Photo-excitation can drive strongly-correlated electron insulators into competing conducting phases[i,ii], resulting in giant and ultrafast changes of their electronic and magnetic properties. The underlying non-equilibrium dynamics involve many degrees of freedom at once, whereby sufficiently short optical pulses can trigger the corresponding collective modes of the solid along temporally coherent pathways. Their characteristic frequencies of these modes range between the few GHz of acoustic vibrations[iii] to the tens or even hundreds of THz for purely electronic excitations. Virtually all experiments to date have used 100-fs or longer pulses, detecting only comparatively slow lattice dynamics[iv,v]. Here, we use sub-10-fs optical pulses to study the photo-induced insulator-metal transition in the magneto-resistive manganite $Pr_{0.7}Ca_{0.3}MnO_3$. At room temperature, we find that the time-dependent pathway toward the metallic phase is accompanied by coherent 31-THz oscillations of the optical reflectivity, significantly faster than all lattice vibrations. These high-frequency oscillations are suggestive of coherent orbital waves[vi,vii], crystal-field excitations triggered here by Impulsive Stimulated Raman Scattering. Orbital waves are likely to be initially localized to the small polarons of this room-temperature manganite, coupling to other degrees of freedom at longer times and seeding the coalescence of photo-domains into a metallic phase.

$Pr_{(1-x)}Ca_xMnO_3$ is a perovskite manganite with low tolerance factor, which maintains semi-conducting properties for all temperatures and doping levels[viii]. Below 220 K, long-range charge, orbital and magnetic order[ix,x] sets in, mediated by a subtle interplay between super-exchange interactions and a long-range Jahn Teller distortion[xi,xii]. For x=0.3 doping, the electronically-ordered insulator becomes particularly precarious, exhibiting an instability against one or more competing metallic phases and a truly "colossal" negative magneto resistance[xiii]. In addition to the application of a magnetic field, other perturbations can "melt" the insulating state: photo-excitation[xiv], application of static electric fields[xv], x-ray irradiation[xvi] and electron irradiation[xvii]. All these processes are related to charge injection[xviii] into the orbitally ordered phase of $Pr_{0.7}Ca_{0.3}MnO_3$.

Ultrafast pulses have indeed been used in the past to manipulate and study the dynamics of photo-induced phase transitions in this[xix] and other compounds. However, virtually all experiments to date have been limited to near-100-fs time resolution. This has only revealed dynamics on comparatively slow timescales, and only lattice vibrations at frequencies of a few THz have been detected (~10 meV energy scale). The experiments reported here are performed with 7-fs pump and 11-fs probe pulses. The order-of-magnitude decrease in pulse duration provides access to coherent modes at frequencies of tens of THz, reaching the hundreds-of-meV energy scale of collective electronic excitations.

We first performed time-resolved resistivity measurements at 77 K, which substantiate our claim of a photo-induced insulator metal transition (figure 1). A current amplifier was placed in series of the sample, which was held between two gold electrodes deposited on the surface. The combined temporal resolution of the oscilloscope and of the current amplifier was 1 ns. After femtosecond optical excitation, a prompt resistivity drop was observed from the static

value of $3 \cdot 10^4$ [Ω cm] to approximately 0.1 [Ω cm], a conductivity change of similar magnitude as that obtained by application of a 6T magnetic field at this temperature and doping[7]. The photo-induced conductivity exhibits non-linear growth with fluence above a threshold of 1 mJ/ cm^2, saturating above 30 mJ/cm^2. This behavior and the long lifetime of the high conductivity state are indicative of cooperativity in the de-stabilization of charge-order and of a photo-induced phase transition.

Figure 2a shows femtosecond pump-probe experiments at 77 K, highlighting the dynamics of the insulator-metal phase change. Optical pulses of 7-fs duration near 550-nm excited the O2p-Mn3d-eg charge transfer resonance in the low-T charge-ordered insulator. The broad bandwidth of the pump pulse coupled the O2p states to a coherent superposition of the Mn-eg levels. The probe pulse duration was set to 11 fs duration, corresponding to a limited bandwidth and allowing for measurements the time-dependent reflectivity response in different spectral regions. After photo-excitation, a large reflectivity change was observed. The spectral dependence of the differential reflectivity signal at 500 fs time delay (see figure 2a) shows an increase in reflectivity at shorter wavelengths and a decrease at longer wavelength, reminiscent of the effect seen upon application of a magnetic field[xx].

The time-profile of the differential reflectivity signal, for instance at the 660 nm wavelength shown in figure 2a, indicates that the phase transition *does not* occur promptly[xxi]. This is clearly indicated by the comparison with the cross correlation between 7-fs pump and 11-fs probe probe pulses, measured in situ. Two time constants of 50 and 150 fs were found. To further substantiate the delay found in the measured optical response, we measured the time-dependent transmission of a film of C$_{60}$ molecules, which exhibits prompt excited state absorption and follows the integral of the pump-probe cross-correlation signal.

The delay found in the formation of the product phase is the first important observation of our experiments, which can set a time and thus and energy scale for the ultrafast insulator-metal transition in manganites. The observed bottleneck timescale indicates that the photo-induced metallic state is not driven by sole carrier injection, but requires rearrangement in slower degrees of freedom of the system. Figure 2a also shows the spectral response of the reflectivity at 500-fs time delay, which exhibits a shift of the charge-transfer excitation similar to what observed upon application of a magnetic field.

We also found that the reflectivity change is accompanied by coherent modulations with a broad frequency distribution centered at 14-THz (see figure 2b). The frequency bandwidth of the oscillations covers many Raman-active modes of perovskite manganites, associated with motions of the oxygen octahedron and likely with the relaxation of the long-range Jahn-Teller distortion that stabilizes the low-T insulator[xxii]. The near-200-fs damping time of these coherent vibrations can probably be attributed to de-phasing of many phonon modes evolving at different frequencies.

Figure 3 shows the possible photo-excitation mechanisms for the coherent vibrations. One mechanism corresponds to a pure transfer of charge from the O2p states to the $Mn^{3+/4+}$ sites (mechanism a). Such photo-doping, if prompt compared to the period of a Raman active mode, can result in its *displacive* excitation in the *electronically excited* state[xxiii]. Displacive Excitation of Coherent Phonons (DECP) is related to the *imaginary part* of the Raman tensor, corresponds to the absorption of light and has a cosine-like temporal response. The second channel is possible only at the Mn^{3+} sites, where photo-excitation populates the upper unoccupied e_g state and de-populates the lower lying one, leaving a quantum of excitation in the system but maintaining charge neutrality (mechanism b). In this case a vibration is excited *impulsively* in the *electronic ground state*[xxiv,xxv]. This process is referred to as

Impulsive Stimulated Raman Scattering (ISRS), is related to the real part of the Raman tensor and has a *sine-like* temporal response. The vibrational oscillations of figure 2a behave like a sine wave, exhibiting zero phase at the instant of photo-excitation and clarifying that the latter mechanism, i.e. ISRS triggers the observed dynamics.

Summarizing our observations for the low temperature, charge ordered phase: coherent lattice vibrations associated with the motion of the oxygen atoms are excited by ISRS. These displacements couple to the Jahn-Teller distortion, and possibly also to the Mn-O-Mn angle (tolerance factor), mediating melting of charge order. This observation is consistent with our understanding of manganites below T_{co}. Because a long-range Jahn-Teller distortion stabilizing the parent insulating phase, melting of charge and orbital order is associated with motions of the network of oxygen atoms.

We now turn to the most provocative observation of our paper, i.e. that involving the dynamics of the phase change when initiated in the room temperature phase. Above T_{co}=220 K, $Pr_{0.7}Ca_{0.3}MnO_3$ behaves as a small-polaron insulator with no long-range Jahn-Teller distortion[xxvi]. In this phase, no colossal negative magneto-resistive behavior is observed. However, with photo-excitation we still observed the formation of a metallic state for approximately the same excitation fluence as that found at low temperatures (see figure 4a). The spectral dependence of the differential reflectivity is qualitatively similar to that reported in figure 2a, although the zero crossing occurs at longer wavelength, due to a shift in the charge transfer transition energy. The response at 660 nm wavelength has then similar size as that at low temperature but opposite sign. The observation of a photo-initiated metallic phase is quite remarkable, and it is indicative of the existence of a competing conducting phase all the way to room temperature. Presumably, colossal negative magneto-resistance does not

occur because of the low energy scale of magnetic fields, whereas the "barrier" between the two phases can be overcome with photo-excitation.

Significantly, the coherent excitations that accompany charge de-localization are near 31 THz, a frequency too high to be associated with lattice distortions in this crystal structure. Rather, this frequency is commensurate with the energy scale of d-d crystal-field excitations, or orbital waves (31 THz: 135 meV). Impulsive Stimulated Raman Scattering of coherent orbital waves, again indicated by sine-like oscillations, is then be qualitatively analogous to the excitation of spin-waves in ferro or anti-ferro magnetic systems, where a spin defect is introduced and a precessional wave is launched. In the present case, the collective orbital excitation likely corresponds to the excitation of a single pseudo-spin on a Mn^{3+} 3d site, effectively "flipping" one orbital and launching a "hybridization" wave (see figure 4b). While these excitations, or orbital defects, are likely to initially extend only over the coherence length of small polarons, an "orbital wave" may propagate beyond this length and accompany the coalescence of different clusters into the metallic phase.

Evidence for orbital modes close to equilibrium has been claimed from Raman experiments in a different perovskite manganite[xxvii] and in titanates[xxviii], where energy shifts corresponding to the frequencies measured here were detected. Yet, a competing interpretation of the manganite experiments has argued that such peaks may have instead arisen from multi-phonon excitation[xxix]. It is important to stress that the conditions of our experiments are far from equilibrium, and the heavily photo-excited state ($\sim 10^{22}$ absorbed photons/cm^3) could well be characterized by a different spectrum of excitations than those probed in Raman scattering. Thus, a direct comparison cannot be made.

However, the possibility of multiple-phonon excitation should be discussed also for our experiments. The theory supporting the existence of large-amplitude, multiple phonon

excitations in Raman experiments addresses this issue in terms of a self-trapping exciton in the Franck-Condon state of a localized MnO_6 "molecule". For the Raman experiments, emission of inelastically scattered radiation is then coupled to a multiply-excited, ground-state vibration, corresponding to multiple-phonon peaks[xxx]. However, our experiments can easily discriminate between these two possibilities, at least in a localized picture. In fact, unlike in Raman experiments where the energy of an excitation is measured, we directly detect its frequency ν. Thus, we can discriminate between a multiply-excited oscillator (which still exhibits the fundamental frequency ν_1, increased amplitude and where $E_{Raman} = 2 h \bullet \nu_1$) and a singly excited one with higher energy (where the frequency ν_2 is high and where $E_{Raman} = h \bullet \nu_2$). Thus, we can safely exclude the possibility of a two-phonon response triggered by self-trapping of a localized exciton.

The other possibility would be the excitation of a true two-phonon state of an extended solid, sometimes referred to as vacuum squeezing of phonon fields[xxxi]. The time-domain oscillations then wouldn't correspond to atomic motions but to oscillations in the variance of the phonon-coordinate expectation value[xxxii]. If this were the case, one should observe both the fundamental frequency and a weaker contribution at the sum frequency, which we do not. This leaves only the possibility of a phonon signal forbidden by symmetry at k=0, where optical probing is performed. However, if this were the case, a low frequency phonon contribution should also not be observable in the low-temperature phase, which has the same crystallographic structure as the high-temperature phase. Yet, at low temperatures we see *only* the low-frequency vibrational excitation. Based on these arguments, we conclude that low and high-frequency oscillations are associated with different modes of the system, namely vibrational and orbital excitations.

In summary, the picture that emerges from probing the photo-induced insulator-metal transition with high temporal resolution is one where collective rearrangements are responsible for a time-delayed charge de-localization process. Different coherent excitations accompany the phase change. In the low-T phase, where a long-range Jahn-Teller distortion stabilizes the parent insulator, a coherent vibrational mode is observed across the ultrafast "melting" pathway of charge and orbital order. More provocative are the observations in the small-polaron phase, where no long-range Jahn-Teller distortion is present. In this case, we also find a phase change to a metastable metallic phase, accompanied by a coherent mode at higher frequencies, suggestive of a coherent orbital wave. Much remains to be understood of the ensuing dynamics, especially how this localized electronic excitation couples to other degrees of freedom, including magnetic excitations. Further, new questions arise on how local photo-domains coalesce into a ferromagnetic metallic phase. In the future, femtosecond x-ray experiments may separately measure dynamics of the lattice[xxxiii] and of electronic[xxxiv] or magnetic degrees of freedom, extending work performed in the past on longer timescales and shedding new light onto the non-equilibrium physics of photo-induced phase transitions in complex materials.

MATERIALS AND METHODS

$Pr_{0.7}Ca_{0.3}MnO_3$ single crystal samples were grown with the floating zone method, cut and polished to a mirror finish for optical experiments. Laue diffraction was used to check the quality of the single crystal samples after processing.

Measurements of the time-dependent sample resistivity (see figure 1) were performed as follows. Gold electrodes with a 200 μm-wide gap are deposited on the sample surface, and are DC-biased at 30 V. Laser pulses excited the sample with the laser spot fully covering the

space between the electrodes. The current flowing through the sample was monitored by measuring the voltage drop across a 50-Ω resistor. The high conductivity state develops within the 4-ns resolution of the electronics, and exhibits a similar resonance behavior as observed in the optical measurements.

For the femtosecond pump probe experiments, independently tunable ultrafast pulses of sub-10 fs duration were derived from two non-collinear optical parametric amplification of white-light continuum in two separate Beta-barium borate non-linear crystals (BBO), followed by independent compression with two pairs of chirped mirrors (see G. Cerullo et al. *Appl. Phys. Lett.* **71**, 3616 (1997)).

FIGURE CAPTIONS

Figure 1: Time-resolved measurement of the nanosecond conductivity transients induced by photo-excitation in single crystal $Pr_{0.7}Ca_{0.3}MnO_3$ at 77 K. The experimental apparatus, sketched in the figure is described in the methods section. The measurements are indicative of a photo-induced change in resistivity of nearly six orders of magnitude.

Figure 2: (a) Femtosecond optical reflectivity measurements of $Pr_{0.7}Ca_{0.3}MnO_3$ at 77 K. Shown in the upper graph are: the reflectivity response of $Pr_{0.7}Ca_{0.3}MnO_3$ (red curve), a fit to the delayed reflectivity response (dashed black curve), a pump-probe cross-correlation (thicker black curve), photo-induced transmission changes in a thin film of C_{60} molecules deposited (thinner black curve). The differential reflectivity for different probing wavelengths at a time delay of 500-fs is shown in the lower panel.

(b) Oscillatory time-profile obtained by subtracting a fitted biexponential rise from the from the measured reflectivity transient. The phase of the oscillation is zero at the instant of photo-excitation, indicative of Impulsive Stimulated Raman Scattering excitation. The amplitude Fourier transform of this over-damped mode is also shown in the right panel, showing broadband excitation of many modes at once.

Figure 3: Excitation process in $Pr_{0.7}Ca_{0.3}MnO_3$ in the 2.5 eV photon-energy range. 7-fs optical pulses excite transitions between the O2p states and a coherent superposition of both Jahn Teller split eg states of the $Mn^{3+/4+}$ sites. Both direct photo-doping (mechanism a) and Impulsive Stimulated Raman Scattering (mechanism b) correspond to the creation of charge and orbital defects. As discussed in the text, analysis of the temporal phase of the oscillatory signal indicates that mechanism b is dominat. On the left had side of the sketch we plot the measured spectrum of the pump pulse, covering a bandwidth of more than 200 nm. On the right hand side we show the corresponding spectra of probing pulses of slightly longer duration, used to measure the response of the system at different wavelengths.

Figure 4: (a) Time resolved reflectivity measurement at room temperature. Heavily damped excitations near 31-THz accompany the phase transition. **(b)** Broadband waves are observed, with a spectrum well beyond the region where vibrational excitations (dashed curve). The sine-like phase of the oscillation clarifies the Impulsive Stimulated Raman Scattering excitation mechanism, amounting to a simple "flipping" of a pseudo-spin. A pictorial representation of a time-dependent orbital wave on a single site is also shown, representing the time and spatially periodic hybridization wave that underpins the physics of coherent orbital waves, is presented above the graph.
