ABSTRACT

We have studied the improvement in simultaneous measurements of concentrations and isotopic compositions for plutonium in input spent-fuel dissolver solutions at a reprocessing plant by isotope dilution gamma-ray spectrometry (IDGS) technique. The IDGS technique uses the high-resolution low-energy gamma-ray spectrometry and isotope dilution method. The dissolver solutions are subsequently measured using high-resolution gamma-ray spectrometry following the fission product separations by extraction chromatography using U/TEVA•Spec resins. The improved method can simplify the separation procedure and save more than 2 hours in sample preparation time. The results of plutonium concentrations and isotopic compositions of dissolver solutions analyzed by IDGS agree very well with those obtained by traditional isotope dilution mass spectrometry. The rapid and accurate IDGS technique with the improved separation method could provide a timely, less expensive, and simpler on-site verification method for the input accountability measurements.

INTRODUCTION

The rapid and accurate measurements of samples derived from spent fuel are a requisite for input accountability analysis and nuclear material control and for on-site verification: essential elements of the near-real-time accounting (NRTA) system at reprocessing plants. Presently, materials are prepared and sent to a centralized location for destructive analysis by isotope dilution mass spectrometry (IDMS); this process is expensive and time consuming and therefore precludes the possibility of timely results. One possible means of reducing the analysis time is to employ on-site nondestructive assay techniques where samples can be analyzed within the processing facility. One such technique that recently has been developed, isotope dilution gamma-ray spectrometry (IDGS), [1-3] employs a standard plutonium spike and passive gamma spectroscopy to determine the plutonium isotopics and concentration in spent-fuel dissolver solutions.

Isotope dilution gamma spectroscopy permits the simultaneous determination of plutonium isotopics and concentration in spent fuel dissolver solutions based on information from two gamma spectra, one each from the spiked and unspiked solutions, and a previously characterized plutonium spike. Resin bead techniques have previously been developed using ion-exchange [1-2] and extraction chromatography [3] to rapidly separate fission fragments and recover plutonium for the spectroscopy measurements. The plutonium isotopic ratios are determined from the high-intensity

low-energy gamma lines since typical samples may contain less than 0.5 milligrams of plutonium; in principle; however, any resolved plutonium lines may be used for this purpose.

For concentration measurements, the technique involves the dissolution of a plutonium spike with well-characterized mass and isotopics: previously used spikes consisted of 0.00245% ²³⁸Pu, 97.921% ²³⁹Pu, 2.0604% ²⁴⁰Pu, 0.0141% ²⁴¹Pu, and 0.001324% ²⁴²Pu. Gamma spectra are acquired for the spent-fuel dissolver solution before and after the spike is added and the relative isotopics are determined for each.

Previously, over 20 dissolver solutions [1-3] with plutonium concentrations varied from 0.6 g Pu/L to 1.6 g Pu/L have been analyzed. The range of plutonium isotopic abundances in weight percent is 0.34% to 1.24% for ²³⁸Pu, 58.24% to 70.84% for ²³⁹Pu, 21.21% to 27.94% ²⁴⁰Pu, 4.00% to 8.9% for ²⁴¹Pu, and 1.4% to 5.2% for ²⁴²Pu. Typically a 1-h counting period produces a precision better than 1% for plutonium concentrations and a bias between IDGS and IDMS of less than 0.2%. Precision of 0.5% and 0.2% is typical for ²⁴⁰Pu/²³⁹Pu ratio and the ²³⁹Pu weight percent, respectively. The agreement between IDGS and IDMS is generally excellent, especially for the ²⁴⁰Pu/²³⁹Pu ratio (average IDGS/IDMS ratio is 1.003) and the weight percent of ²³⁹Pu (average IDGS/IDMS ratio is 1.000). Success in these isotopic measurements is essential if an accurate determination of the total plutonium concentration is to be made.

To reduce sample preparation and measurement time, we have studied several separation scheme options. This paper will discuss the improvement in fission product separation and measurement methods on input spent-fuel dissolver solutions and will also examine the results of plutonium by using this simplified sampling method incorporated into the IDGS technique.

IMPROVEMENTS IN SAMPLE PREPARATION

In addition to ion exchange, we have developed a new sample preparation method, extraction chromatography using U/TEVA•Spec resin [3] (for uranium and tetravalent actinides specifically) to purify and recover both plutonium and uranium from dissolver solutions. U/TEVA•Spec is a novel extraction chromatographic resin [4] composed of diamyl amylphosphonate sorbed on an inert polymeric support (Amberlite XAD-7 or Amberchrom CG-71). The resin is commercially available from EIChroM Industries, Inc.

The separation scheme for preparing the sample by using the extraction chromatography is showed in Fig. 1. Each 1 mL aliquot for the spiked samples and the unspiked samples were taken from dissolver solutions, and the weight of the taken 1 mL aliquot sample was measured by a precise electronic balance. The spiked samples were prepared by dissolving the dissolver solutions (1 mL aliquot) with large size dry (LSD) spikes at 90°C on a heater and then mixing them by a magnetic stirrer. Plutonium in these samples was completely adjusted to tetra-valence with Fe (II) and NaNO₂, and they were dissolved again with 8M-HNO₃: (1 mL) after heating them to near-dryness at 90°C. Each sample was individually passed through the extraction chromatographic columns (U/TEVA • Spec resin) adjusted with 8M-HNO₃, fission products and americium were separated from uranium and plutonium by washing with 8M-HNO₃, 3M-HNO₃, and 0.01M-HNO₃. Uranium

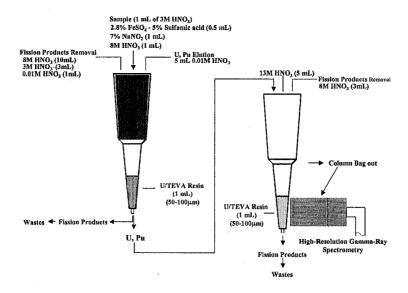

Fig. 1. Plutonium and Uranium separation scheme using U/TEVA•Spec® resin

and plutonium were eluted with 0.01M-HNO₃. Eluted ones were absorbed in the columns again, and fission products like ruthenium were completely separated by washing with 3M-HNO₃. Because gamma rays of fission products have possibly influencing the gamma-ray measurements if significant amount of fission products were still contained in the samples. Each sample was carefully removed not to contaminate with a plastic bag from a glove box and measured by a high-resolution gamma-ray spectrometry (HRGS). A typical gamma-ray spectrum of spent-fuel dissolve solution after chemical separation with extraction chromatography using U/TEVA•Spec resins is shown in Fig. 2.

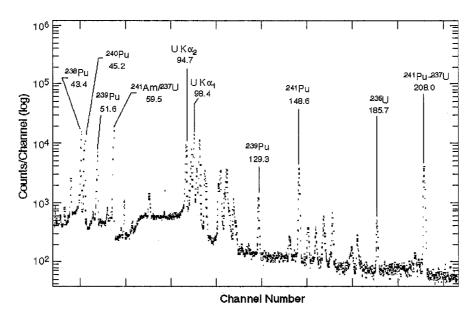

Fig. 2. Gamma-ray spectrum of spent-fuel dissolve solution after chemical separation with extraction chromatography using U/TEVA•Spec resins.

For plutonium concentration measurements, the spiked samples were prepared by dissolving the dissolver solutions (1 ml aliquot) with LSD spikes at 90°C on a heater and then mixing them by a magnetic stirrer. The spiked dissolver solutions were then separated, eluted, recovered, and measured as described above for unspiked dissolver solutions.

We refer the separation scheme discussed above as Scheme O. To improve and simplify the sample preparation, we have considered and examined several optional separation schemes as follows:

- 1. Scheme A: Same as Scheme O discussed above and shown in Fig. 1, except heat at 90°C for 30 min. after valency adjustment with NaNO₂.
- 2. Scheme B: Same as Scheme O discussed above and shown in Fig. 1, except heat at 90°C for 10 min. after valency adjustment with NaNO₂.
- 3. Scheme C: First part of Scheme A. No elution with 0.01M-HNO₃ and the second fission products re-washing in Scheme A. Bag out the column for HRGS measurement after the first fission products removal. Scheme C is shown in Fig. 3.
- 4. Scheme D: First part of Scheme B. No elution with 0.01M-HNO₃ and the second fission products re-washing in Scheme B. Bag out the column for HRGS measurement after the first fission product's removal. Scheme D is shown in Fig. 3.

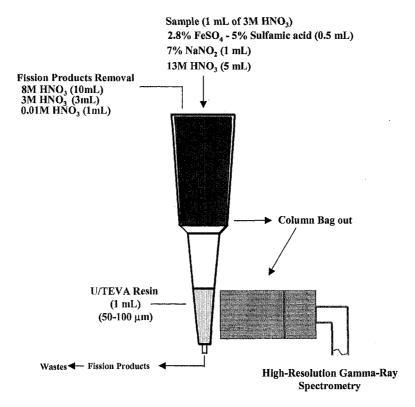

Fig. 3. Simplified separation scheme using U/TEV•Spec® resin.

ANALYSIS METHODS

Details of the IDGS measurement technique and method are described in [1] and [2]. Briefly, in IDGS the isotopic composition is determined by measuring the respective gamma rays emanating from the isotopes within the dissolver solution. The measurement method of the plutonium isotopic ratios is based on high-resolution, low-energy, gamma-ray spectrometry (LEGS). Because the assay necessitates the use of small sample volumes (containing less than 0.5 mg of plutonium), the isotopic ratios ²³⁸Pu/²³⁹Pu, ²⁴⁰Pu/²³⁹Pu, and ²⁴¹Pu/²³⁹Pu are best determined from the very highintensity, low-energy gamma-ray ratios 43.48 keV/51.63 keV, 45.23 keV/51.63 keV, and 148.6 keV/129.3 keV, respectively. [1-3] To measure the total plutonium concentration, the unknown solutions are spiked with plutonium of accurately known plutonium mass and isotopic composition. The isotopic compositions of both unspiked dissolver solution (unknown sample only) and spiked dissolver solution (unknown sample plus the spike) samples [1-2] are measured by LEGS. The concentration of plutonium, C (Pu), in the unknown dissolver solution is then determined by calculating the difference among the isotopic ²⁴⁰Pu/²³⁹Pu ratios of the spike, the spiked samples, and the unspiked samples.

$$C(\operatorname{Pu}) = \frac{M_s}{V_u} \bullet \frac{W_s^9}{W_u^9} \bullet \frac{R_m - R_s}{R_u - R_m} , \qquad (1)$$

where

 M_S = mass of plutonium in the spike,

 V_u = volume of dissolver solution taken,

 W_s^9 = weight fraction of ²³⁹Pu in the spike, W_u^9 = weight fraction of ²³⁹Pu in the dissolver solution,

 $R_m = \text{the }^{240} \text{Pu}/^{239} \text{Pu ratio in the spiked sample,}$

 R_S = the ²⁴⁰Pu/²³⁹Pu ratio in the spike, and

 R_u = the ²⁴⁰Pu/²³⁹Pu ratio in the dissolver solution sample.

In this equation, the spike-related parameters W_s^9 and R_s are known values while M_s are V_u are determined by standard analytical techniques. This leaves the quantities W_u^9 and R_u in the unspiked dissolver-solution sample and R_m in the spiked sample to be determined via gamma-ray spectrometry.

RESULTS AND DISCUSSIONS

Table I shows the gamma-ray plutonium isotopic compositions (in weight percent) for the dissolver solutions as determined by IDGS. The range of plutonium isotopic abundances (wt. %) is 0.34% to 1.24% for ²³⁸Pu, 58.24% to 70.84% for ²³⁹Pu, 21.21% to 28.57% for ²⁴⁰Pu, 4.00% to 8.9% for ²⁴¹Pu, and 1.4% to 5.2% for 242 Pu. The uncertainties represent the estimated precision (1 σ) of gamma-ray spectroscopy as calculated from counting statistics, including uncertainties from relative efficiencies. The Dissolver Solutions 1-6 data are taken from the previous experiment (with Scheme O) in Ref. 3 for comparisons. The Dissolver Solutions 7-12 data are obtained from this experiment. The plutonium isotopic compositions of dissolver solutions as determined by IDGS and IDMS are also compared in Table I. The IDGS results of five separation schemes are similar. The results of Schemes A, B, C, and D agree with the IDMS reasonably well and are consistent with those of Scheme O.

10	10 B		1.584	1.0003							
11	11 C		1.276	1.0035							
12	D	1.575	1.584	0.9945							

concentrations of dissolver solutions varied from 0.62 g Pu/ ℓ to 1.58 g Pu/ ℓ . The plutonium concentrations obtained by IDGS in this experiment agree with those obtained by IDMS within 1%. These results are consistent with those of previous experiments by the Scheme O method [3] and by the anion-exchange resin and filter techniques. [1-2]

From results of plutonium isotopic compositions and concentrations, schemes C and D are very encouraging for rapid plutonium assay of input dissolver solutions at reprocessing plants. The simplified separation schemes C and D could save more than two hours in sample preparation time. We are planning to measure more samples with schemes C and D to confirm the present results.
