk}|Y) = V^T Cov(\beta|Y)V \tag{14}$$

It so happens that Equations (12) and (14) produce valid estimates for tank layers, even when no data actually exists for that layer. To produce these estimates, one must only include columns in the design matrix, X that represent all layers to be estimated.

For a tank having no data, it can be shown that the best estimate is actually reduced to

$$\hat{\mu}_{ijk} = \hat{\mu} + \hat{G}_j + \hat{D}_i + \hat{DG}_{ij} \tag{15}$$

because T_{jk}, and DT_{ijk} are estimated as zero. In other words, when no data exists for a tank, the ANOVA uses group averages to estimate the layer concentrations, a strategy that makes intuitive sense. Of course, estimates associated with unsampled tanks are much less certain than the sampled-tank estimates, and their uncertainties are inflated by the amount $Var(T) + Var(DT)$. The actual estimates for all tank layers are automatically produced by an ANOVA estimation program in Splus (see [16]), using Equation (9).

The variance σ_e^2 represents within-layer variability (contaminated with some measurement error) and is particularly important in the combustible waste calculation because it describes how homogeneous the waste is. If this variance were zero, one measurement from a tank layer would be sufficient to determine whether or not it is safe in terms of CWF. This variability is also affected by the physical dimensions of the sample used to produce the data for the ANOVA. Making the samples dramatically larger or smaller than those currently called for by Tank Waste Characterization (TWC) sampling might produce a significantly different σ_e^2.

Since the measurement $Y_{ijk\ell}$ is typically on a core segment, the unit of waste being described in the ANOVA model is actually a cylinder 1 inch in diameter and about 20 inches in height. This analysis therefore evaluates the variability for units of waste that are about 20 inches (or 0.4M) in dimension. It so happens that a unit of waste of this dimension is approximately the size of concern for safety.

3.4 Estimation of Dry Combustible Waste

The ANOVA results presented in Section 3.3 are used to calculate the dry CWF. These fractions are then used to screen tanks into pass/fail categories as briefly described earlier. This section gives a more detailed description of the calculation of the dry fractions.

For layer i in tank jk, the ANOVA fitting procedure produces the desired distribution parameters (for dry-TOC on logistic scale) $\hat{\mu}_{ijk}$ and $\hat{\sigma}^2_{ijk} = \hat{\sigma}^2_e$. These two parameters are used to produce an estimate for the dry CWF $R_{dry.ijk}$ by equation (2). The subscript $i = 1$ corresponds to the surface layer, and $i = 2$ corresponds to the sub-surface layer. To obtain a CWF for the whole tank, the CWF's from the surface and sub-surface layers are averaged together, using the layer volumes as weights:

$$R_{dry.jk} = \frac{V_{surf}}{V_{surf} + V_{subs}} R_{dry.1jk} + \frac{V_{subs}}{V_{surf} + V_{subs}} R_{dry.2jk} \tag{16}$$

As discussed previously, the calculation must produce more than simple point estimates, because there is substantial uncertainty in such an estimate. We actually desire to calculate the posterior (uncertainty) distribution of $R_{dry.jk}$ given the available data. This more complicated problem is discussed in the next section, but the solution is closely related to the point estimate presented above.

3.5 Calculation of Uncertainty Distributions

The ANOVA estimation method can produce approximate posterior distributions for the parameters μ_{ijk} and σ^2_e. To simplify the discussion, we will concentrate on tank jk, so that the indices jk can be dropped from the parameters. For tank jk, we desire the joint posterior distribution on $(\mu_1, \mu_2, \sigma^2_e)$ (1=surface, 2=sub-surface), which can be denoted by:

$$f(\mu_1, \mu_2, \sigma^2_e | \text{data}) \tag{17}$$

Because the transformed data is normally distributed, the posterior is related to the estimates according to the approximate formula:

$$f(\mu, \sigma^2_e | \text{data}) = \mathcal{N}(\mu : \hat{\mu}, \hat{A}) \mathcal{IG}(\sigma^2_e : \hat{\sigma}^2_e, dof) \tag{18}$$

where $\mathcal{N}(x : y, z)$ represents a multivariate normal distribution with mean y and a covariance matrix of z. In the above formula, μ represents (μ_1, μ_2), so the normal distribution is two dimensional. The covariance matrix $\hat{A}$ is produced by the ANOVA fitting procedure. The variance, σ^2_e, is distributed according to an inverse gamma distribution, which is denoted by $\mathcal{IG}(x : y, z)$. The random variable x is defined to have an inverse gamma distribution with parameters y and z if $1/x$ has a gamma distribution with mean y and z degrees of freedom. The degrees of freedom represent the total number of data points minus number of tank layers with data.

Equation (18) describes the uncertainty in the dry-TOC distribution parameters μ and σ^2_e. Furthermore, equations (2) and (16) relate these parameters to CWF R_{dry}, a relationship that we can express by writing $R_{dry}(\mu, \sigma^2_e)$. Thus, the uncertainty distribution of R_{dry} is given by:

$$\begin{aligned} F(R_0|\text{data}) &= Pr(R_{dry} < R_0 | \text{data}) \\ &= \int_{R_{dry}(\mu, \sigma^2_e) < R_0} f(\mu, \sigma^2_e | \text{data}) d\mu_1 d\mu_2 d\sigma^2_e \end{aligned} \tag{19}$$

This distribution describes the dry combustible waste fraction in tank jk, and is the final output of the calculation. A best estimate is produced from this distribution by using its median. To classify tanks as pass or fail, the upper 95% quantile from this distribution is used.

4 Results of the Dry CWF Calculation

4.1 ANOVA Fit to Dry TOC

The ANOVA model that was fitted to the dry-TOC data as described by Equation (4). The variance components of this model (i.e., σ_e^2, σ_T^2, etc.) were summarized in Table 8. The estimates are produced in logistic-transformed space. In the table, they have been converted to relative standard deviations (RSD) in the non-transformed space.

Table 8: ANOVA Table For Dry-TOC

Variance Component	ANOVA Estimate	Approx. RSD (%)
σ_D^2	0	0 %
σ_G^2	0.267	52 %
σ_T^2	0.557	75 %
σ_{DG}^2	0	0 %
σ_{DT}^2	0.185	43 %
σ_e^2	0.519	72 %

One would like most of the variability to be associated with the tank grouping terms large because this would result in more effective predictions on unsampled tanks. To see how these variabilities are related to the ability to predict the state of unsampled tanks, we can compute the *within-group correlation*, which measures how well a sampled tank can be used to predict TOC in an unsampled tank in the same group. The formula for this correlation is;

$$\rho = \frac{\sigma_D^2 + \sigma_G^2 + \sigma_{DG}^2}{\sigma_D^2 + \sigma_G^2 + \sigma_T^2 + \sigma_{DG}^2 + \sigma_{DT}^2} \tag{20}$$

As one can see from the equation, if $sigma_D^2 + \sigma_G^2 + \sigma_{DG}^2$ is large, then this correlation will be near one, indicating that the results from sampled tanks are very good descriptions for the unsampled tanks. A correlation near one also indicates that all tanks in a group have the same TOC distribution.

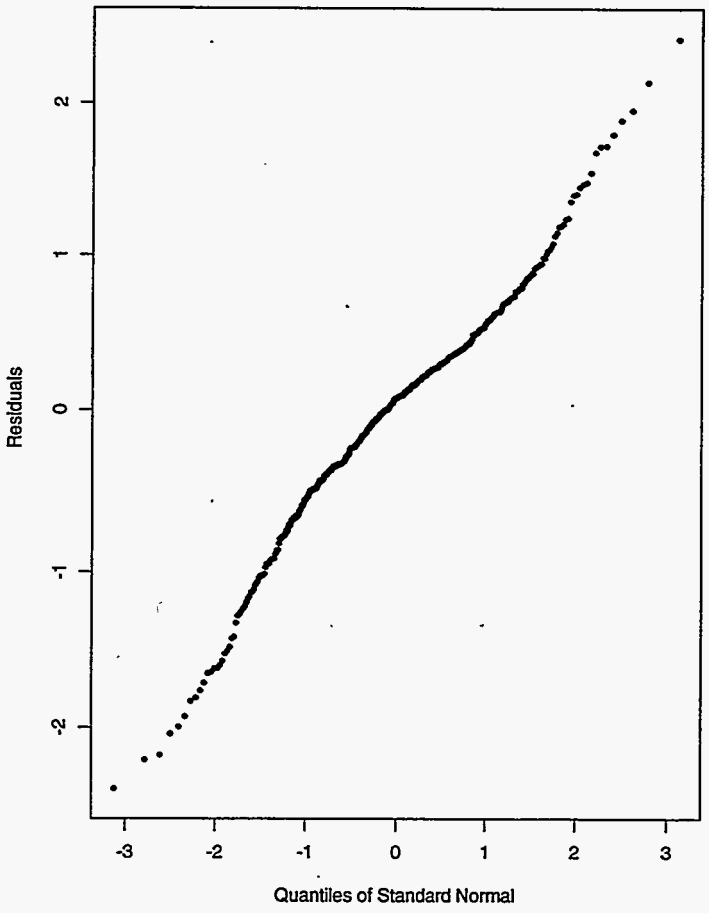
The within group correlation is 26%. This correlation is different from zero, indicating that the grouping is useful. However, we would expect a value above 70% for a truly effective grouping.

The logistic-mean TOC for all sampled tanks, μ, is estimated as $\mu = -4.06$, which translates into a concentration of 0.34%. One can see that, on average, the TOC in the Hanford single-shell tanks is very low. If the waste were homogeneous, no combustible waste would exist in these tanks.

The ANOVA table contains a fairly large tank-to-tank variability of $\sigma_T^2 = 0.56$. In previous evaluations, this number was much lower. The addition of more tanks to the database increased this variability. It is also important to note that the terms involving waste

layers (σ_D and σ_{DG}) are zero, indicating that there is no difference between surface and sub-surface dry-TOC, an important observation.

Figure 2: QQ Plot of Dry-TOC ANOVA Residuals verses. Normal



The ANOVA model assumes that the data is logistic-normally distributed, and this assumption is quite important in calculating the combustible waste fractions. Figure 2 presents a QQ plot of the ANOVA residuals to check the hypothesis of logistic-normality. These residuals are from logistic-transformed data, so they should be normally distributed if the assumption is correct. When the residuals are normally distributed, the QQ plot should produce roughly a straight line. As one can see, this is largely the case, except for a "bump" in the middle of the distribution.

The distribution tails seem to fit a logistic normal distribution quite well. The fit of the logistic-normal distribution to the right-hand tail of the distribution is particularly important because the CWF calculation relies on this portion of the distribution. The fact that there seem to be no "outlier" data-points is reassuring.

The bump in the middle of Figure 2 gives some indication that the distribution may be

composed of a mixture of two populations with different sigmas. Figures 3 to 13 also suggest the same possibility. The dry-TOC data within each layer in each tank are plotted in these figures as solid dots. From these figures, there is some evidence that there are two groups of tanks: one, such as A-101 and AX-101, has smaller within-layer spatial variability than the other, represented for example by S-107 and SX-101.

This difference in spatial variabilities is perhaps the greatest weakness with the existing model. We considered modifications on the existing model to rectify the problem, but it isn't clear some of the modifications would result in a model that is mathematically intractable. The most obvious modification would be to introduce a grouping variable that separated the high variance tanks from the low variance tanks. However, because the model has to be applied to both sampled and unsampled tanks, the grouping can't be on the basis of existing TOC data; it must rely on historical information available for each tank.

The ANOVA also predicts the logistic means for the two layers in each tank. These predictions are also presented graphically as open circles in Figures 3 to 13. The figures list tanks by TOC groups, with the group mean identified by the solid line on each plot. Of course, these predictions have uncertainties associated with them and this is represented in the plots by square brackets, which identify the 95% bounds on the prediction (the prediction is represented by the open circle).

The figures also present the data used in the ANOVA fit; this data is represented on the plots as solid dots. Each data point in the plot is actually the average of all raw data (usually sample/duplicate measurements) from a single location. Thus, the scatter of the data points represents the spatial variability of dry-TOC within the defined layer. The dry-TOC data used in this fit is also listed in Appendix A, for the reader's reference.

As one can see from the plots, the ANOVA basically computes a layer estimate by averaging existing data on the logistic scale. If the layer has only one or two data points, this estimate might deviate from the simple logistic mean, because the ANOVA includes the group mean in the averaging process. One can also see a substantial difference in confidence bound widths on the plots. Layers that have data can have confidence bounds that are about an order of magnitude smaller than layers without data.

Another way to check the model fit is to look at the plot of observed dry-TOC verses. fitted dry-TOC, and if the points cluster closely around the 45 degree line, it is an indication that the fit is good. Figure 14 shows such a plot and it can be seen that the fit is reasonable.

4.2 Calculation of Dry CWF's

The ANOVA results presented in the last section were used to calculate the dry CWF's. This section presents the best estimates (medians) for these fractions, as well as their upper 95% bounds. These fractions were then used to screen tanks into pass/fail categories. The current screening criterion is that if the upper 95% bound is less than 5% CWF, then the tank is considered to pass, otherwise it is considered to fail.

The ANOVA estimate $\hat{\sigma}_e^2$ is actually composed of within layer spatial variability of the dry-TOC as well as some measurement errors in the (H_2O, TOC) measurements. To determine how much of this variance is due to measurement errors, we used the replicate measurements of (H_2O, TOC), such as primary, duplicate and/or triplicate, at locations where such replicate measurements were available in the database, to calculate the relative standard deviation, (RSD). The distributions (CDF) of these RSD's for H_2O and TOC are plotted in Figure 15. From this figure, it can be seen that the medians of the distributions are about 20%. In the dry CWF calculations, we subtract 10% RSD from the ANOVA estimated $\hat{\sigma}_e$ to get the estimated within-layer spatial variability. We use 10% because this is the stated accuracy for the laboratory procedures.

Table 9: Failing Combustible Waste Fractions

		#	Dry-TOC Est. (%)		Dry CWF (%)	
Tank	Grp	Obs	Surf	Sub-Surf	Median	Upper 95
U-106	h	8	2.074	3.061	24.6	44.2
AX-102	h	1	1.501	2.024	7.3	40.9
A-102	h	1	1.306	1.073	2.5	22.6
C-104	h	11	1.5	1.816	6.8	16.1
A-103	h	2	0.908	1.049	1.1	9.8
U-105	h	22	1.426	1.611	4.9	9.6
T-111	l	8	0.923	1.34	2.6	8.3
U-111	h	2	0.757	0.711	0.2	8.3
A-106	h	2	0.853	0.965	0.9	8.3
C-105	h	1	0.734	0.791	0.4	7.8
BY-103	l	1	0.69	0.557	0.1	5.4

Table 9 lists the failing tanks from the dry-CWF calculations. There are 11 such tanks, and they are listed in order of the 95% bound on estimated CWF. Tank U-106 has the largest CWF, with a best estimate of 25% and an upper 95% estimate of 44%. A tank with a CWF as high as this is an obvious failure .

On the other hand, there are several tanks that are "close to" the pass/fail CWF threshold of 5% (BY-103, C-105, A-106, U-111, T-111), and their categorization is more ambiguous. A small change in assumptions (such as the completeness of dry-out) or in the existing data could change their status. It should be noted that there are also several tanks just below

Figure 14: Fitted verses Observed Dry-TOC

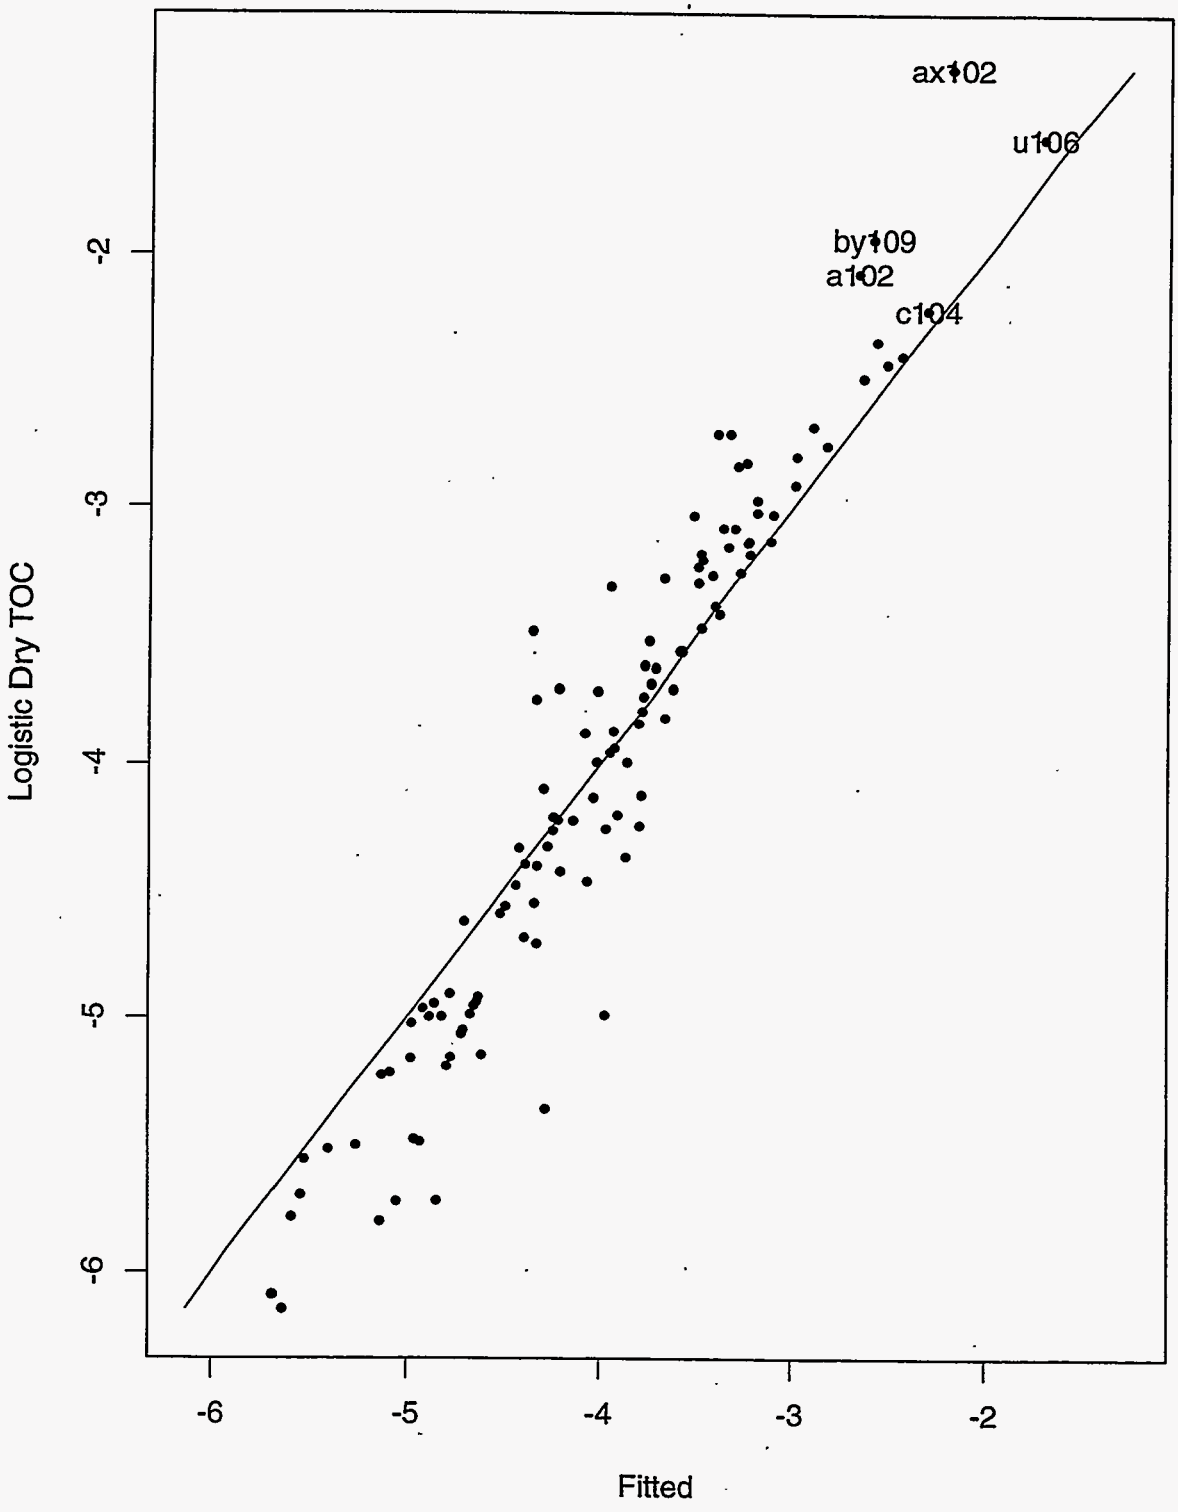

Figure 15: RSD Distributions for measurement error

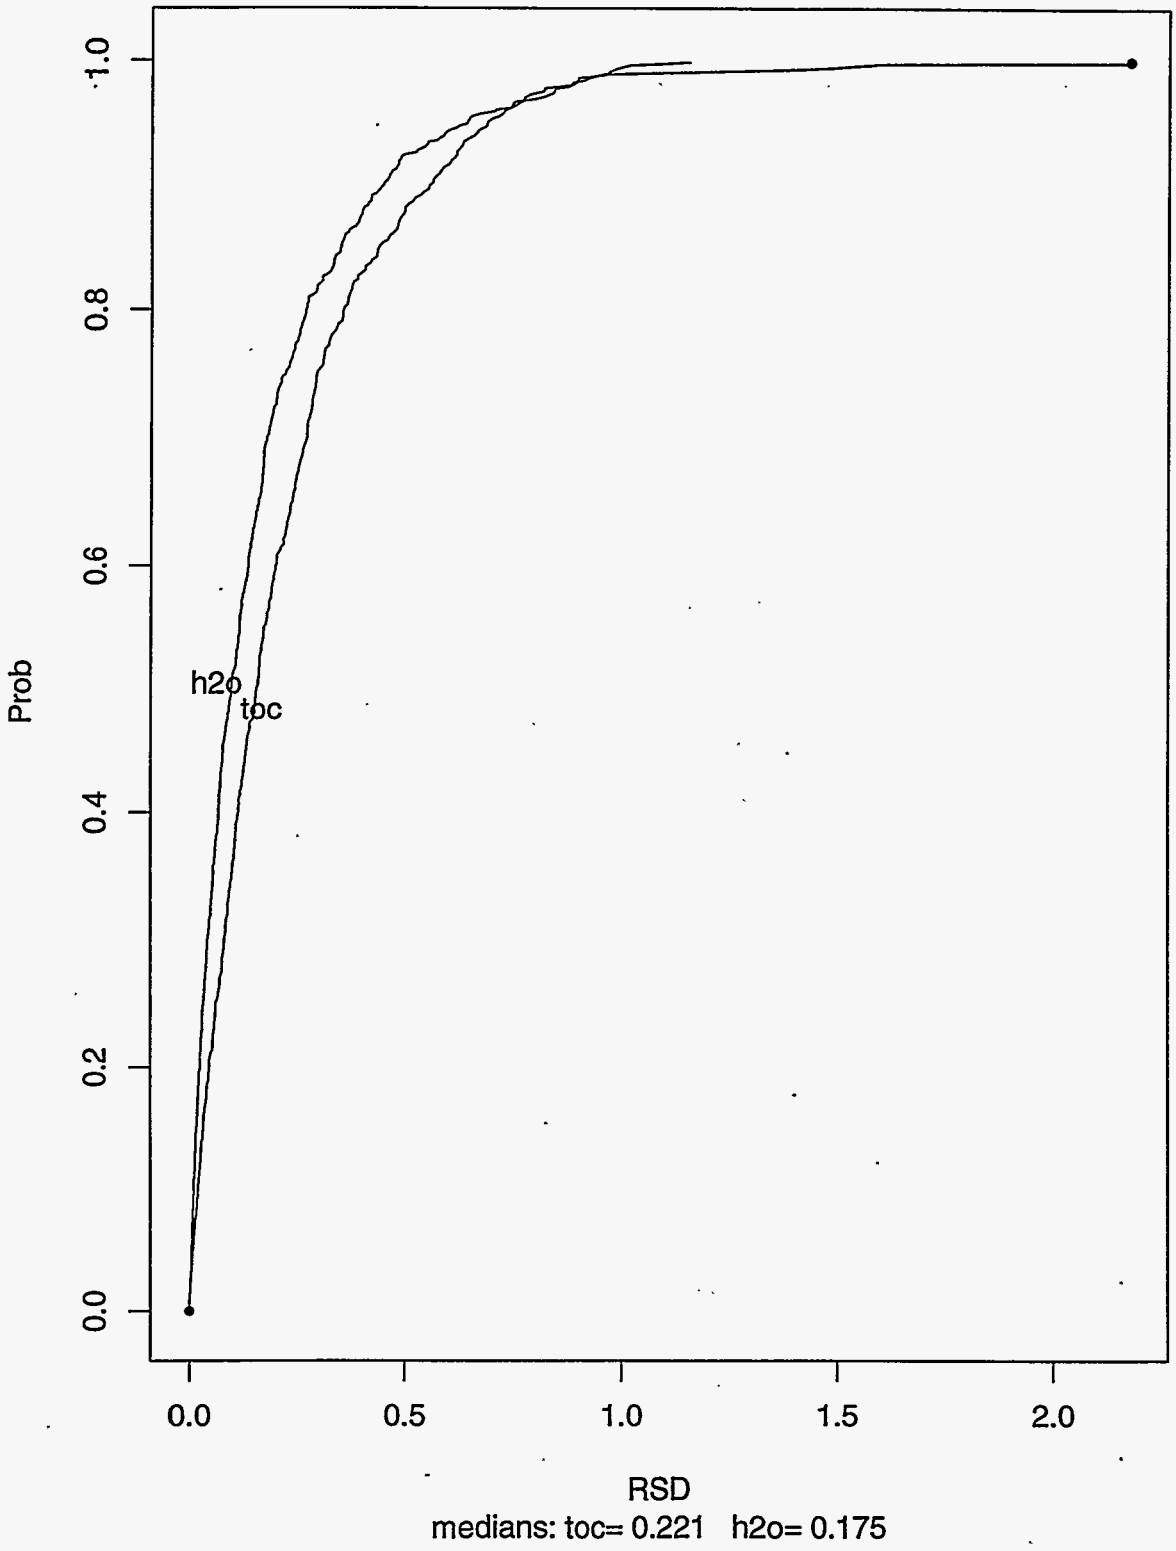

the 5% threshold that might move onto the list of failures with a slight change in data or assumptions.

In previous evaluations, the list of failed tanks has indeed changed as the data changed, with the alterations occurring for "boundary" tanks. Such ambiguities are unavoidable when one is required to use a specific pass/fail threshold.

Table 10 presents the median and upper bounds on the dry CWF's for all relevant tanks. The fractions' upper bounds are compared to the 5% screening threshold and those that are below 5% are marked with a P (Pass), while those above are marked with an F (Fail). Note that no CWF estimates are presented in the table for the "special" tanks.

This screening is a first step in final categorization of the tanks. Tanks that fail this CWF criterion may be judged safe because of other information. One column in the table "grp" also identifies the TOC group that the tank belongs to. The TOC groups are: h=High, m=Medium, l=low, n=NonTOC, and s=Special.

To better understand the results and see if they make intuitive sense, we can plot the dry CWF's against dry-TOC's for all the tanks. Figure 16 is such a plot, and it shows that higher dry-TOC corresponds to higher dry CWF.

We also used a regression analysis to summarize the results. Intuitively we know that higher dry-TOC should result in higher dry CWF; and also higher uncertainty in the estimate of dry-TOC should result in a higher 95% upper bound of dry CWF. We regress the upper 95% bound of dry CWF on the dry-TOC ANOVA mean and uncertainty, and plot the result in Figure 17. This figure shows a good regression relationship between dry CWF and the dry-TOC and the predictor variables. This further confirms that the dry CWF results make sense, and we can actually use this regression model to predict the dry CWF in tanks. The prediction is good to a factor of two. The prediction equation is;

$$\text{Dry CWF} = 3.81\hat{\mu}_{toc} + 3.23SD(\hat{\mu}_{toc}) \tag{21}$$

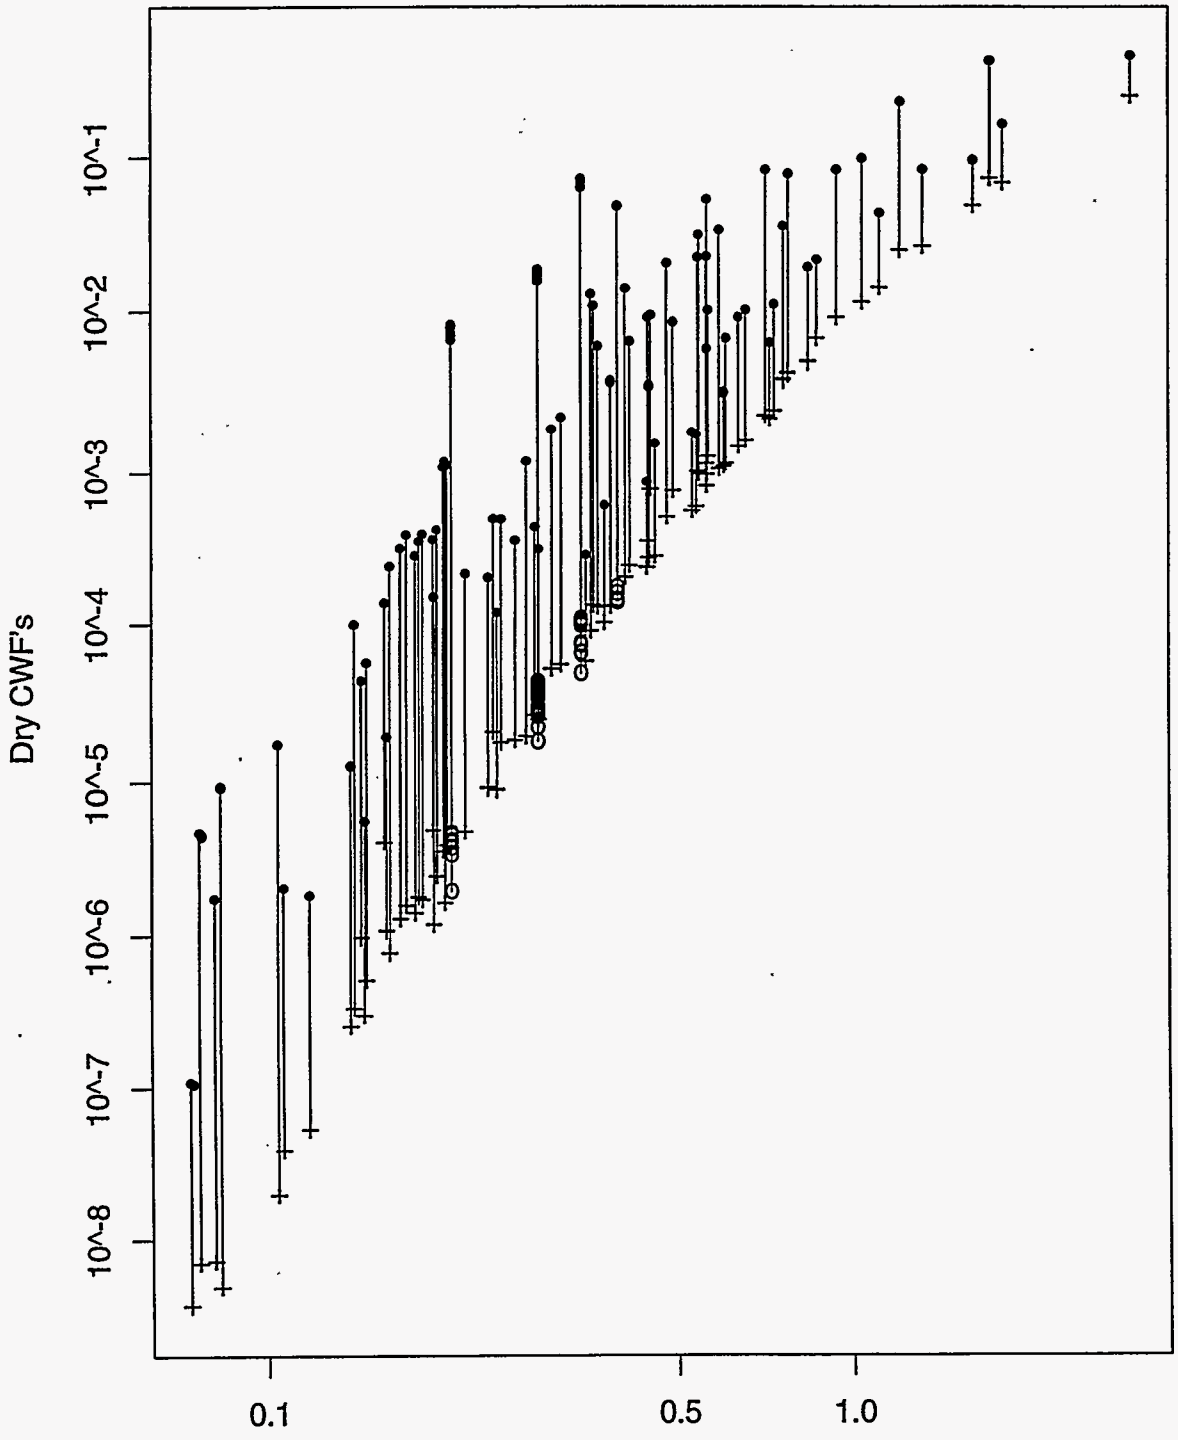

Figure 17: Dry CWF verses Dry-TOC Estimates

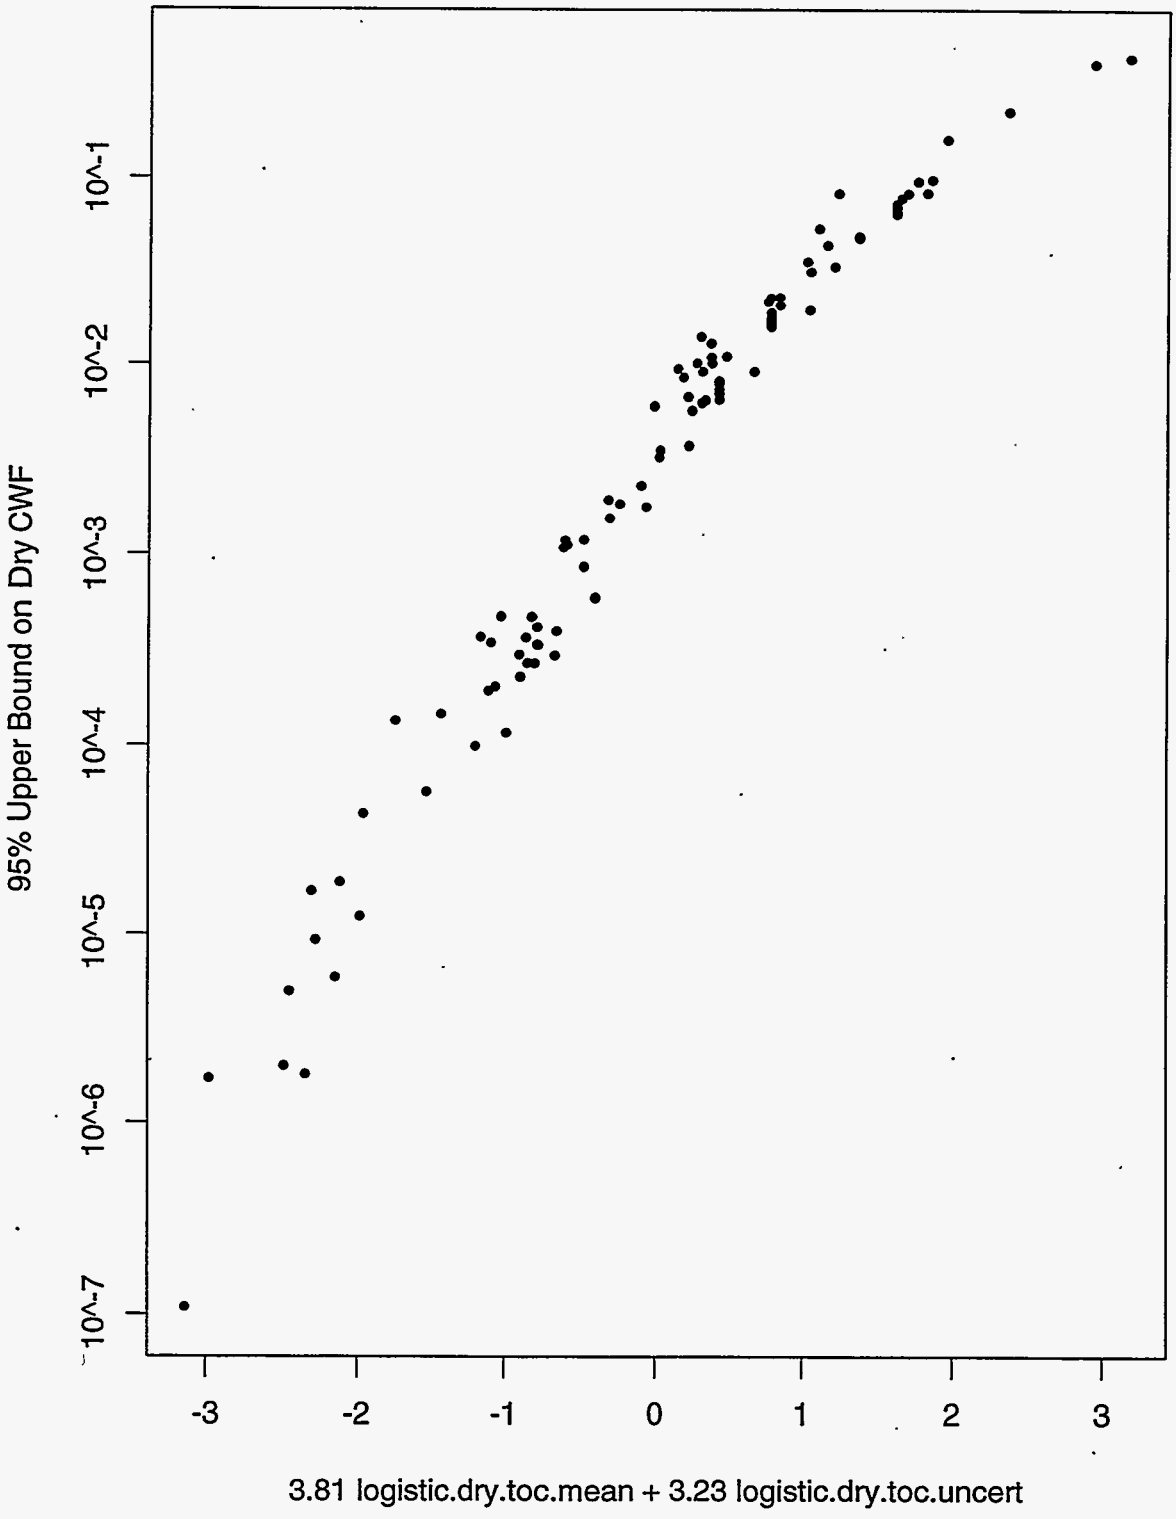


5 Estimation Methodology for Wet CWF

5.1 Quantities to be Estimated

The wet CWF calculation resembles the dry CWF calculation discussed in Section 3. However, some of the steps are complicated by the fact that the definition for combustible waste involves both the amount of TOC and H_2O in the waste. This requires the construction of the joint distribution for (H_2O,TOC) for each tank.

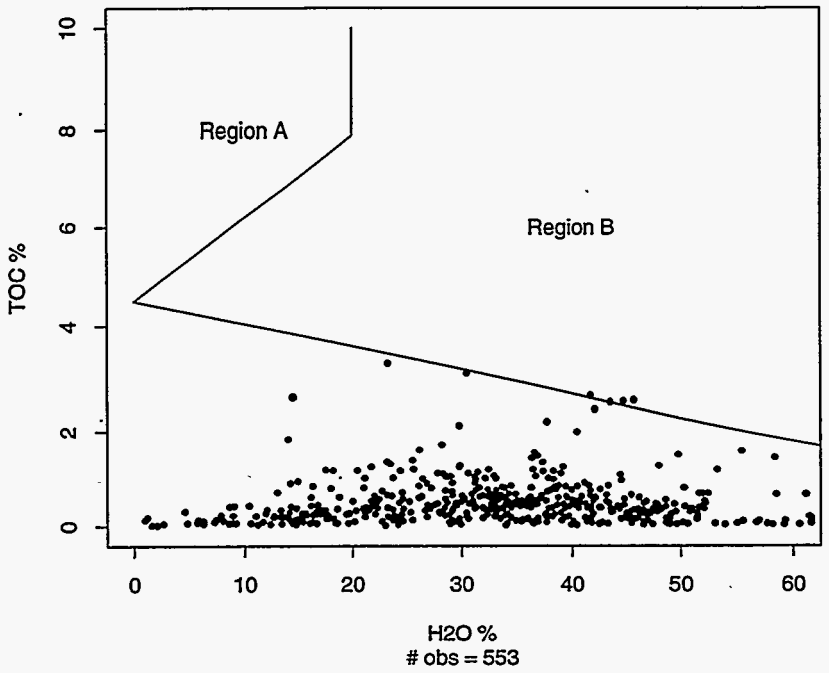
As in the dry CWF calculation, the procedure must produce more than a single point estimate for wet CWF. Bayesian uncertainty distributions are produced to describe how close the the estimate is to the true wet CWF.

The wet combustible waste is defined as waste with (H_2O, TOC) satisfying:

$$TOC > 4.5 + 0.17 \cdot H_2O \ \& \ H_2O < 20 \text{ Wt. } \% \tag{22}$$

We will denote this region in the 2-dimensional space of (H_2O, TOC) as A. Figure 18 illustrates the wet combustible waste region (Region A) as well as the dry combustible waste region ($A + B$) and all the available paired (H_2O, TOC) data from single shell tanks.

Figure 18: Combustible Waste and Data



To estimate the wet CWF for each tank, we must estimate the joint distributions of (H_2O, TOC) for each tank. For the same reasons as discussed in the calculation of dry CWF, a random-effects ANOVA model has been chosen, together with the tank groupings based on

historical information, to estimate this joint distribution. Two ANOVA models, one for H_2O and one for TOC, were fit to H_2O data and TOC data separately. The residuals from the two fits were used to estimate the correlation between H_2O and TOC within a tank, assuming that the correlation between H_2O and TOC is the same for all the tanks. In the ANOVA models, the H_2O or TOC concentrations are assumed to have logistic-normal distributions. Detailed discussion of this assumption of logistic-normal distribution was given in Section 3. The ANOVA procedure, together with the correlation calculation produced an estimated joint distribution of (H_2O, TOC) for each tank. The distribution is a logistic-binormal distribution, i.e., the logistic transformations of H_2O and TOC have a joint normal distribution with ANOVA estimated means and standard deviations, and a common correlation based on residuals of the two ANOVA models.

From the joint distribution of (H_2O, TOC) for each tank, we calculated the wet CWF, R_{wet}, in the tank by integrating the density function of the joint distribution of (H_2O, TOC) over the wet combustible waste region A defined in Equation (22).

As with the dry CWF calculation, this fraction R_{wet} depends on the estimated parameters in the joint distributions while the true parameters are unknown. We use Bayesian uncertainty distributions to assess how close the estimated fraction is to the true one.

The calculations can be summarized in five steps:

1. Perform an ANOVA analysis on H_2O measurements.

2. Perform an ANOVA analysis on TOC measurements.

3. Calculate the correlation between the residuals of the H_2O ANOVA and the TOC ANOVA.

4. The above three steps yield estimated values for all the parameters of the joint distribution of (H_2O, TOC) for each tank. We then calculate the wet CWF for each tank based on this distribution.

5. We finally calculate the Bayesian uncertainty distribution for the wet CWF for each tank to assess how close the estimated fraction is to the true one. The upper 95% quantile on the wet CWF uncertainty distribution is compared to the 5% screening threshold to determine whether or not the tank is currently safe.

5.2 Tank Grouping

For TOC grouping, we used the same groups as used in the dry-TOC calculation. For H_2O grouping, we formed 4 groups according to the waste surface condition (dry or wet) and the predominant waste state (sludge or saltcake). We had 59 tanks in the dry.saltcake group, 40 tanks in the dry.sludge group, 21 tanks in the wet.saltcake group, and 29 tanks in the wet.sludge group. See [14] for more details about these groupings.

5.3 ANOVA Models

The distribution for H_2O or TOC in a tank is assumed to be a logistic-normal distribution. The formula for a logistic transformation is given in Equation (3). For both H_2O and TOC, the minimum bound has been set to $X_{min} = 0$. For H_2O, the maxmum bound has been set to $X_{max} = 100\%$, and for TOC, $X_{max} = 20\%$.

As for the dry-TOC analysis, the ANOVA model for H_2O assumes that (1) the σ_e^2 parameter is the same for all tanks and that (2) the mean, μ, is described by the same random-effect ANOVA formula as in the dry-TOC ANOVA model. The ANOVA model is described by Equation (4). Similar assumptions are made for the TOC ANOVA model. The same procedure is applied here to get the estimated parameters in the H_2O and TOC distributions for each tank.

5.4 Estimation of the Wet Combustible Waste Fraction

We calculate the wet CWF on the surface (top) layer of a tank by:

$$R_{wet.top} = \int_A f_{top}(X_{H_2O}, X_{TOC}) dX_{H_2O} dX_{TOC} \tag{23}$$

where $f_{top}(X_{H_2O}, X_{TOC})$ is the PDF of the joint distribution of (H_2O,TOC) on the top layer.

Similarly, we can calculate wet CWF on the sub-surface (bottom) layer of a tank by:

$$R_{wet.bot} = \int_A f_{bot}(X_{H_2O}, X_{TOC}) dX_{H_2O} dX_{TOC} \tag{24}$$

where $f_{bot}(X_{H_2O}, X_{TOC})$ is the probability density function of (H_2O,TOC) in the sub-surface layer.

Total wet CWF can then be calculated by:

$$R_{wet} = \frac{V_{top}}{V_{top} + V_{bot}} \cdot R_{wet.top} + \frac{V_{bot}}{V_{top} + V_{bot}} \cdot R_{wet.bot} \tag{25}$$

where V_{top} and V_{bot} are waste volumes in top layer and bottom layer for the tank.

As can be seen, R_{wet} depends on the estimated values of parameters μ and σ_e^2. There is substantial uncertainty in such an estimate. We actually desire to calculate the posterior (uncertainty) distribution of R_{wet} for each tank. This is discussed in the next section.

5.5 Calculation of Uncertainty Distributions

The ANOVA estimation method produces approximate posterior distributions for the parameters μ_{ijk} and $\sigma_{ijk}^2 = \sigma_e^2$ for H_2O and TOC, just as it did in the dry calculation. The posterior distributions are approximated by Equation (18). The posterior distributions describe the uncertainty in the parameters μ and σ_e^2 of the (H_2O,TOC) joint distribution. As mentioned earlier, R_{wet} is a function of μ and σ_e^2. Thus we can conceivably get a posterior distribution of R_{wet} that reflects the uncertainty associated with the estimated values of the parameters, through the posterior distribution of (μ, σ_e^2). However, it is not easy to directly

calculate such a posterior distribution of R_{wet}. Therefore, we use Monte Carlo methods to estimate this distribution.

For each layer i ($i = 1$ represents top layer, $i = 2$ represents bottom layer) in tank jk, the Monte Carlo method is carried out in the following steps:

1. Generate 1000 random values of $\sigma^2_{ijk.h2o} = \sigma^2_{e.h2o}$ according to

$$\sigma^2_{e.h2o} \sim \frac{dof \cdot \hat{\sigma}^2_{e.h2o}}{\chi^2_{dof}} \tag{26}$$

   where $\hat{\sigma}^2_{e.h2o}$ is from the H_2O ANOVA fit, dof is the degrees of freedom, and χ^2_{dof} is the χ^2 distribution with degrees of freedom $= dof$.

2. Generate 1000 random values of $\sigma^2_{ijk.toc} = \sigma^2_{e.toc}$ according to

$$\sigma^2_{e.toc} \sim \frac{dof \cdot \hat{\sigma}^2_{e.toc}}{\chi^2_{dof}} \tag{27}$$

   where $\hat{\sigma}^2_{e.toc}$ is from the TOC ANOVA fit, dof is the degrees of freedom, and χ^2_{dof} is the χ^2 distribution with degrees of freedom $= dof$. Note that the dof from the TOC ANOVA fit could be different from the dof from the H_2O ANOVA fit.

3. Generate 1000 random values of $\mu_{ijk.h2o}$ according to

$$\mu_{ijk.h2o} \sim N(\hat{\mu}_{ijk.h2o}, \hat{A}_{ijk.h2o}) \tag{28}$$

   where $\hat{\mu}_{ijk.h2o}$ is the mean and $\hat{A}_{ijk.h2o}$ the covariance from the H_2O ANOVA fit.

4. Generate 1000 random values of $\mu_{ijk.toc}$ according to

$$\mu_{ijk.toc} \sim N(\hat{\mu}_{ijk.toc}, \hat{A}_{ijk.toc}) \tag{29}$$

   where $\hat{\mu}_{ijk.toc}$ and $\hat{A}_{ijk.toc}$ are from the TOC ANOVA fit.

5. Use a Latin hypercube design, i.e. for tank jk, randomly mix up the above σ's and μ's to form 1000 vectors of the form:

$$(\sigma^2_{1jk.h2o}, \sigma^2_{2jk.h2o}, \sigma^2_{1jk.toc}, \sigma^2_{2jk.toc}, \mu_{1jk.h2o}, \mu_{2jk.h2o}, \mu_{1jk.toc}, \mu_{2jk.toc}). \tag{30}$$

   For each such vector, calculate one R_{wet} by formulas (23), (24) and (25). So the result is 1000 values of R_{wet} for each tank jk.

These 1000 values of R_{wet} produce an approximation of the uncertainty distribution of the true R_{wet} for tank jk.

6 Results of the Wet CWF Calculation

6.1 ANOVA Fit to H_2O Data

We summarize the H_2O ANOVA fit results in Table 11. As in the dry-TOC ANOVA analysis, we can calculate the within-group correlation, which measures how well the model predicts H_2O in unsampled tanks. This correlation is 16%, which shows that the moisture grouping isn't very effective. The logistic-mean H_2O for all sampled tanks, μ, is estimated as $\mu = -0.544$, which translates into a concentration of 37%.

Table 11: ANOVA Table For H_2O

Variance Component	ANOVA Estimate	Approx. RSD (%)
σ_D^2	0	0 %
σ_G^2	0.098	31 %
σ_T^2	0.574	76 %
σ_{DG}^2	0.021	14 %
σ_{DT}^2	0.063	25 %
σ_E^2	0.264	51 %

The ANOVA table contains a fairly large tank-to-tank variability of $\sigma_T^2 = 0.57$, while most of the other components are small. It is interesting to note that the terms involving tank layers (σ_D, σ_{DG}, and σ_{DT}) are all small. One would expect to see large differences between surface and sub-surface moisture, which would result in large tank layer variabilities.

Figure 19 presents a QQ plot of the ANOVA residuals verses a standard normal quantiles to check the hypothesis of logistic-normality. These residuals are from logistic-transformed data, so they should be normally distributed if the assumption is correct. The plot has a similar shape to Figure 2, and the discussion concerning Figure 2 in Section 4 is also valid for this plot.

Figure 31 shows the plot of fitted H_2O values verses observed ones. From this plot, it can be seen that the ANOVA estimation procedure produces reasonable results.

As with the dry-TOC ANOVA, we also plot the H_2O ANOVA results in Figures 20 to 30. The H_2O data used in this fit is listed in Appendix A for the reader's reference.

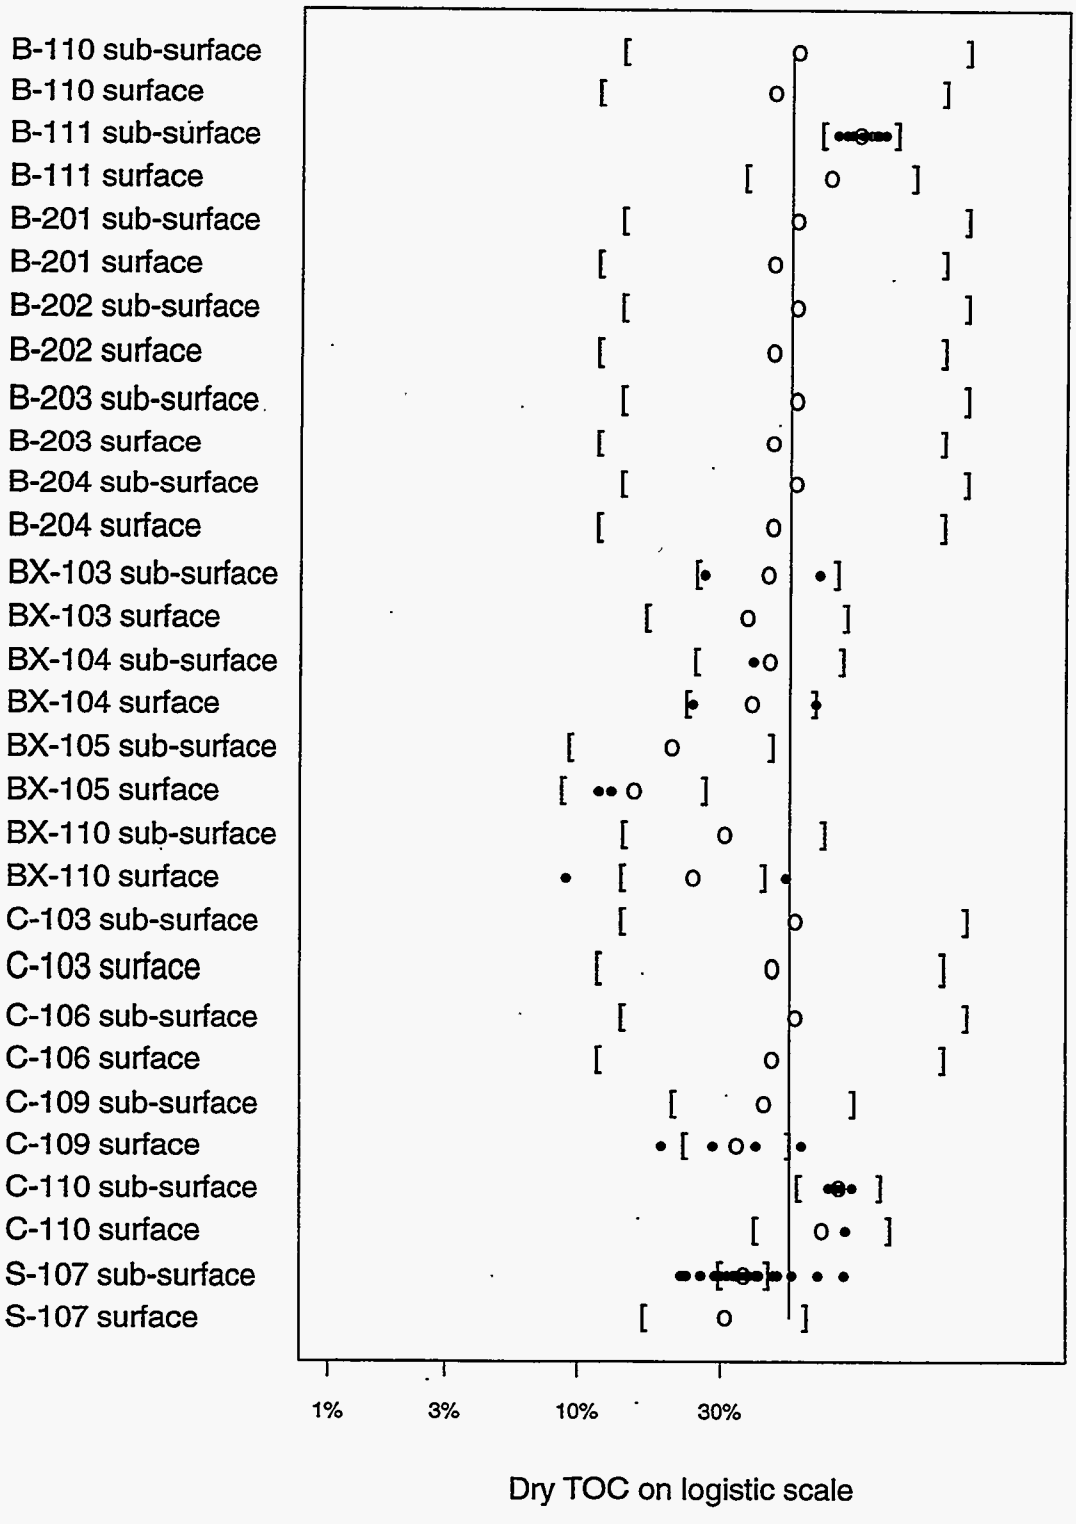

Figure 30: H_2O ANOVA Results: Wet Sludge Group, Tanks T-102 to U-204

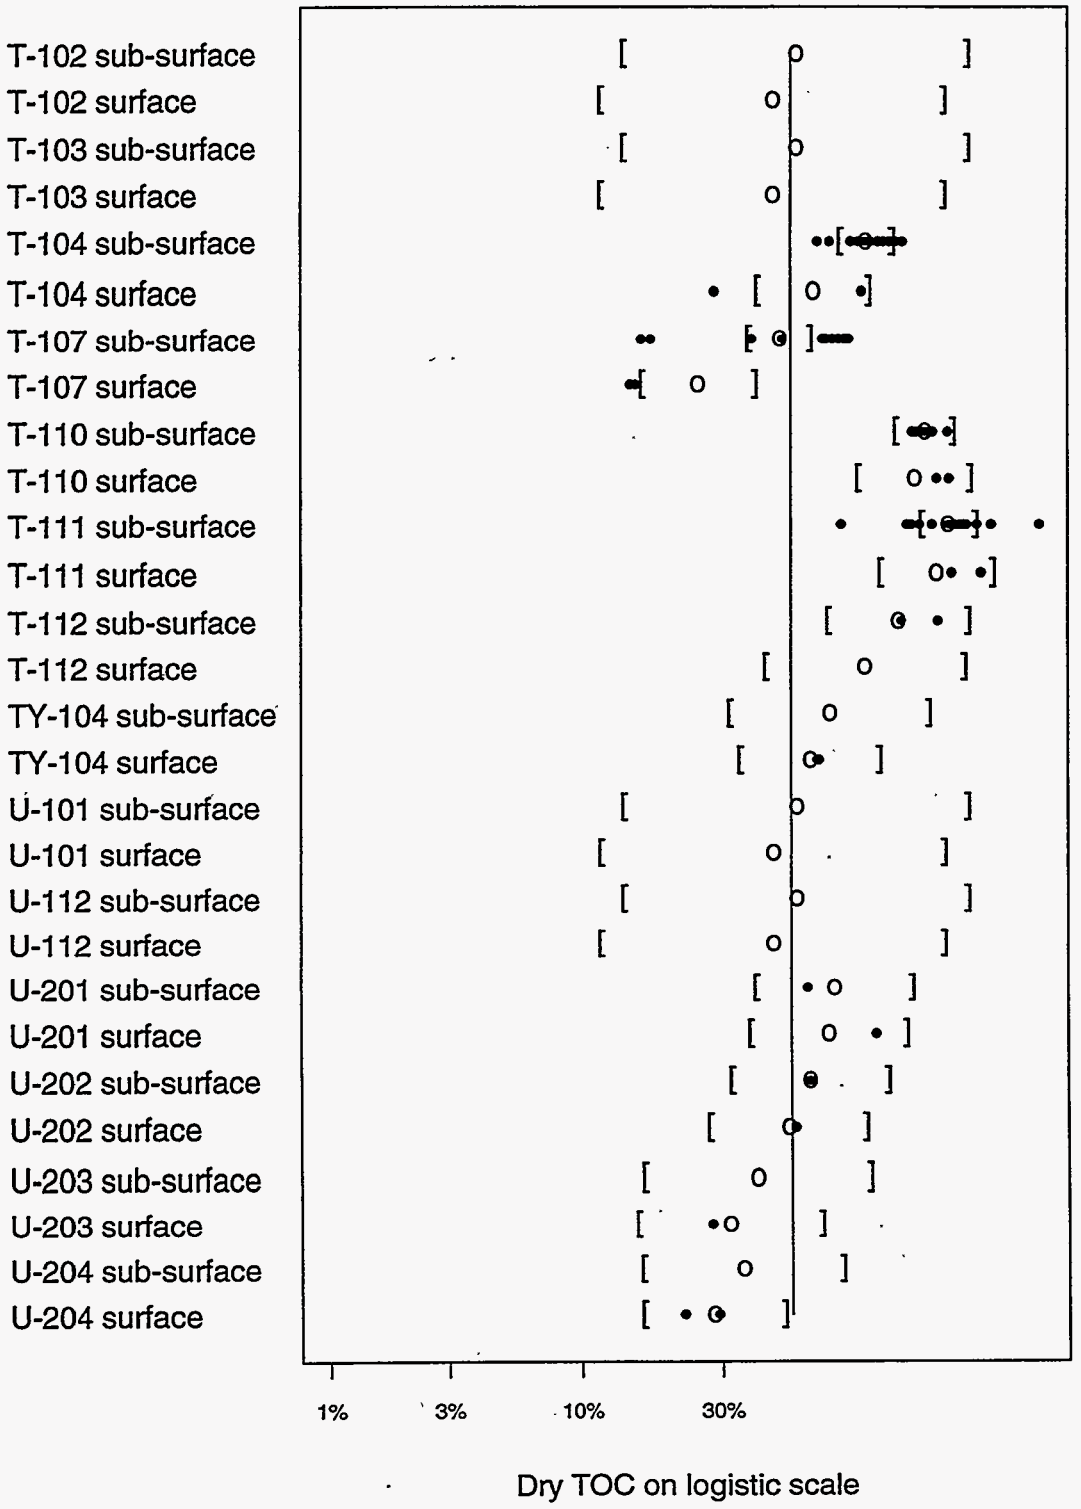

Figure 31: Fitted verses Observed H_2O

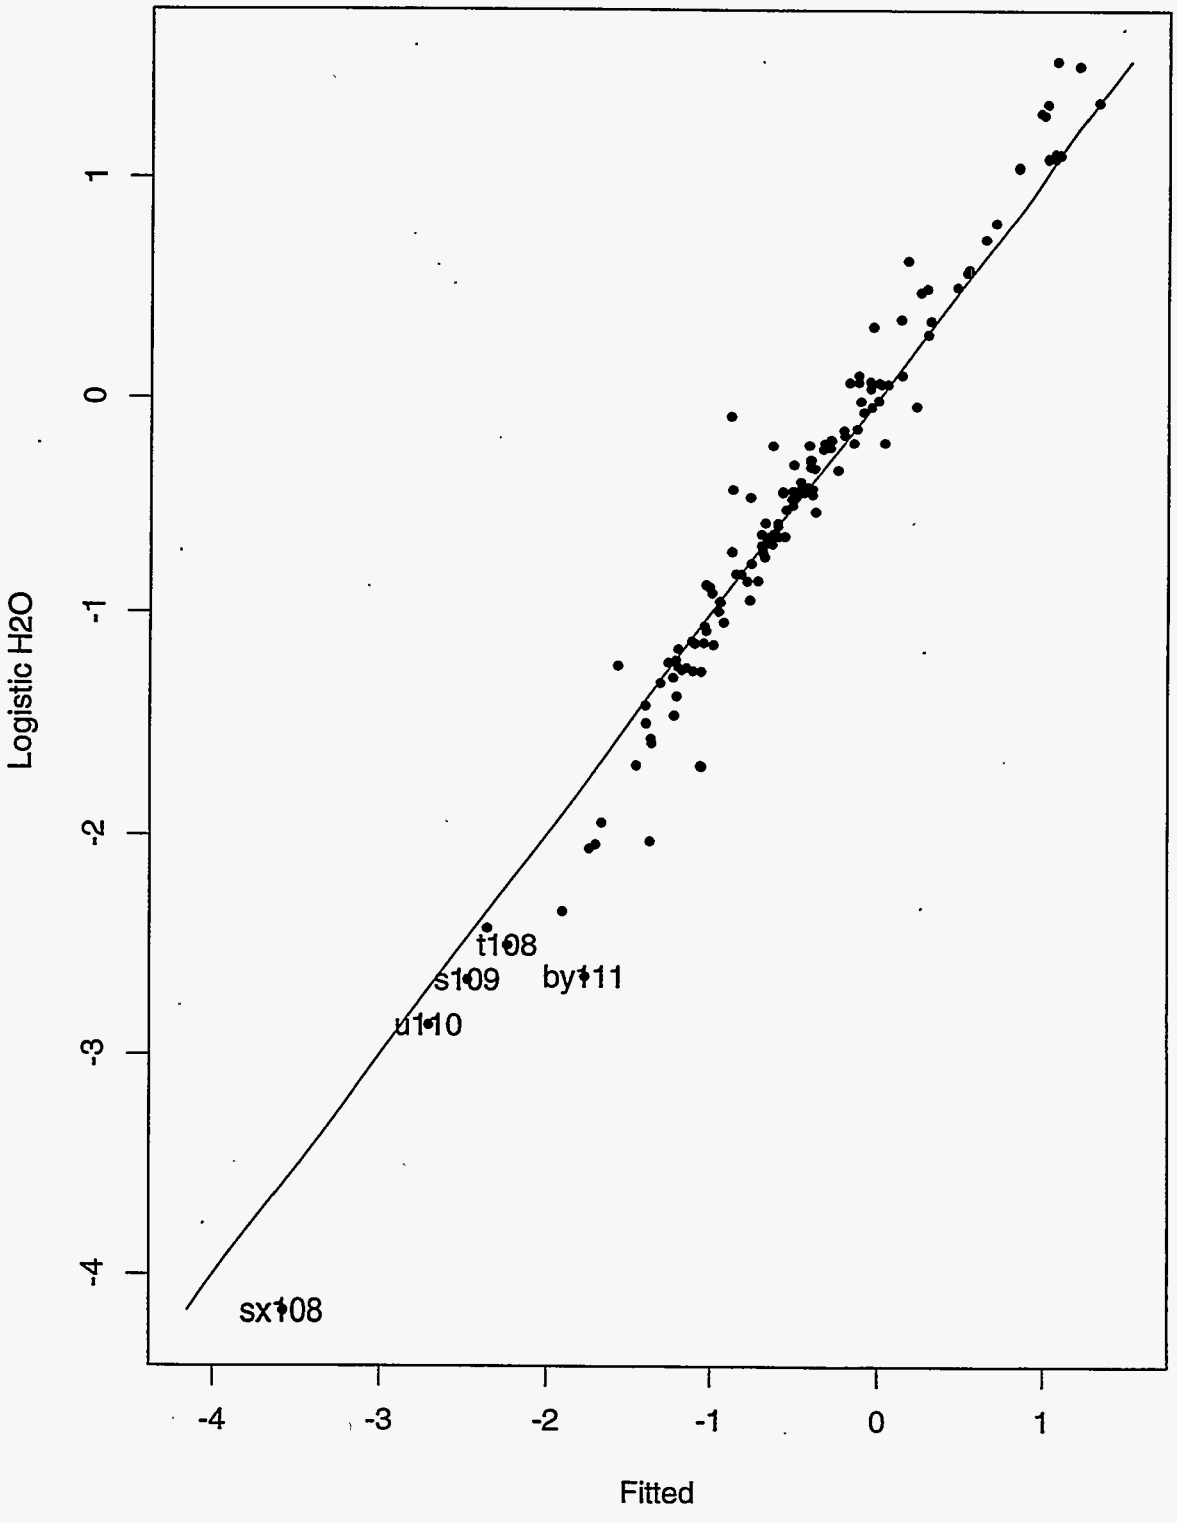

6.2 ANOVA Fit to TOC Data

The TOC ANOVA results are summarized in Table 12. The within-group correlation is 27%, a larger correlation than was achieved for the H_2O fit. The logistic-mean TOC for all sampled tanks, μ, is estimated as $\mu = -4.545$, which translates into a concentration of 0.21%.

Table 12: ANOVA Table For TOC

Variance Component	ANOVA Estimate	Approx. RSD (%)
σ_D^2	0.013	11 %
σ_G^2	0.287	54 %
σ_T^2	0.631	79 %
σ_{DG}^2	0	0 %
σ_{DT}^2	0.193	44 %
σ_E^2	0.445	67 %

The tank-to-tank variability is the largest term in the ANOVA table, as was the case with the other two ANOVA fits presented in this report. Figure 32 presents a QQ plot of the TOC data residuals verses standard normal, that has the same general shape as experienced in the other two ANOVA fits.

As with the dry-TOC and H_2O ANOVA, we also plot the TOC ANOVA results in Figures 33 to 43. Figure 44 shows the plot of fitted TOC values verses observed ones. From this plot, it can be seen that the fit is reasonable.

6.3 Calculation of Wet CWF's

The ANOVA results presented in the last two sections are used to calculate the wet CWF's, as described in Section 5. This section presents the best estimates (medians) for these fractions as well as their upper 95% bounds. They are then used to screen tanks into pass/fail categories. The current screening criterion is that if the upper 95% bound is less than 5%, then the tank is considered to pass, otherwise it is considered to fail.

As discussed in Section 4, we subtract 10% RSD from the ANOVA estimated $\hat{\sigma}_e$ to get the estimated within-layer spatial variability.

To see what the ANOVA estimates mean with respect to wet combustible waste, we plot the H_2O and TOC ANOVA results on the top and bottom layers in (H_2O, TOC) space in Figures 45 and 46. In the plots, the upper-left region is the wet combustible waste region. The open circles are the best estimates of (H_2O, TOC) for each tank from the ANOVA's. The solid dots are the worst 95% bounds of the ANOVA estimates of (H_2O, TOC) that reflect the uncertainties associated with the estimates. The worst 95% bound means the point in the (H_2O, TOC) space where H_2O takes the lower 95% bound of the best estimate, and TOC takes the upper 95% bound of the best estimate. Although all the worst 95% bounds are outside the wet combustible waste region, this does not mean that all tanks are safe. These bounds only reflect the locations of the means of the (H_2O, TOC) joint distributions which describe the spatial variability of (H_2O, TOC) in the waste. There is a substantial amount of spatial variance in the waste. The spatial variance is quantified by σ_e^2 and ρ which are obtained from the ANOVA results. Integrating the joint (H_2O, TOC) distribution over the wet combustible waste region will give us the fraction of wet combustible waste in the tank.

Table 13 presents the medians and upper bounds on the wet CWF's for all relevant tanks. The fractions are compared to the 5% screening threshold and those that are below 5% are marked with a P (Pass), while those above are marked with an F (Fail). As one can see, no tanks failed this screening. In the table, the column "grp" identifies the H_2O/TOC group the tank belongs to. The H_2O groups are: 1=dry.saltcake, 2=dry.sludge, 3=wet.saltcake, and 4=wet.sludge. The TOC groups are: h=High, m=Medium, l=Low, n=NonTOC, and s=Special.

As with the dry CWF calculations, we plot the wet CWF's against TOC and H_2O in Figures 47 and 48. These figures show the relationships between wet CWF and TOC, and wet CWF and H_2O. The plots show that higher TOC corresponds to higher wet CWF, while higher H_2O does not have a strong effect on wet CWF.

As with the dry CWF calculations, we can also use a regression analysis to summarize our results. Intuitively we know that higher TOC and/or lower H_2O should result in higher wet CWF, and higher uncertainties in the estimate of TOC and/or H_2O should result in higher 95% upper bounds on wet CWF. The upper 95% bound of wet CWF was regressed on the TOC and H_2O ANOVA means and uncertainties, and the result was plotted in Figure 49. This figure shows a good regression relationship between wet CWF and the TOC and H_2O ANOVA estimated means and their associated uncertainties. The prediction equation produced by the regression was;

$$\text{Wet CWF} = 4.48\hat{\mu}_{toc} - 3.79\hat{\mu}_{h2o} + 3.1SD(\hat{\mu}_{toc}) + 3.1SD(\hat{\mu}_{h2o}) \qquad (31)$$

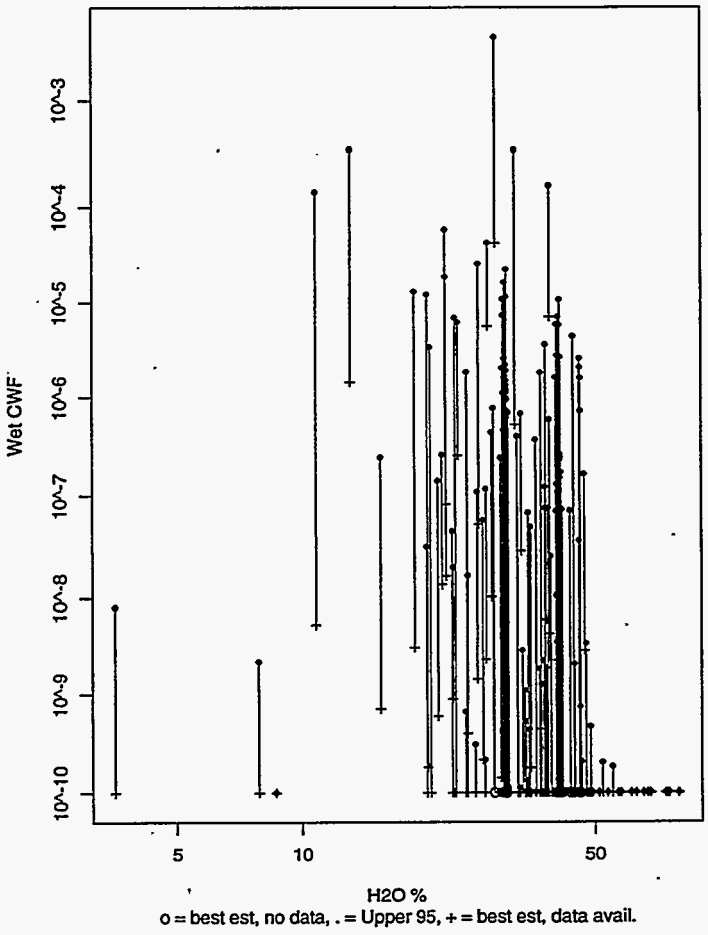

Figure 49: Wet CWF verses H_2O and TOC Estimates

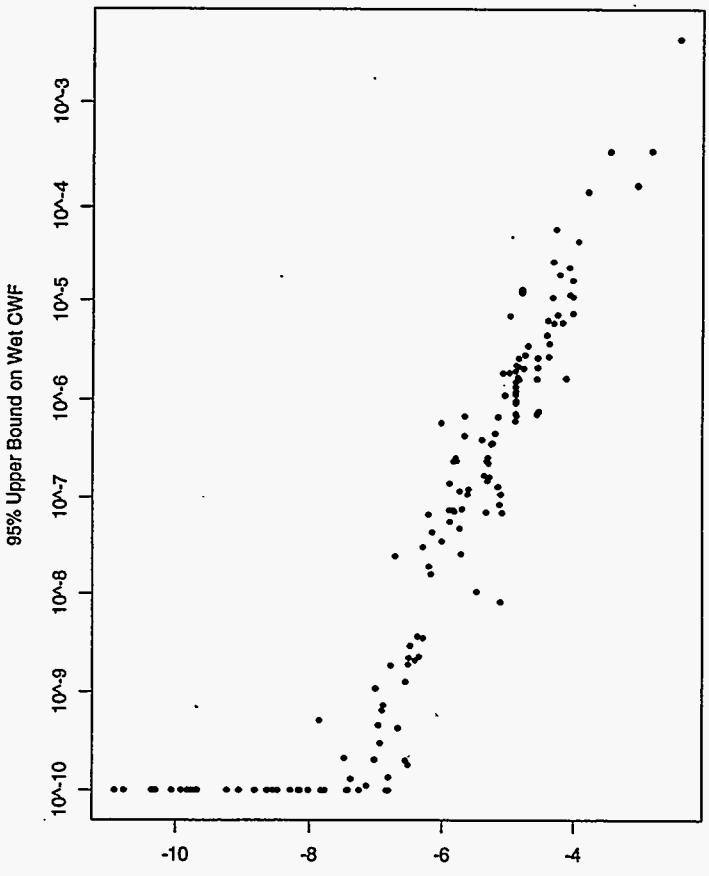

7 Validation of the Dry ANOVA Model

The ANOVA modeling results presented previously in this report should produce reasonable predictions of dry-TOC in unsampled tanks. "Reasonable" in this context means that the predictions and actual values agree within the limits of uncertainty produced by the ANOVA model. In this section, a validation test for the predictive capabilities of this model is discussed and applied.

Data from six recently sampled tanks are compared to the predictions made by the ANOVA model. To make a fair comparison, the ANOVA model was run without the data from these six tanks and these model predictions were then compared to the available data. The tanks used for this validation are AX-103, BX-103, BX-104, BY-109, S-106, and S-110. In table 14, the ANOVA estimates (on the logistic scale) for these tanks are given with the logistic averages obtained from sample data.

7.1 A Chi-Squared Validation Test

In mathematical terms, the ANOVA produced predictions $\hat{\mu}_{ij}$ for each layer j in each of the i tanks listed above, as well as the associated standard errors S_{ij}. The sampling data that is available can be averaged together (on the logistic scale) to form data-derived estimates for each of the layers, which we denote by X_{ij}. Each of these averages will have a standard error given by:

$$Stderr(X_{ij}) = \sigma_e/\sqrt{N_{ij}} \tag{32}$$

where N_{ij} represents the number of sample measurements averaged together to produce X_{ij} and σ_e is the within-layer standard deviation produced by the ANOVA ($\sigma_e^2 = 0.531$).

The most standard test for X_{ij} versus $\hat{\mu}_{ij}$ uses a Chi-squared statistic that compares the distance between the predictions and data to their standard errors. This statistic has the form:

$$\chi^2 = \sum_{i,j} \frac{(X_{ij} - \hat{\mu}_{ij})^2}{S_{ij}^2 + \sigma_e^2/N_{ij}} \tag{33}$$

If the two sets of estimates are the same, we would expect this statistic to have a Chi-squared distribution. On the other hand, if there are significant differences between the ANOVA predictions and the data-derived estimates, the statistic will be much larger than a chi-squared variate.

7.2 Prediction Interval Test

The Chi-squared statistic compares all the predictions with the data-derived estimates in one calculation. One may also desire to check each prediction individually. To accomplish this, we can use the ANOVA estimates to produce a 95% prediction interval for X_{ij}. This prediction interval is given by;

$$\hat{\mu}_{ij} \pm 1.96\sqrt{S_{ij}^2 + \sigma_e^2/N_{ij}} \tag{34}$$

When X_{ij} falls within this interval, the ANOVA prediction can be considered a success; if not, it is suspect. Since these are 95% prediction intervals, one would expect about 5% of the prediction intervals to fail, even when there is nothing wrong with the model, so it would not be unusual to see one or two failures among 20 prediction intervals. However, more than three prediction interval failures would be considered significant.

Table 14: Comparison of ANOVA Predictions to Data

# of	ANOVA Pred.		Data Results			Prediction Test

Chi-Squared Value=13.2 DOF=10 P-value=0.213

7.3 Test Results

Table 14 presents the comparisons for the designated tanks. Available data allows one to compare 10 ANOVA estimates to data. For example, the ANOVA estimate for the top layer in AX-103 is -3.508 (0.6% TOC), while the sample data produces an estimate of -3.023 (0.9% TOC), a fairly close agreement. The test statistic column in the table describes how many standard deviations separate the two estimates from each other (i.e. $-3.508 + 3.023)/0.944 = -0.514$). If the two estimates are more than 1.96 standard deviations from each other, one would conclude that the ANOVA estimate does not fit the data. For the example, we see that the test statistic (-0.514) shows that AX-103's ANOVA estimate and data are in good agreement.

An examination of the last column in Table 14 shows that all the individual TOC test statistics have a magnitude less than 1.96, except for tank BY-109 (surface). This tank is in the low TOC tank group and has measured values that are atypically high for this group. The ANOVA estimates, which are basically the group means, are -4.300 (0.27% TOC) while the data-derived estimate is 2.5% TOC, a very large difference.

Even including the tank that does not fit, the over-all Chi-squared test (with a value of 13.2) is not significant at the 5% level. The P-value for the test is 21%, which indicates good agreement between ANOVA predictions and sampling data.

8 Conclusions

The CWF estimates calculated by the methodology described in this report produce the following classification for Hanford single shell tanks:

- Number of unsafe tanks: 0 (Unsafe means the 95% bound on wet CWF is above 5%).
- Number of conditionally safe tanks: 11 (Conditionally safe means the 95% bound on wet CWF is below 5%, but the dry CWF bound is above 5%).
- Number of safe tanks: 127 (Safe means that both the dry and wet 95% CWF bounds are below 5%.
- And 11 special tanks have not been screened, producing a total of 138 tanks screened.

Figure 50: Tank Farm Overview

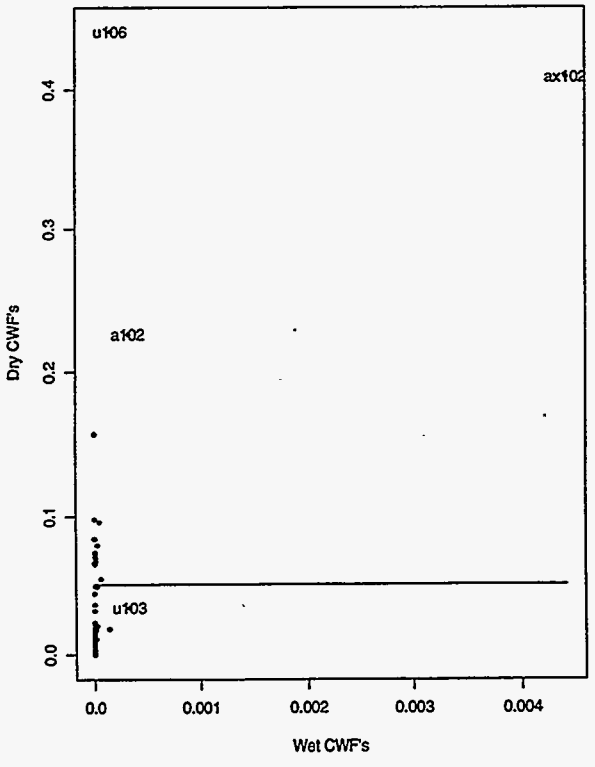

Figure 50 plots all dry CWF bounds verses wet CWF bounds to produce a graphical representation of the screening results. The points above the horizontal 5% line represent the conditionally safe tanks. A vertical line at 5% would demarcate conditionally safe tanks from unsafe tanks. However, because the wet CWF's are so small, this line is not shown on the plot. In fact, the tank with the largest wet CWF is AX-102, and it has a CWF of

0.4%, a value far removed from the 5% threshold. As one can see, the estimates show that all evaluated tanks are currently safe.

The 11 tanks that these calculations have identified as conditionally safe are of most interest. These tanks are those that may be unsafe after dry-out, and as a next step in an evaluation (which is a topic dealt with in [14]), one would want to determine if more detailed information could eliminate any of these tanks from the conditionally safe category.

Using the results in Table 9 and Figure 50, one can predict what effect additional data might have on these 11 tanks. In Figure 50, the conditionally safe tanks can be roughly divided into two groups; Those near the 5% threshold and those far away from it. There are four tanks (U-106, AX-102, A-102, and C-104) that are "far away" from the 5% threshold, with the remaining 7 tanks (A-103, U-105, T-111, U-111, A-106, C-105, and BY-103) near (within a factor of two) to the 5% threshold.

One can generally say that the reason that the tanks near the 5% threshold exceed the 5% threshold is because the CWF is not estimated accurately enough. The "best estimates" for these seven tanks are all below 5%, suggesting that if more data were taken their 95% bounds would eventually approach a value below the 5% threshold and they would become safe.

On the other hand, the four tanks that are "far away" from the 5% threshold do not generally share this property. The best (median) estimate for wet CWF for U-106 is 24.5%, that of AX-102 is 7.3%, that of A-102 is 2.5%, and that of C-104 is 6.8%. Except for A-102, all best estimates for tanks in this group are above the 5% threshold. This suggests that more data would not alter the conditionally safe categorizations of three of these tanks.

It is important to note that none of the conditionally safe tanks are unsampled tanks (see Table 9). Previous estimates of CWF have produced unsampled tanks that were classified as conditionally safe. In the past two years all unsampled tanks that this model has categorized as conditionally safe have been sampled.

APPENDIX A Summary of (H_2O,TOC) Data and CWF Results by Tanks

The results for each tank are summarized in this appendix, which displays the (1) raw data, (2) the location averages for TOC and H_2O, (3) the ANOVA model results, and finally (4) the CWF uncertainty distributions.

The "Tank Statistics" portion of the summary gives all the values from the ANOVA that are used to calculate reactive waste distributions. This portion also includes a few other miscellaneous values relevant to the calculation. Here is a detailed description of all the statistics that appear;

wet.waste.vol Total waste volume in cubic meters under the current wet condition.

wet.vol.top Waste volume in cubic meters of the surface layer under the current wet condition.

wet.vol.bot Waste volume in cubic meters of the sub-surface layer under the current wet condition.

dry.waste.vol Total waste volume in cubic meters under the dried-out condition.

dry.vol.top Waste volume in cubic meters of surface under the dried-out condition.

dry.vol.bot Waste volume in cubic meters of sub-surface under the dried-out condition.

tank.dia Tank diameter in meters.

rho Correlation between H2O and TOC on the logistic scale.

h2o.mu.top, h2o.mu.bot Logistic means of moisture in the top and sub-surface (bottom) waste layers, units are Logistic(percent-conc).

h2o.sterr.top, h2o.sterr.bot Uncertainties, in the form of a standard deviation, for the two previous mean estimates.

h2o.sigma within layer variability, on the logistic scale, expressed as a standard deviation.

h2o.dof The degrees of freedom associated with h2o.sigma; This defines its uncertainty.

toc stats: toc.mu.top, toc.mu.bot, toc.sterr.top toc.sterr.bot toc.sigma toc.dof; same as the previous statistics, except for TOC. Units are logistic(percent-conc.).

h2o.nobs, h2o.mu Number of H2O data points in the tank, and mean of $\log_{10}(H_2O)$.

toc.nobs, toc.mu Same as the previous statistics, except for TOC.

rw.h2o.mu Best estimates for moisture and TOC in the combustible waste in the tank. Units are %.

h2o.grp Grouping information.

dry.mu.top to dry.nobs Statistics for the dry-TOC ANOVA. These statistics have the same definitions as listed above for the H_2O ANOVA.

toc.mu.top to toc.grp Statistics for the TOC ANOVA. These statistics have the same definitions as listed above for the H_2O ANOVA.

The "Combustible Waste Fractions" portion of the summary gives the percentiles that describe the probability distribution of fraction of combustible waste under the current (Cur) condition and under the dried-out (Dry) condition. This probability distribution describes the uncertainties in the estimates. The 95% bounds on the CWF that are used for screening are listed under the 95% heading in this table.

The definition of combustible waste under wet conditions is given by:

$$TOC > 4.5 + 0.17 \cdot H_2O \ \& \ H_2O < 20 \text{ Wt. } \% \qquad \text{(A–1)}$$

while the definition under dry conditions is:

$$\text{dry-TOC} > 4.5\% \qquad \text{(A–2)}$$

The "Data From Tank" portion contains the data used in the analysis. The fields are:

lab.id Sample id assigned by the lab that did the analysis. This id is reported in TCR's and Lab reports.

ris Riser id.

seg Segment of a core sample. It ranges from 1 to 23, 1 being the top segment. Segment number 99 indicates a data quality problem. Segment number 999 indicates a core composite. Auger and grab samples were assigned 1 as segment number.

repl Indicates whether the result is a primary result (1), a duplicate (2) or a triplicate (3).

date date of sampling.

layer supernate (super), surface (surfa) or sub-surface (sub-s).

h2o H2O in weight %.

toc TOC in weight %.

drytoc Average dry TOC in weight % for the location.

logh2o Average H_2O for the location on the logistic scale.

logtoc Average TOC for the location on the logistic scale.

lgtdry Average dry-TOC for the location on the logistic scale.

The "Data From Tank" portion of the summary is organized by location, which is defined as riser×segment. Data from the same location are grouped into one block, at the bottom of which are the averages of H_2O and TOC of the block. These the logistic transforms of these averages were used as input to the ANOVA's. Unused data records are listed at the end of the data summary for each tank.

APPENDIX B Dry-TOC Plots for Each Tank

This section contains dry combustible waste distribution plots for each tank. The points on the plot represent data points, and these are formed into an empirical complementary cumulative distribution function. The curves on the plot represent the distributions calculated from the ANOVA statistics. Two curves are on each plot, because we distinguish between surface and sub-surface waste. The combustible waste fractions are labeled as "RW fractions," (Reactive Waste fractions) on these plots.

The vertical line represents the combustion threshold (4.5% for dry-TOC). Waste above this threshold should be combustible. Two points are identified on this line. The "best" estimate of combustible waste fraction, and the 95% bound on this fraction. On some of the plots these estimates are very small and cannot be plotted.
