Abstract

A comprehensive model has been established for calculating thermodynamic properties of multicomponent aqueous systems containing the Na⁺, K⁺, Mg²⁺, Ca²⁺, Cl⁻, and NO₃⁻ ions. The thermodynamic framework is based on a previously developed model for mixed-solvent electrolyte solutions. The framework has been designed to reproduce the properties of salt solutions at temperatures ranging from the freezing point to 300 °C and concentrations ranging from infinite dilution to the fused salt limit. The model has been parameterized using a combination of an extensive literature database and new isopiestic measurements for thirteen salt mixtures at 140 °C. The measurements have been performed using Oak Ridge National Laboratory's (ORNL) previously designed gravimetric isopiestic apparatus, which makes it possible to detect solid phase precipitation. Water activities are reported for mixtures with a fixed ratio of salts as a function of the total apparent salt mole fraction. The isopiestic measurements reported here simultaneously reflect two fundamental properties of the system, *i.e.*, the activity of water as a function of solution concentration and the occurrence of solid-liquid transitions. The thermodynamic model accurately reproduces the new isopiestic data as well as literature data for binary, ternary and higher-order subsystems. Because of its high accuracy in calculating vapor-liquid and solid-liquid equilibria, the model is suitable for studying deliquescence behavior of multicomponent salt systems.

1. Introduction

Accurate knowledge of the deliquescence behavior of multicomponent brines is expected to enhance the understanding of the evolution of the chemical environment in contact with metal surfaces at the proposed radioactive waste repository at Yucca Mountain, Nevada, USA. It is anticipated that a layer of dust containing volcanic tuff and a mixture of salts originating from evaporation of seepage waters will tend to accumulate over time on all surfaces. The air inside the placement drifts will be relatively dry after final closure due to the temperature remaining well above the boiling point of water. As the temperature slowly decreases for several centuries due to radioactive decay, the relative humidity may reach sufficiently high levels for the mixture of initially dry salts to form concentrated brines through deliquescence. The concentrations of ions present in solutions contacting metal surfaces affect corrosion processes as, for example, the $\text{Cl}^-/\text{NO}_3^-$ ratio is an important consideration in corrosion calculations. Hence, thermodynamic properties of mixed aqueous solutions are needed for reliable predictions of the composition of the brines formed under the expected scenarios of in-drift temperature and humidity evolution.

Complete phase diagrams, showing relative humidity (or water activity) as a function of composition, are scarce even for solutions containing two salts. There are very few accurate experimental data sets available on deliquescence behavior of multicomponent aqueous salt solutions at elevated temperature. This underscores the importance of having an accurate thermodynamic model that would be capable of predicting the behavior of multicomponent systems in a wide temperature range using parameters determined from limited experimental data. While the well-known Pitzer ion-interaction model provides a useful framework for the prediction of solubilities in multicomponent solutions using activity data on binary systems with a common ion, the temperature dependence of solute-specific parameters is often not available with sufficient accuracy. Also, the molality-based Pitzer model is applicable for concentrations typically up to *ca.* 6 molal, which is often insufficient for highly concentrated systems that contain nitrates. Thus, it is necessary to develop a model that would be applicable to multicomponent, concentrated solutions up to solid saturation or, under some conditions, even the fused salt limit. Further, it is desirable to verify model results against measurements made in the temperature range that is of direct interest for studying deliquescence phenomena.

The main purpose of the measurements described here is to demonstrate that the unique ORNL high-temperature isopiestic apparatus can be used to investigate the relationship between deliquescence, relative humidity (*RH*) and temperature for multicomponent aqueous solutions. The points where a new phase appears or disappears can be detected when a series of measurements of solvent mass and the corresponding vapor pressure are made as water is added or withdrawn. When the relative humidity over a mixture of solid salts increases, the solution first appears at the eutonic point of the mixture where the solution is simultaneously saturated with respect to all components. The relative humidity at the eutonic point – the mixture deliquescence *RH* – is the lowest relative humidity coexisting with a liquid solution. The tendency to deliquesce (the hygroscopic character) of solutes depends mainly on their solubility, but also on the particular character of solute-solvent interactions, described also as nonideality, or vapor-pressure lowering ability. Since an addition of a new electrolyte to a saturated solution initially lowers its vapor pressure without causing precipitation, the deliquescence *RH* of multicomponent solutions decreases as the number of solutes increases.

The second objective of this paper is to develop a comprehensive thermodynamic model for predicting the thermodynamic behavior of aqueous mixtures containing the Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , and NO_3^- ions. These are the key ionic components in natural environments that may give rise to the formation of concentrated solutions through deliquescence phenomena. Comprehensive modeling of such mixtures requires calibrating the model to match the properties of the constituent binary (*i.e.*, salt – water), ternary (*i.e.*, salt 1 – salt 2 – water) and higher-order subsystems. For all such systems, the primary requirement for the model is to reproduce the solid-liquid equilibria and vapor pressures as a function of temperature and composition. In the development of the model, both literature data and the new isopiestic measurements are used. While literature data are primarily used to ensure the correct representation of the properties of simpler (*i.e.*, binary and ternary) subsystems, the new isopiestic data are essential for verifying the performance of the model for concentrated multicomponent mixtures at high temperatures.

2. Experimental

The isopiestic method is based on equilibration of a number of solutions together with reference standards in a common chamber, until all transfer of the solvent ceases and all solutions reach the same water activity. The ORNL high-temperature isopiestic apparatus, described previously [1-5], has been used during the last several decades to measure vapor pressures and obtain osmotic and activity coefficients for many aqueous solutions of pure electrolytes and their mixtures at temperatures typically between 150 and 250 °C. The main feature of this apparatus is its internal electromagnetic balance with optical detection. Since only the solvent is exchanged between samples while the masses of nonvolatile solutes placed initially in the platinum cups remain constant, the amounts of water present at any time and hence the molalities of the solutions can be determined gravimetrically without interrupting the equilibrium. The isopiestic apparatus provides, in general, a greater reliability and accuracy of the results than other recently reported experimental methods of investigating deliquescence [6,7] thanks to the precise control of relative humidity over arbitrarily long times, the absence of atmospheric air, the high accuracy of the gravimetric method for molality and of the relative isopiestic method for vapor pressure, and the fast equilibration times due to the efficient heat exchange between the solution cups.

The internal balance was calibrated during each series of weighings using platinum and titanium mass standards placed in the sample holder between the sample cups. All twenty cups containing the samples, the reference solutions and the mass standards were weighed at each equilibrium point two to three times. The corrections for buoyancy in water or air were applied to all weighings. Each solution contained 10 to 15 mmole of salts (about 1 g) and no more than 3 g of water. The accuracy of the balance was better than ± 1 mg. The estimated absolute error of the resulting average molalities m ($\text{mol}\cdot\text{kg}^{-1}$) was less than $0.0001 \text{ mol}^{-1}\cdot\text{kg}\cdot\text{m}^2$.

The apparatus was also equipped with quartz pressure transducers (Digiquartz, Paroscientific Inc.) allowing for accurate monitoring of the approach to equilibrium. The set of four Digiquartz transducers (with the ranges of 2.1, 6.9, 21 and 69 bar), kept in an air oven at a constant temperature of about 39.0 ± 0.1 °C, provided an accurate and relatively simple means of

measuring water vapor pressure. While only a dead-weight instrument with a precise pressure difference indicator could deliver a substantially greater accuracy, at 140 °C, and at the pressures between 0.35 bar and 2.7 bar, the relative isopiestic method based on reference solutions was still significantly superior to direct pressure measurement. The accuracy of the direct pressure measurement was limited by the effects of temperature, viscosity, surface tension and hydrostatic pressure of the liquid water present inside the transducers and in the tubing connecting them to the vapor space maintained at elevated temperature. The results reported here are not based on the measured pressures, but instead on the calcium chloride reference solution [5].

Stock solutions were prepared by weight using distilled and deionized water (from a Barnstead NANOpure four-stage water purification system) and the chemicals supplied by Alfa Aesar Chemical Co. without any purification other than drying. Two grades of pure salts were used. The chlorides were the "ultra dry" grade chemicals, with metal-basis purities specified by the vendor as 0.99998 for NaCl and KCl, 0.99995 for LiCl, and 0.9999 for CaCl₂ and MgCl₂. These salts, received in the form of powders or small beads stored in glass ampoules under argon, were also certified to contain at most 100 ppm oxide and hydroxide, and were used without drying. The nitrates of sodium, potassium, calcium, and magnesium were the "Puratronic" grade chemicals with metal-basis purities better than 0.99995. These salts, in particular the hydrates of Ca(NO₃)₂ and Mg(NO₃)₂, were dried carefully in a vacuum oven for several days, while avoiding deliquescence and possible decomposition by slowly increasing temperature to about 140 °C.

All stock solutions of the "ultra dry" salts contained some amount of insoluble impurities. In the case of CaCl₂ and MgCl₂ this was determined by XRD to be mostly sulfate. The exact quantities of impurities were not determined; however, they were apparently higher than expected for this type of chemicals. It is likely that the purity of these materials was lower than stated by the vendor. There were no noticeable insoluble impurities in the solutions of the "Puratronic" salts.

This work describes the first use of the ORNL isopiestic apparatus specifically for determination of solubilities in multi-component solutions. The water initially injected in the apparatus was previously degassed by boiling and sparging with helium. The solutions were all liquid at the starting relative humidity of 75 %. The relative humidity was then decreased in about 20 steps to the final value of 10% by releasing water from the autoclave under atmospheric pressure or vacuum when necessary. At least 16 hours were allowed for equilibration at each step. Since the measurements started with liquid samples of approximately the same molality as the stock solutions, it was convenient to conduct the measurements by progressively decreasing the relative humidity. The process observed was in fact precipitation (efflorescence) of salts from the solution instead of deliquescence. However, measurements can also be made in the reverse direction by starting from solid salt mixtures. It is assumed that the results are completely reversible with respect to the direction of the changes in relative humidity.

The phase changes occurring in the mixed solutions were clearly visible as breaks in the curve representing initially the osmotic coefficient of the solution as a function of relative humidity. The osmotic coefficient, ϕ , was calculated as

$$\phi = 1000 w_s / M_s \sum n_i \ln a_s \quad (1)$$

where M_s ($\text{g}\cdot\text{mol}^{-1}$) is the molecular weight of water, a_s is the activity of water, n_i are the numbers of moles for each ion and w_s (kg) is the mass of water. Naturally, after the appearance of a solid phase, because the distribution of the salts between solid and liquid phases is not known, the quantity calculated from the above equation does not represent the actual osmotic coefficient. As the first component begins to precipitate from the solution, the ratio n_i/w_s exceeds the actual molality of the liquid phase and the osmotic coefficient appears to sharply decrease. This process continues gradually as the relative humidity continues to decrease and more water evaporates from the solution. After reaching the eutonic composition, all the remaining water evaporates at a constant relative humidity. By using samples of varying solute ratios, a complete solubility diagram can be obtained.

The compositions of the samples are summarized in Table 1. For all the 13 samples defined in Table 1, Table 2 gives the masses of water (and, hence, the overall system compositions) that correspond to 21 values of water activity.

3. Thermodynamic model

For modeling the properties of aqueous Na-K-Ca-Mg-Cl-NO₃ mixtures, we use a thermodynamic framework that has been previously developed at OLI Systems for mixed-solvent electrolyte systems (Wang *et al.* [8-10]). This framework is capable of reproducing the properties of multicomponent salt solutions ranging from infinite dilution to the fused salt limit and, therefore, it is particularly suitable for studying deliquescence phenomena. The model was described in detail in previous papers [8-10] and, therefore, only a brief summary is given here.

The thermodynamic framework combines an excess Gibbs energy model for mixed-solvent electrolyte systems with a comprehensive treatment of chemical equilibria. In this framework, the excess Gibbs energy is expressed as

$$\frac{G^{ex}}{RT} = \frac{G_{LR}^{ex}}{RT} + \frac{G_{II}^{ex}}{RT} + \frac{G_{SR}^{ex}}{RT} \quad (2)$$

where G_{LR}^{ex} represents the contribution of long-range electrostatic interactions, G_{II}^{ex} accounts for specific ionic (ion-ion and ion-molecule) interactions and G_{SR}^{ex} is the short-range contribution resulting from intermolecular interactions.

The long-range interaction contribution is calculated from the Pitzer-Debye-Hückel formula [11] expressed in terms of mole fractions and symmetrically normalized, *i.e.*,

$$\frac{G_{DH}^{ex}}{RT} = - \left(\sum_i n_i \right) \frac{4A_x I_x}{\rho} \ln \left(\frac{1 + \rho I_x^{1/2}}{\sum_i x_i [1 + \rho (I_{x,i}^0)^{1/2}] } \right) \quad (3)$$

where the sum is over all species, I_x is the mole fraction-based ionic strength, $I_{x,i}^0$ represents the ionic strength when the system composition reduces to a pure component i , i.e., $I_{x,i}^0 = 0.5z_i^2$; ρ is related to the hard-core collision diameter ($\rho = 14.0$) and the A_x parameter is given by

$$A_x = \frac{1}{3} (2\pi N_A d_s)^{1/2} \left(\frac{e^2}{4\pi\epsilon_0\epsilon_s k_B T} \right)^{3/2} \quad (4)$$

where d_s and ϵ_s are the molar density and dielectric constant of the solvent, respectively. The specific ion-interaction contribution is calculated from an ionic strength-dependent, symmetrical second virial coefficient-type expression [8]:

$$\frac{G_{II}^{ex}}{RT} = - \left(\sum_i n_i \right) \sum_i \sum_j x_i x_j B_{ij}(I_x) \quad (5)$$

where $B_{ij}(I_x) = B_{ji}(I_x)$, $B_{ii} = B_{jj} = 0$ and the ionic strength dependence of B_{ij} is given by

$$B_{ij}(I_x) = b_{ij} + c_{ij} \exp(-\sqrt{I_x + a_1}) \quad (6)$$

and where b_{ij} and c_{ij} are binary interaction parameters and a_1 is set equal to 0.01. In general, the parameters b_{ij} and c_{ij} are calculated as functions of temperature as

$$b_{ij} = b_{0,ij} + b_{1,ij}T + b_{2,ij}/T + b_{3,ij}T^2 + b_{4,ij} \ln T \quad (7)$$

$$c_{ij} = c_{0,ij} + c_{1,ij}T + c_{2,ij}/T + c_{3,ij}T^2 + c_{4,ij} \ln T \quad (8)$$

The last two parameters of Eqs. (7) and (8) are typically necessary only when there is a need to reproduce experimental data over a very wide range of temperatures, e.g., from -50 to 300 °C. Finally, the short-range interaction contribution is calculated from the UNIQUAC equation [12]. In systems containing only strong electrolytes, such as the Na-K-Ca-Mg-Cl-NO₃ mixtures considered here, the short-range term is unnecessary and all interactions are accounted for by Eq. (5).

The excess Gibbs energy model is used to calculate nonideality effects on solid-liquid equilibria and chemical equilibria, such as ion pairing. For example, solubility of a salt MX is represented as a chemical equilibrium between the solid salt MX_(s) and the ions that result from its dissociation, M^{m+} and X^{x-}. The chemical equilibrium is governed by the chemical potentials of

all species that participate in a given reaction. The chemical potential of each ionic or neutral species i is determined by its standard-state contribution, $\mu_i^\circ(T, P)$ and its activity coefficient, $\gamma_i(T, P, x)$, *i.e.*,

$$\mu_i(T, P, x) = \mu_i^\circ(T, P) + RT \ln x_i \gamma_i(T, P, x) \quad (9)$$

The standard-state chemical potentials for aqueous species, $\mu_i^\circ(T, P)$, are calculated as functions of temperature and pressure using the Helgeson-Kirkham-Flowers-Tanger (HKF) equation of state [13-14]. The parameters of the HKF model are available for a large number of aqueous species including ions and ion pairs [15-18]. It should be noted that standard-state properties calculated from the model of Helgeson *et al.* are based on the infinite-dilution reference state and on the molality concentration scale. To make the equilibrium calculations consistent when the standard-state properties are combined with the mole fraction-based and symmetrically normalized activity coefficients, two conversions are performed: (1) the activity coefficients calculated from Eq. (2) are converted to those based on the unsymmetrical reference state, *i.e.*, at infinite dilution in water and (2) the molality-based standard-state chemical potentials are converted to corresponding mole fraction-based quantities [8].

4. Determination of parameters

The parameters of the model are determined using thermodynamic data of various types, including

- (1) Vapor-liquid equilibria
- (2) Activity and osmotic coefficients
- (3) Solid-liquid equilibria
- (4) Enthalpies of dilution or mixing
- (5) Heat capacities
- (6) Densities

The parameters for the Na-K-Mg-Ca-Cl-NO₃ systems were evaluated and/or verified using a combination of literature data and the new isopiestic data reported in this study. There is a very large body of literature data that covers all the eight binary subsystems (*i.e.*, NaCl, KCl, MgCl₂, CaCl₂, NaNO₃, KNO₃, Mg(NO₃)₂ and Ca(NO₃)₂ with H₂O), most of the twenty-eight possible ternary subsystems and an appreciable number of quaternary and quinary subsystems of this senary mixture [7,19-305]. References to binary and ternary data are collected in Table 3 in the form of a matrix defined by the eight fundamental constituent salts. The diagonal elements of the matrix (*i.e.*, salt A – salt A) show references to the sources of experimental data for the binary subsystems (*i.e.*, salt A – H₂O). The off-diagonal elements refer to the data for the ternary subsystems (*i.e.*, salt A – salt B – H₂O). As shown in Table 3, there is a wealth of information for all binary systems. In the case of the ternary subsystems, there is extensive experimental coverage for mixtures containing two chlorides. Also, there are a reasonable number of experimental data sources for the ternaries that contain two nitrates and those that combine the nitrates and chlorides of sodium and potassium. However, the experimental coverage is much

sparser for mixed chloride – nitrate ternaries that contain magnesium and calcium in addition to sodium and potassium.

Table 4 summarizes the sources of experimental data for quaternary and higher-order systems. Since a complete matrix representation is not practical in this case, Table 4 groups the subsystems according to the availability of experimental data. It is noteworthy that a fairly large number of data sources deal with chloride-only multicomponent mixtures. Much less information is available for mixtures of chlorides and nitrates. Here, the new isopiestic measurements fill important gaps.

The model parameterization procedure adopted in this work consisted of several steps. First, binary parameters were determined using data for the eight binary subsystems. These regressions were based on data of various types as described above. This produced the interaction parameters (Eqs. 7-8) between the cations and anions that constitute each subsystem. Also, thermochemical parameters (*i.e.*, the Gibbs energy and entropy) for some hydrated salts were simultaneously adjusted to match solid-liquid equilibrium data. Such adjustments were not necessary for the solids for which thermochemical properties are known with high accuracy.

In the second step, data for ternary subsystems were used to determine the cation-cation and anion-anion interaction parameters. At the same stage, thermochemical parameters were adjusted for the double salts that do not occur in binary subsystems but precipitate in ternary and higher-order mixtures. The thermochemical properties of such double salts are typically known with lower accuracy than those of pure solids and, therefore, needed to be adjusted to match their solubilities. Finally, data for quaternary and higher-order systems were used to verify the predictions of the model. In some cases, quaternary data were used to fine-tune model parameters when they extended to temperatures that were not covered by the relevant ternary subsystems.

In all cases, parameters were determined to cover the temperature range from the freezing point of salt solutions (typically between -50 and 0 °C) and 300 °C. The upper limit of 300 °C is an inherent limitation of excess Gibbs energy models when applied to aqueous systems. Above 300 °C, the system becomes too close to the critical locus to be handled by classical excess Gibbs energy models. However, the temperature range from the freezing point to 300 °C comfortably encompasses the conditions that are of interest for studying deliquescence.

Table 5 shows the parameters that represent the properties of the ternary system NaCl–NaNO₃–H₂O. The underlying experimental data for this system and its constituent binaries extend over a wide range of temperatures (up to 300 °C) and, therefore, four or five coefficients are necessary to reproduce the temperature dependence of the binary cation-anion parameters. Also, the need to use a fairly complex temperature dependence of the parameters is due to the high accuracy of the available experimental data for the NaCl–H₂O and NaNO₃–H₂O binaries. On the other hand, the Cl⁻–NO₃⁻ interaction parameters can be represented using a much simpler temperature dependence. The Cl⁻–NO₃⁻ interaction parameters have been determined on the basis of all available chloride-nitrate ternaries and, therefore, they are not limited to the NaCl–NaNO₃–H₂O ternary. For completeness, Table 5 also includes the thermochemical properties of the solids

that may precipitate in this system. These thermochemical properties are used to calculate the chemical potential of the solids according to standard thermodynamics.

5. Results and discussion

In this section, we compare the modeling results with experimental data for all constituent binary subsystems and selected ternary and higher-order systems. First, we focus on solubility relationships for the binary and ternary systems. Then, we analyze vapor-liquid equilibrium data for solid-saturated ternary systems using literature data [7]. Finally, we apply the model to the new isopiestic data and analyze them in the light of solid-liquid equilibrium predictions obtained from the model.

5.1. Solid-liquid equilibria in binary systems

Figures 1-8 show the calculated and experimental solid-liquid equilibria for the eight binary subsystems for temperatures up to approximately 300 °C. In all cases, the SLE diagrams include the solubility of ice (denoted by $\text{H}_2\text{O}(\text{s})$) in a salt solution. The lowest temperature in each diagram corresponds to the eutectic point, at which ice coexists with the anhydrous or hydrated salt that is stable at the lowest temperature. Then, solubility curves are included for all solid forms that are stable up to 300 °C.

It is evident that the complexity of the solubility behavior depends primarily on whether the cation belongs to the first group of the periodic table (Na, K) or the second (Mg, Ca). The sodium salts show relatively simple solid-liquid equilibrium patterns. As shown in Figs. 1 and 2, NaNO_3 and KNO_3 form only one, anhydrous, solid precipitate at temperature from sub-zero to *ca.* 300 °C. In both cases, the solubility continuously increases with temperature up to the melting point of the pure solid. It is noteworthy that the model accurately reproduces the solubility up to the melting point. Unlike NaNO_3 and KNO_3 , the nitrates of calcium and magnesium form more than one stable solid phase. This is illustrated in Figs. 3 and 4, which show the stability ranges for the various hydrated and anhydrous forms of $\text{Ca}(\text{NO}_3)_2$ and $\text{Mg}(\text{NO}_3)_2$, respectively. The solubility behavior is particularly noteworthy for $\text{Mg}(\text{NO}_3)_2$ (Fig. 4). In the case of this binary, the $\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ phase melts congruently, which results in a solubility maximum. Thus, in the temperature range from *ca.* 45 to 90 °C, the salt has three values of solubility, *i.e.*, two for $\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ on both sides of the solubility maximum and one for $\text{Mg}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$ at higher salt concentrations. The solubility behavior of chlorides (Figs. 5-8) essentially parallels that of the nitrates with respect to the complexity of their phase behavior. However, the solubility of the chlorides is substantially lower than that of the nitrates. Similarly to the corresponding nitrates, sodium and potassium chlorides form only one stable anhydrous solid phase at the temperatures of interest. The only exception is the hydrate $\text{NaCl} \cdot 2\text{H}_2\text{O}$, which is stable only below 0 °C (*cf.* Fig. 5). The chlorides of calcium and magnesium form a series of stable hydrates as shown in Figs. 7 and 8, respectively. For all binary subsystems, the model reproduces the measurements essentially within the scatter of experimental data.

5.2. Solid-liquid equilibria in ternary systems

Figures 9–15 show solid-liquid equilibrium diagrams for seven representative ternary systems. In these figures, solubility isotherms are plotted using the weight percent of both salts as independent variables. Thus, the points on the individual salt concentration axes correspond to solubilities in the binary subsystems. In general, the chemical identity of the stable solid phase may vary with the overall composition of the system and may not be the same as in the binary subsystems. Therefore, the solid phases that are in equilibrium with saturated solutions are marked next to the solubility curves in Figs. 9–15.

Figure 9 shows the solubility behavior in the ternary system $\text{NaNO}_3\text{--Ca}(\text{NO}_3)_2\text{--H}_2\text{O}$. In this case, the diagram is fairly simple because the stability of the solid phases that precipitate for the constituent binary subsystems persists in the ternary system. Thus, the diagram shows two branches that extend from the solubility points for the binary subsystems. These two branches correspond to the precipitation of NaNO_3 and $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ or $\text{Ca}(\text{NO}_3)_2$, depending on the temperature. The solubility behavior of the $\text{Mg}(\text{NO}_3)_2\text{--Ca}(\text{NO}_3)_2\text{--H}_2\text{O}$ system (Fig. 10) is qualitatively similar in that the identity of the stable phases does not change by moving from the binary subsystems to the ternary. However, the relative stability of the magnesium and calcium salts strongly changes with temperature. For example, $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ precipitates over a wide range of conditions at lower temperatures whereas the stability range of $\text{Ca}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$ is very narrow at 50 °C and is limited to a region close to the binary axis.

Figure 11 illustrates solid-liquid equilibria for the $\text{NaNO}_3\text{--KNO}_3\text{--H}_2\text{O}$ system. In this case, simple solubility behavior is observed at low and moderate temperatures (up to *ca.* 150 °C). However, a solid solution phase appears at higher temperatures and manifests itself as two breaks in the solubility isotherms at 175 and 200 °C. This solid phase is tentatively identified as $\text{NaNO}_3 \cdot \text{KNO}_3$.

Figures 12–15 show the behavior of mixed nitrate-chloride ternaries. The solubility isotherms for the $\text{NaCl--NaNO}_3\text{--H}_2\text{O}$ (Fig. 12) and $\text{KCl--KNO}_3\text{--H}_2\text{O}$ (Fig. 13) ternaries show simple solubility behavior without a phase change on moving from the binaries to the ternary. However, the $\text{MgCl}_2\text{--Mg}(\text{NO}_3)_2\text{--H}_2\text{O}$ system shows a very complicated solubility pattern as shown in Fig. 14. This pattern results partly from the presence of a congruently melting solid phase, $\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$, in the binary subsystem $\text{Mg}(\text{NO}_3)_2\text{--H}_2\text{O}$. Because of this, the solubility of $\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ forms a loop in the ternary phase diagram at intermediate temperatures. In addition to the loop, an additional solubility curve is observed that connects the solubilities of $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ and $\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ in the binary subsystems. At higher temperatures, the solubility loop disappears. However, the solubility behavior is further complicated by the transition of the stable solid form from $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ to $\text{Mg}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$ through $\text{MgCl}_2 \cdot 4\text{H}_2\text{O}$ and then $\text{MgCl}_2 \cdot 2\text{H}_2\text{O}$. These transitions are visible in the solubility curves as characteristic break points. It is noteworthy that this complex phase behavior is accurately reproduced by the model.

The ternary system $\text{NaCl--KNO}_3\text{--H}_2\text{O}$ is shown in Fig. 15. In this case, simple solubility behavior is observed at temperatures up to *ca.* 50 °C. However, a different phase, KCl , appears at higher temperatures.

5.3. Vapor pressures of saturated solutions

The vapor pressures of saturated solutions are of particular interest for studying deliquescence. At solid saturation, a minimum of the vapor pressure is reached for a given salt composition. Figs. 16–21 show the experimental and calculated vapor pressures and the corresponding concentrations of ions in saturated solutions of two mixed salts in water. In these figures, the composition of a mixture of salt A and salt B is expressed using mole fractions on a water-free basis, i.e., $x'_A = n_A / (n_A + n_B)$ where n_A and n_B are the numbers of moles of salts A and B. Each of the ternary mixtures contains water in the amount that is necessary to achieve solid-liquid saturation. The overall compositions (including water) of the mixtures in Figs. 16-21 are consistent with those shown in the corresponding ternary solid-liquid equilibrium diagrams. By plotting the vapor pressures on a water-free basis, it is easy to see how the equilibrium pressure changes as one salt is gradually replaced with another in a saturated solution.

Figure 16 represents the vapor pressure of the $\text{NaNO}_3\text{--NaCl--H}_2\text{O}$ system as the overall composition varies from pure NaNO_3 to pure NaCl . The solid phases that are in equilibrium with the saturated solutions are indicated next to the vapor pressure curves. These solid phases are consistent with the SLE diagram for the same system, which is shown in Fig. 12. The minimum in the vapor pressure is reached at the eutonic point, at which both NaCl(s) and $\text{NaNO}_3\text{(s)}$ coexist. The model predicts the eutonic point with very good accuracy. As shown in Fig. 17, the model also accurately predicts the equilibrium concentrations of the Na^+ , Cl^- and NO_3^- ions along the solid saturation line. This provides an additional confirmation of the SLE diagram (*cf.* Fig. 12). The vapor pressures of the system $\text{NaNO}_3\text{--KNO}_3\text{--H}_2\text{O}$ show a very similar pattern as illustrated in Fig. 18. The corresponding concentrations of ions at saturation are shown in Fig. 19.

The system $\text{NaCl--KNO}_3\text{--H}_2\text{O}$ (Figs. 20-21) exhibits a somewhat more complex behavior although the experimentally observed patterns are partially obscured by higher experimental uncertainties for this mixture. In this case, the vapor pressure curve shows two break points, which correspond to the transition from $\text{KNO}_3\text{(s)}$ to KCl(s) and then from KCl(s) to NaCl(s) as sodium nitrate is progressively replaced by sodium chloride in the saturated solution. This transition is consistent with the SLE diagram in Fig. 15. The predicted vapor pressures (Fig. 20) and equilibrium ionic compositions (Fig. 21) agree with the data within the experimental uncertainty.

5.4. Comparison with the new isopiestic data

The isopiestic measurements reported here simultaneously reflect two fundamental properties of the system: the activity of water as a function of solution concentration and the occurrence of solid-liquid transitions. Thus, the isopiestic data provide a stringent test of the model's capability to represent simultaneously the vapor-liquid and solid-liquid equilibria. Figures 22-26 compare the calculated and experimental water activities (upper diagrams) and osmotic coefficients (lower diagrams) for the systems defined in Table 1. While the water activity is of direct interest for studying deliquescence, osmotic coefficients are more convenient for analyzing the data, in

particular at lower concentrations. This is due to a stronger variability of osmotic coefficients at lower concentrations, at which water activities do not differ much from unity.

The systems in Figures 22-26 have been grouped according to their increasing complexity. In all cases, calculations were performed by increasing the total apparent mole fraction of the salt from zero (or reducing the apparent mole fraction of water from one) while keeping the ratios of the various salts as defined in Table 1. Here, the apparent mole fraction is defined by including the salts and water in both the solution and in the various solid phases that may precipitate. The apparent mole fraction is identical to the mole fraction in the solution only if there is no solid phase in the system. Once a solid phase precipitates, the plot of water activity or osmotic coefficient against the apparent mole fraction exhibits a change in slope due to the appearance of a solid phase. The points at which new solid phases start to precipitate are shown by arrows in Figs. 22-26 and the compositions of the solids are identified next to the arrows. The breaks are typically more pronounced on the osmotic coefficient plots, especially at lower concentrations. Starting at the precipitation point, the apparent mole fraction ceases to be equivalent to the solution composition and the calculated water activity starts to reflect the property of a solid-liquid assembly.

First, Fig. 22 summarizes the results of calculations for simple binary solutions containing NaCl, $Mg(NO_3)_2$, LiCl, $CaCl_2$ and $Ca(NO_3)_2$ (samples 1, 3, 6, 11 and 12 in Table 1). Once a solid phase precipitates (as indicated by the vertical arrows), the water activity becomes constant. This is a consequence of the phase rule. The constant water activities are shown as horizontal portions of the curves in Fig. 22. Since the model was calibrated using extensive experimental data for binary systems (*cf.* Table 3), the obtained agreement between the calculations and experimental data is not surprising and simply verifies the consistency of the new isopiestic data with earlier thermodynamic data for the binary systems.

A more stringent test of the model is provided by the multicomponent systems. Figure 23 shows the results for two systems containing only nitrates, *i.e.*, the ternary system $NaNO_3$ - KNO_3 - H_2O (sample 10) and the quinary mixture $NaNO_3$ - KNO_3 - $Ca(NO_3)_2$ - $Mg(NO_3)_2$ - H_2O (sample 4). In ternary and higher-order systems, precipitation of a solid phase does not lead to a constant value of water activity. Instead, a change in slope is observed. In the case of these two nitrate systems, two discontinuous slope changes occur. The first one is associated with the transition from a one-phase to a two-phase (*i.e.*, liquid + $NaNO_3(s)$) system and the second one reflects a change from a two-phase to a three-phase system as indicated by the arrows in Figure 23. The model accurately predicts the water activities including the change in slope and the exact composition of the system at which the transition occurs. Thus, the model makes it possible to identify the phases that precipitate as the total salt fraction is increased.

Figure 24 groups the results for three systems containing chlorides and nitrates of sodium and potassium (samples 2, 7 and 8). As with the nitrate-only systems, the water activities and the accompanying phase transitions are accurately predicted by the model. The transitions for the quaternary system $NaCl$ - $NaNO_3$ - KNO_3 - H_2O appear to be particularly complex. In this case, the system transitions from a liquid to a liquid + $NaCl(s)$ mixture, then to liquid + $NaCl(s)$ + $KCl(s)$, then to liquid + $NaCl(s)$ + $KCl(s)$ + $KNO_3(s)$ and, finally, to liquid + $KCl(s)$ + $KNO_3(s)$. Figure 25 shows the results for mixed chloride-nitrate systems containing calcium and magnesium

rather than sodium and potassium. Water activity drops to substantially lower values in calcium and magnesium salts before saturation is achieved. In this case, saturation results in the formation of hydrated double salts such as $\text{MgCl}_2 \cdot 2\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$. As with the Na-K-Cl- NO_3 system, transitions of the type liquid \rightarrow liquid + solid A are followed by transitions of the type liquid + solid A \rightarrow liquid + solid A + solid B. The predicted water activities are in very good agreement with the data.

Finally, Fig. 26 shows the results for a six-component system that contains all ions that are the subject of this study (i.e., Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , and NO_3^-). As indicated in Table 1, the mixture was actually made from eight salts in addition to water (i.e., NaCl, KCl, NaNO_3 , KNO_3 , CaCl_2 , MgCl_2 , $\text{Ca}(\text{NO}_3)_2$, and $\text{Mg}(\text{NO}_3)_2$). However, the system contains six independent components in the sense of the phase rule. Because of its complexity, this system exhibits four transitions as indicated by the vertical arrows in Figure 26. At very high total apparent salt fractions (above *ca.* 0.6), the predicted water activities are somewhat less accurate, which might indicate that a different solid phase precipitates at some conditions (possibly a double or triple salt that does not occur in simpler systems).

6. Conclusions

A comprehensive model has been established for calculating the thermodynamic properties of Na-K-Mg-Ca-Cl- NO_3 systems. The parameters of the model have been determined using a combination of an extensive literature database and new isopiestic measurements that provide important information for multicomponent systems at elevated temperatures (140 °C).

The experimental method based on the use of the ORNL gravimetric isopiestic apparatus allows for the detection of solid phase precipitation and therefore a definitive determination of complete relative humidity *vs.* composition phase diagrams. For salt mixtures several samples are needed to cover the entire range of compositions, however, one sample is sufficient for determination of the mixture deliquescence *RH*.

The model has been shown to provide accurate predictions of thermodynamic properties in wide ranges of temperature (from the freezing point to 300 °C) and concentration (from infinite dilution to the melting point). In particular, the model comprehensively reproduces solid-liquid equilibria and water activities in binary, ternary and higher-order systems. Also, the model accurately reproduces the new isopiestic data, including the changes in the slope of water activity *versus* the total salt mole fraction. These changes in the slope reflect the precipitation of various solid phases, thus providing a stringent test for the model.

The Na-K-Mg-Ca-Cl- NO_3 mixtures provide a good approximation of the behavior of deliquescing systems. Among the common anions that occur in nature, chlorides are the most important aggressive species and nitrates are the most important inhibitors in the corrosion of engineering alloys. Thus, the concentration of chlorides and nitrates is particularly important for predicting materials performance. Compared with the Cl^- and NO_3^- ions, other anions (e.g., hydroxides and carbonates) are expected to occur in lower concentrations in deliquescing systems. Most of the other oxygen-containing anions have weak inhibitive properties. However,

their inhibitive behavior is much less pronounced than that of nitrates and, therefore, their role in corrosion phenomena is less significant. While the inclusion of anions such as OH^- , CO_3^{2-} and SO_4^{2-} is beyond the scope of this study, the mixed-solvent electrolyte model can be relatively easily extended to achieve a more general coverage of solution chemistry.

Table 1. Compositions of the samples. Solute contents in each cup are given as the total number of millimoles corresponding to the salt formula.

-
1. NaCl : 14.672
 2. NaCl + NaNO₃ : 7.4646 + 6.8248
 3. Mg(NO₃)₂ : 8.8921
 4. NaNO₃ + KNO₃ + Ca(NO₃)₂ + Mg(NO₃)₂ : 5.2873 + 1.2967 + 2.3614 + 1.2197
 5. CaCl₂ + MgCl₂ + Ca(NO₃)₂ + Mg(NO₃)₂ : 5.0878 + 0.77353 + 2.6309 + 1.4123
 6. LiCl : 13.197
 7. NaCl + KCl + NaNO₃ + KNO₃ : 5.4795 + 2.3108 + 2.7690 + 1.0563
 8. KCl + KNO₃ : 8.1026 + 2.8021
 9. NaCl + KCl + NaNO₃ + KNO₃ + CaCl₂ + MgCl₂ + Ca(NO₃)₂ + Mg(NO₃)₂ :
4.1946 + 2.0027 + 2.8693 + 0.70451 + 0.53286 + 0.20404 + 0.40974 + 0.13368
 10. NaNO₃ + KNO₃ : 9.0689 + 2.2832
 11. CaCl₂ : 9.3057
 12. Ca(NO₃)₂ : 7.9988
 13. CaCl₂ + Ca(NO₃)₂ : 4.5080 + 4.0814
-

Table 2. Masses of water (mg) in each of the 13 sample cups at 21 values of water activity a ($t = 140\text{ }^{\circ}\text{C}$).
