ABSTRACT

General Atomics is developing manufacturing methods for vanadium alloys as part of a program to encourage the development of low activation alloys for fusion use. The culmination of the program is the fabrication and installation of a vanadium alloy structure in the DIII-D tokamak as part of the Radiative Divertor modification. Water-cooled vanadium alloy components will comprise a portion of the new upper divertor structure. The first step, procuring the material for this program has been completed. The largest heat of vanadium alloy made to date, 1200 kg of V-4Cr-4Ti, has been produced and is being converted into various product forms. Results of many tests on the material during the manufacturing process are reported. Research into potential fabrication methods has been and continues to be performed along with the assessment of manufacturing processes particularly in the area of joining.

Joining of vanadium alloys has been identified as the most critical fabrication issue for their use in the Radiative Divertor Program. Joining processes under evaluation include resistance seam, electrodischarge (stud), friction and electron beam welding. Results of welding tests are reported. Metallography and mechanical tests are used to evaluate the weld samples. The need for a protective atmosphere during different welding processes is also being determined.

General Atomics has also designed, manufactured, and will be testing a helium-cooled, high heat flux component to assess the use of helium cooled vanadium alloy components for advanced tokamak systems. The component is made from vanadium alloy tubing, machined to enhance the heat transfer characteristics, and joined to

end flanges to allow connection to the helium supply. Results are reported.

I. INTRODUCTION

To realize the environmental benefits of fusion energy, low activation materials must be utilized. The development of these materials has been proceeding in the U.S. and throughout the world. In the U.S., the primary work has been performed under the auspices of the Materials Program of the Department of Energy's Office of Fusion Energy Sciences from which vanadium alloys have been identified as the leading fusion structural material based on their high temperature capability and irradiation performance (stability). While vanadium is a fairly common element, it is primarily used as an alloying element in steels. Outside the fusion program, uses of vanadium alloys' unique characteristics have not been identified and thus development of the alloys has proceeded only within the fusion program. The production and fabrication of vanadium alloys has been primarily limited to small research heats to study alloy composition and irradiation stability with no development of components. The largest heat of vanadium alloy produced in the U.S. before the present effort was 500 kg with all others well below 100 kg. To date, no significant components have been made from vanadium alloys although some pure vanadium components were made as part of the nuclear weapons programs.

II. UTILIZATION OF VANADIUM IN DIII-D

To enhance the development of low activation alloys for fusion applications, General Atomics, along with Argonne National Laboratory (ANL) and Oak Ridge National Laboratory (ORNL), has written and is

implementing a plan for the utilization of vanadium alloys in the DIII-D tokamak. This plan will culminate in the fabrication, installation, and operation of a vanadium alloy structure as part of the DIII-D Radiative Divertor Program (RDP) (Fig. 1). The use of vanadium in DIII-D provides a meaningful step towards advancing development of low activation materials for fusion power applications by 1) demonstrating the in-service behavior of a vanadium alloy in a typical tokamak environment, and 2) developing knowledge and experience on design, processing, and fabrication of full-scale vanadium alloy components.

The program consists of three phases: (1) expose small vanadium alloy specimens and coupons in DIII-D; (2) design, manufacture and test a small vanadium alloy component in conjunction with the existing DIII-D divertor; and (3) design, manufacture, and install the structure for the private flux baffle of the new double-null, slotted divertor from vanadium alloy. A major portion of the program supports fabrication of the material and product forms, and development of welding processes to complete the manufacture of the components. The plan is being carried out in conjunction with General Atomics, the DIII-D Program, and the Materials Program of the Department of Energy's Office of Fusion Energy, primarily ANL, ORNL and Pacific Northwest National Laboratory (PNNL).

A. Phase 1: Specimen And Coupon Exposures And Analysis

In March of 1995, miniature Charpy V-notch (CVN) impact and tensile specimens of vanadium alloy were installed in DIII-D in positions behind the divertor baffle, away from energetic particles, for long-term exposure (~1 year). ANL supplied the samples, and General Atomics designed, fabricated and installed the sample holder. The environment was monitored and these samples were removed after nine months having been exposed to typical tokamak operations. General Atomics has collated the environmental data that will be used to provide a preliminary assessment of the behavior of the alloy in the tokamak environment. ANL is performing an evaluation of the specimens. During the January 1996 vent, a second set of CVN and tensile specimens were installed in DIII-D and exposure will continue until the next vent.

In parallel, other vanadium alloy samples were exposed utilizing the DIII-D Divertor Material Exposure System (DiMES), which allows for short term exposure and does not require a vent to retrieve the samples. A post-vent bake cycle represents what is expected to be the most severe environmental condition. Therefore, a vanadium alloy disc was exposed during the initial baking and

Fig. 1. Location of vanadium structure in radiative divertor.

cleaning of DIII-D after the February 1995 vent. The disc is currently being analyzed at ANL to determine the pickup of any impurities. Additional exposure of five miniature CVN specimens to a similar baking cycle was performed in July 1995, and evaluation is occurring at ANL. Other DiMES exposures are planned to evaluate the specific effects of other DIII-D environmental conditions such as discharge cleaning and boronization.

B. Phase 2: Small Component Exposure

A second step in the DIII-D Vanadium Plan is to install a small vanadium alloy component in DIII-D. This component will be manufactured utilizing many of the methods proposed for the Phase 3 water-cooled structural panels. The component will be installed, exposed for some period of tokamak operations, and removed. Samples from the component will be excised and metallurgical analyses and property measurements will be made.

C. Phase 3: Radiative Divertor Program

The design, manufacture, and installation of a vanadium private flux baffle structure for the upper divertor of the RDP will be done as the third phase of the vanadium alloy program. The vanadium alloy structure consists of toroidally-continuous, water-cooled structural panels with graphite tiles mechanically attached to make the plasma facing surface. The panels will be water cooled during tokamak operations, experiencing a maximum temperature of ~60°C, but during baking of the vacuum vessel, hot air will replace the water in the structure and it will be baked to 400°C. Due to the lower electrical resistivity of the V-4Cr-4Ti alloy compared to the Inconel 625 components, the toroidal current flow during plasma disruption will be approximately 4 times larger than in other RDP components. The design of the panels and supports will be modified to react the larger loads.

Each panel will be made in six segments, fabricated by welding two 4.8 mm sheets creating an internal coolant channel. Resistance seam welding will provide the strength for the panels while a perimeter electron beam weld would make the vacuum seal. Other methods of joining are proposed for different areas of the design. To facilitate installation, bi-metallic tube joints are planned so that all field welds will be Inconel to Inconel.

III. PRODUCTION OF VANADIUM ALLOY

A heat of vanadium alloy is required for the fabrication of the RDP project. In preparation for the production, a detailed material specification was written for V-4Cr-4Ti alloy from the starting material all the way to completion of product forms. The alloy V-4Cr-4Ti is presently selected by the U.S. fusion materials program. The specification outlined the production steps along with control and quality tests required. This specification was written by General Atomics with assistance from Teledyne Wah Chang Albany (TWCA), ANL and ORNL. Goals for the levels of impurities were specified, with a focus on keeping the levels of potentially embrittling elements (O, N, C, etc.) low. Consideration was also given to minimizing the levels of Nb, Mo, Ag. In the future low levels of these elements will be required to achieve low activation properties for the material. Processing started in September of 1995 with the selection of raw vanadium derbies to be electron beam melted into two pure vanadium ingots. Two ingots were electron beam melted; one (900 kg) and the other (~1000 kg). Samples were taken from the two ingots for chemical analysis and for rolling by ORNL into sheet and machining into Charpy V-notch (CVN) specimens by ANL. Impact testing at -196°C was performed to evaluate ductility. The data agreed reasonably with test results for the raw material used for the 500 kg V-4Cr-4Ti alloy ingot.

The entire 900 kg ingot was chipped and blended with 400 kg of the second ingot to produce approximately 1200 kg of vanadium alloy. The consolidation of the vanadium along with high purity chromium and double vacuum melted titanium proceeded in February 1996. The ingot was vacuum arc melted twice to form a 1200 kg V-4Cr-4Ti ingot.

The outside diameter of the ingot was machined and cut into two pieces for vacuum canning in stainless steel for extrusion into sheet bar. The material was extruded into ~4 in. x 10 in. sheet bar at 1150°C. The first extrusion was processed successfully but the second stalled roughly half way through the die. The vacuum can was not breached during processing, and the material was not compromised. Estimates revealed that enough material was produced to meet the needs of the RDP program. The

remaining pieces of the ingot can be processed further at a later date if necessary.

The next step in the processing will be the warm cross-rolling of the extrusion into 4.8 mm plate and machining and swaging into 0.4 in. diameter rod. Completion of the product forms is scheduled for late summer of 1996.

IV. JOINING DEVELOPMENT

As most of the work within the fusion vanadium program has been focused on alloy development and irradiation properties, a key goal of the DIII-D vanadium program was to develop manufacturing techniques. For the success of the RDP program, welding and joining process development is important. Vanadium, being a refractory metal, is highly susceptible to embrittlement by oxygen, nitrogen, carbon, and hydrogen, at elevated temperatures, and most welding has required a high purity protective environment. Welding studies on gas Tungsten arc (GTA), e-beam, and laser welding are ongoing at ANL and ORNL but additional processes are required for the DIII-D program. Thus, studies have been initiated on resistance, friction, stud, and electron beam welding techniques of vanadium alloys.

A. Resistance Welding

Resistance welding is planned for structurally joining two sheets of vanadium together to make the water-cooled panels for the RDP. It will not provide the vacuum-tight weld, however. Initial spot welding trials were made, joining 1 mm thick sheets together. These trials were made in air and produced a weld nugget with microhardness only 10% greater than the bulk material. This was a very promising result, in that a protective atmosphere may not be required. A parameter search of pressure and current for welds of thicker material was started. No weld nugget was achieved on 3.8 mm sheet, based on parameters for welding Inconel, although the diffusion bond demonstrated considerable strength (up to 135 MPa) in crude shear tests.

It was then decided to use carbon steel parameters as the next reference point, due to similar resistivity and strength. These trials were successful, forming weld nuggets approximately 7 mm in diameter (Fig. 2). Microhardness measurements showed less than a 10% increase in hardness. Spot weld trials were then performed on 4.8 mm thick material, the thickness of the RDP sheets, and were also successful. The strength of these spot welds are being evaluated and resistance seam welding trials are being planned.

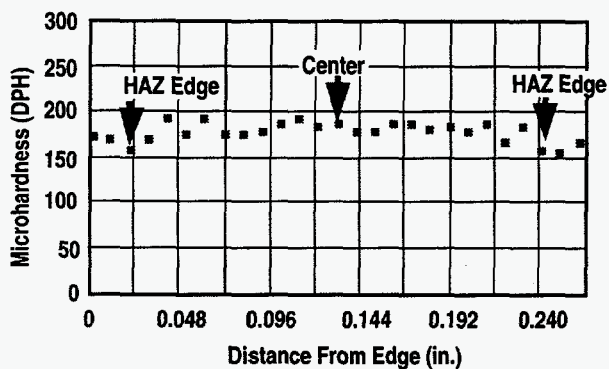

Fig. 2. Resistance spot weld of 3.8 mm thick V-4Cr-4Ti alloy sheets with microhardness profile across the weld nugget.

B. Friction Welding Studies

Two types of friction welding trials are in progress. Inertia and portable friction welding will be used for joining vanadium alloy to itself, and inertia welding for creating a bi-metallic joint. The first inertia weld trials of vanadium rod to vanadium plate were successful in air, without any protective environment. Metallography showed complete bonding with no indications of porosity or cracking. Microhardness measurements showed only slight increases in hardness in the weld and heat affected zones (HAZ). In this process, the temperature is kept below melting and can better be described as a hot forging process rather than welding. The interface maintained a fine grain structure, with little or no grain growth (Fig. 3). Tensile and torsion tests resulted in failures in the parent material away from the joint and HAZ.

Trials continued with evaluation of the joining of Inconel 625 to vanadium alloy. A bi-metallic joint would allow for field welding of only Inconel components in

Fig. 3. Etched cross-section of V-5Cr-5Ti alloy inertial weld trial sample showing location of weld joint and microhardness measurements.

DIII-D with all vanadium welds carefully characterized in the shop. Some bonding was achieved on the first samples but full strength was not developed. Additional trials using different diameter rods for the two materials, attempting to match the forgabilities, were successful. Metallography showed complete bonding with no porosity or cracking in the joint. Tensile pull tests were performed on three weld trial samples. Two samples failed in the Inconel 625 section well away from the weld area (at ~930 MPa stress) and one sample failed at the approximate weld interface, at a stress level of ~760 MPa. With the joining ability of the two materials demonstrated, the development was shifted to creating a bi-metallic tube joint. These trials have now been performed, and tests to evaluate their strength and leak tightness are in progress.

Preliminary portable friction welding trials of rod to plate have been performed to develop methods of *in-situ* replacement of studs on the water cooled panels. The initial trials achieved substantial bonding but hardness of the weld interface increased significantly. In addition, large grain growth occurred at the interface and heat

affected zone (Fig. 4). It was noted that in the trials, the temperature of the interface was significantly higher than in the inertia weld process and the time to create the weld was longer. It was believed that both of these factors led to the grain growth and increase in hardness. Additional trials are in progress.

Fig. 4. Etched cross-section of V-5Cr-5Ti alloy portable friction weld trial sample showing location of weld joint.

C. Stud Welding Studies

Stud welding trials utilizing a drawn arc method were performed between vanadium alloy stud and plate materials. A range of welding parameters was used without success. The molten material was consistently blown out of the interface zone and little or no bond was achieved. Audible cracking was noted during cool down of the materials indicating a pick up of impurities, embrittling the material. A second set of trials utilizing a different stud geometry was performed, but was also unsuccessful. These failures, and the successes achieved in the vanadium alloy inertial weld trials, prompted the investigation of the portable friction welding previously described as the process for attachment of the studs.

D. Electron Beam Welding Studies

Preliminary electron beam welding trials have also been initiated at General Atomics to complement the work being performed at ORNL. Initial weld parameters were obtained from ORNL and weld penetration tests performed using 6.35 mm thick vanadium alloy plate. These trials established specific weld parameters for creating a lap weld of two 3.85 mm thick vanadium alloy sheets. The lap weld, once created, was metallurgically

examined. Good weld penetration was obtained with no indications of cracking or porosity. Microhardness measurements showed less than ~10% increase in hardness. A weld was made in a single sheet to produce three tensile specimens to develop strength data on the weld. The tensile specimens all failed in the parent material well away from the weld joint and HAZ at values equal to the yield strength of the material.

V. TUBING FABRICATION

General Atomics has designed and manufactured a high heat flux test module made from vanadium alloy. The module is helium-cooled and is designed to handle an incident heat flux up to 3 MW/m^2 . The vanadium tube was manufactured by cold drawing a machined tube blank. The starting material was 29 mm V-4Cr-4Ti plate. The drawing process required a total reduction of 50% with an intermediate vacuum anneal after 30% reduction. After drawing, the inside diameter had axial grooves electro discharge machined for heat transfer enhancement. A swirl rod insert made from stainless steel, was placed in the bore to create annular helium flow. Testing of the module is planned for July 1996.

VI. CONCLUSIONS

A program for utilizing vanadium alloys in DIII-D has been developed to enhance the development of low activation vanadium alloys for fusion. The production of 1200 kg of material for this program is in progress. Two vanadium ingots have been electron beam melted as base materials for the ~1200-kg V-4Cr-4Ti alloy ingot. The alloy ingot has been double vacuum arc melted and extruded into sheet bar. Preliminary successes have been achieved in developing welds in vanadium alloy using resistance, inertia, friction, and electron beam welding methods. Fabrication of tubing was demonstrated with the production of a high heat flux test module.
