Abstract

To provide a compact high-brightness heavy-ion beam source for Heavy Ion Fusion (HIF), we have been experimenting with merging multi-beamlets in an injector which uses an RF plasma source. An array of converging beamlets was used to produce a beam with the envelope radius, convergence, and ellipticity matched to an electrostatic quadrupole (ESQ) channel. Experimental results were in good quantitative agreement with simulation and have demonstrated the feasibility of this concept. The size of a driver-scale injector system using this approach will be several times smaller than one designed using traditional single large-aperture beams. The success of this experiment has possible significant economical and technical impacts on the architecture of HIF drivers.

BACKGROUND

Following a proposal that the usual limits on brightness for compact ion-beam sources used in Heavy Ion Fusion can be circumvented by using a multi-beamlet injector¹, we performed experiments to examine practical issues. The final source envisioned will start with 200 5-mA beamlets across a 100-kV gap. The beamlets will be focused by Einzel Lens while their energy is increased to about 1.2 MeV. The beamlets are then merged to produce a 1-A beam with a normalized 4th rms emittance of about 1 π -mm-mrad at 1.6 MeV. For the envisioned source we need a low-temperature source that can provide ion emission densities of ~ 100 mA/cm², and would like to use electrical fields with strength on the order of 100 kV/cm. The main beam transport issues involved in the multi-beamlet approach are emittance growth and envelope matching in the merging process.

INDIVIDUAL BEAMLETS

We used an rf plasma source to produce the argon ion beamlets. The plasma chamber had a 26-cm inner diameter with multicusp permanent magnets to confine plasma. RF power (13 MHz) was applied to the source via a 2-turn, 11-cm diameter antenna inside the chamber. The RF power was typically applied for about 400 μ s while the accelerating gap voltage was typically applied on for 20 μ s. We have shown that we could extract 100 mA/cm² from the chamber. Optimum performance at 80 kV was

achieved with ~ 2 mTorr gas in the plasma chamber using 22 kW of rf drive power. The lowest emittance (optics) was achieved when the beamlet current was slightly below the peak current value. Current density was found to increase with RF power as long as there was sufficient extraction voltage. At 80 kV, we have reached our goal of producing 100 mA/cm² of Ar⁺ ions (i.e. 4.9 mA per beamlet). For operation with 10 kW of drive powers we estimated that less than 5% of the extracted ions were in the Ar⁺⁺ state. The thermal temperature of the ions was below 1 eV. Additional details about the rf plasma source have been published^{2,3,4}.

GRADIENT EXPERIMENTS

The Full Gradient Experiment was designed to test the electrical gradient limit in the working environment of the RF Plasma source. The dimensions and electric fields are typical of what we would like to use in a driver scale injector. Since we were limited to about 400-kV of pulsed voltage, only the first 5 gaps of a full system could be tested (See Fig. 1). To reduce the cost we did not use curved plates. The highest vacuum electric field gradient occurred between the 2nd plate and the 3rd plate, and was 100 kV/cm on axis for a 1.2 cm gap. Fields at the edge of the holes were expected to be about 120 kV/cm for this experiment. For these experiments we tested a 61-beamlet extraction array using a series of Einzel lens⁴. The source apertures were 2.2 mm in diameter while all the other electrodes had 4.0 mm diameter holes. The current per beamlet was 3.8 mA at an extraction current density of 100 mA/cm². There were 61 beamlets for a total current of 232 mA.

One of our goals was to test the high gradient insulators which were used to assemble the electrode plates. When tested individually, each would hold 80 kV DC without beam. The insulators were either 4.27 cm or 2.13 cm in length. A conservative working voltage is about 30 kV/cm for a 20- μ sec pulse in the gap environment. Achieving these gradients required conditioning of the surfaces.

Figure 1. Side view of the electrodes used in the Full Gradient Experiment. Electric Field between the 2nd and 3rd cup was 100 kV/cm.

Figure 6: Comparison of the measured unnormalized x emittance and the same emittance predicted by simulation.

of the phase space in the experiments. The optical emittance scans used a 90% amplitude cutoff. The slit scanner emittances fit the emittance vs. cutoff curve, and projected back to 100% level. The simulations line is the $4\sigma_{rms}$ emittance taken for 90% of the ions.

The unnormalized emittance does not depend on the injector voltage if the perveance is held constant and the focusing fields are scaled to the beam voltage. The main contribution to the phase area was the “trapped” area when the beamlets were merged.

Figure 7 shows the beam current into the Faraday cup as a function of the beam voltage. The simulation beam current assumes a flat emitting meniscus. Higher current can be obtained at the expense of interior beam optics if the ion-emitting surface are allowed to bulge into the extraction gap by overdriving the RF plasma. At near 400 kV we believe that we were losing current from gas collision near the Faraday Cup. Obtaining good transport required that we operated near the correct perveance. At 400 kV we measured 70 mA into the Faraday Cup.
