MAIN PRO-APOPTOTIC MEMBER OF BCL-2 FAMILY PROTEINS – BAX

Abstract: Programmed cell death (apoptosis) plays a vital role in the regulation of cellular homeostasis. Because of apoptosis fundamental importance, this process is highly regulated. One important set of factors involved in apoptosis regulation is the Bcl-2 family proteins. Bcl-2 family members form a complex regulatory network that controls cell survival and death in response to different physiological and pathological signals. This family includes both pro- and anti-apoptotic members, and Bax protein (Mol wt 21 kDa) is a major pro-apoptotic factor with multifunctional activity. This review summarizes new data about the main representative of Bcl-2 family – Bax, its structure and mechanism(s) by which this protein modulates apoptosis.

Key words: apoptosis, Bcl-2 family, Bax, apoptosis mitochondrial pathway

1. INTRODUCTION

Apoptosis is a precisely controlled mode of eliminating injured, mutated or unwanted cells from the body or an organ of multicellular organism that, in contrast to necrosis, does not trigger the inflammation (HENGARTNER 2000; WYLLIE 2010). It is widely accepted that apoptosis may go through two major pathways (extrinsic and intrinsic), one of which involves mitochondria with proteins localized inside the intermembrane compartment of these organelles (KILIAŃSKA 2002). The mitochondrial (intrinsic) pathway of apoptosis is activated in response to several proapoptotic stimuli such as DNA damages, alterations in cytoskeleton stability

(RODOLFO, PIACENTINI 2002; NDOZANGUE-TOURIGUINE *et al.* 2008), reactive oxygen species (ROS), endoplasmic reticulum (ER) stress (MEIR *et al.* 2010), hypoxia (GREIJER, VAN DER WALL 2004), cytokine deprivation (SAVARAJ *et al.* 2010; WYLLIE 2010), oncogene overdrive (WYLLIE 2010) as well as a large number of anticancer drugs (ŻOŁNIERCZYK *et al.* 2009; ROGALIŃSKA *et al.* 2010). All these death signals lead to permeabilization of outer mitochondrial membrane (OMM) and to the leakage of proapoptotic factors (procaspases, including procaspase-9, cytochrome c, Smac/DIABLO (Second mitochondria-derived activator of caspases/Direct IAP-binding protein with low pI), apoptosis inducing factor – AIF, endonuclease G, Omi/HtrA2 (High temperature requirement protein A2) protease as well as some heat shock proteins – Hsp10 or Hsp 60) into the cytosol where they initiate caspase activation and DNA fragmentation (KRAJEWSKI *et al.* 1999; SHAN *et al.* 2003; LOWE *et al.* 2004; BEDNAREK, KILIAŃSKA 2005). It is thought that protein efflux out of mitochondria is irreversible step of apoptosis. Therefore, it must be accurately controlled (CHIPUK *et al.* 2006; CHIPUK, GREEN 2008). A key role in this regulation is attributed to Bcl-2 (B-cell leukemia/lymphoma 2) family proteins many of which have become the objects of targeted therapy in oncology (BORNER 2003; WARR, SHORE 2008; WYLLIE 2010). This review focuses on the current data concerning the structure and biological activity of the main pro-apoptotic member of Bcl-2 family proteins, Bax, and especially the mechanisms by which it evokes OMM permeabilization and apoptosis induction.

2. BCL-2 FAMILY PROTEINS

Up to now, over 30 proteins have been identified in higher eukaryotic cells that belong to Bcl-2 family (SKOMMER *et al.* 2007). They are all generally characterized by the presence of at least one highly conserved motif referred as Bcl-2 homology domain (BH) in their molecules. These domains, in number 1-4, take part in the mutual interactions between Bcl-2 family proteins as well as in the communication with other factors endowed with similar BH domain i.e. HAX-1 (Hematopoietic-specific protein 1-associated protein X-1) (YEDAVALLI *et al.* 2005;

HOSSINI, EBERLE 2008). The Bcl-2 family comprises three subfamilies of proteins (Fig. 1):

- **Bcl-2-like survival factors** – multi-domain anti-apoptotic proteins i.e. Bcl-2, Bcl-X_L (Bcl-2 related gene, long isoform), Bcl-w (Bcl-2 widely expressed), Mcl-1 (Myeloid cell leukemia-1), Bcl-B (Bcl-2 family protein resembling Boo) and A1/Bfl-1 (KE *et al.* 2001; BORNER 2003; CORY *et al.* 2003; DROIN, GREEN 2004; REED 2008; SCHRÖDER 2008). These subfamily members typically possess 4 BH domains in their structure and they are usually anchored to intracellular membranes of the cell.
- **Bax-like death factors** – multi-domain pro-apoptotic proteins e.g. Bax (Bcl-2 associated x protein), Bak (Bcl-2 antagonist/killer 1), Bok/Mtd (Bcl-2-related ovarian killer/Spanish: Matador – the killer), Bcl-X_S. They have three (or 4 in case of Bok/Mtd) BH domains and play a role as effector molecules capable of directly inducing mitochondrial permeabilization and apoptosis (BORNER 2003).
- **BH3-only death factors** – single-domain pro-apoptotic proteins e.g. Bad (Bcl-2 antagonist of cell death is equivalent to Bcl-2 associated death promoter), Bid (BH3-interacting domain death agonist), Bik (Bcl-2 interacting killer), Bim (Bcl-2 interacting mediator of cell death), Bmf (Bcl-2 modifying factor), BNIP3 (Bcl-2 and adenovirus E1B 19-kDa protein interacting protein 3), Bnip3L (Bnip3-like), Hrk (Harakiri), Noxa/APR, Puma (p53-upregulated modulator of apoptosis) and Spike (Small protein with inherent killing effect). The members of this subfamily contain exclusively one domain – BH3; some of BH3-only proteins contain transmembrane domain, TM. They interact with Bax-like as well as Bcl-2-like proteins determining the fate of a cell (GUO *et al.* 2001; MOLDOVEANU *et al.* 2006; SKOMMER *et al.* 2007; HOSSINI, EBERLE 2008; REED 2008).

Recently, several other pro-apoptotic proteins have been discovered, however their classification turned out to be very difficult due to the presence of only two BH domains in their structure. For example, Bfk (Bcl-2 family kin) and Bcl-G proteins contain BH2 and BH3 while Bcl-X_S (Bcl-2 related gene, short isoform) and Bcl-X_{AK} (Bcl-2 related gene, alternative killer) are equipped with BH3

and BH4 or BH2 and BH4 domains, respectively; the latter is usually connected with anti-apoptotic potential of proteins (BORNER 2003; KARST, LI 2007; HOSSINI, EBERLE 2008). Similarly, Bcl-rambo shares the structural homology with anti-apoptotic factors of Bcl-2 family although its overexpression induces apoptosis (KATAOKA *et al.* 2001; HOSSINI, EBERLE 2008). Boo/Diva (Death inducer binding to vBcl-2 and Apaf-1) protein that comprises 4 BH domains may in turn act as pro-apoptotic or pro-survival molecule depending on the cellular context (LEE *et al.* 2001).

Fig. 1. Domain structure of Bcl-2 family proteins (based on: CHIPUK *et al.* 2006; CHIPUK *et al.* 2008; BORNER 2003). The Bcl-2 family of proteins (multi-domain – A; BH3-only – B) is divided into 3 functional subfamilies (1, 2, and 3) based on their composition of BH (1-4) domains. For more details see text. α 1-9 – α -helices; BH – Bcl-2 homology domain; TM – transmembrane domain. The BH3 domain in the pro-apoptotic proteins is a ligand for the hydrophobic pocket formed by the BH1-BH3 domains of the anti-apoptotic members of Bcl-2 family.

The classification of Bcl-2 family proteins based on their role in apoptosis seems to be rather conventional since the phenotype of many pro- or anti-apoptotic

proteins can be changed into the opposite one under some special conditions (LIN *et al.* 2004; HANSON *et al.* 2008). For example, Bcl-X_L protein, known as anti-apoptotic factor, may interact with mitochondria and induce OMM permeabilization after the binding phosphorylated K-Ras (phosphorylation on Ser¹⁸¹). Likewise, interaction of Bcl-2 protein with orphan receptor – Nur 77 (Nuclear receptor 77) converts the anti-apoptotic potential of Bcl-2 to pro-apoptotic (KOLLURI *et al.* 2008). It was demonstrated that Nur 77 also affected other generally anti-apoptotic proteins, such as Bcl-B, A1/Bfl-1, leading to reversion of their phenotype (LUCIANO *et al.* 2007).

2.1. Structure of Bcl-2 family proteins

Examination of the solution structure of Bcl-2 family proteins revealed some structural resemblances between pro- and anti-apoptotic molecules. These proteins adopt donut-shaped structure with two central, hydrophobic α -helices surrounded with 6-7 amphipathic α -helical regions. Additionally, they contain a long (60 aa), unstructured loop between the first and the second helical region of proteins (PETROS *et al.* 2004; SKOMMER *et al.* 2007; BORNER 2003).

BH1, BH2, and BH3 domains play an important role in the interactions of anti-apoptotic proteins with their pro-apoptotic opponents (PETROS *et al.* 2004; HOSSINI, EBERLE 2008)]. In pro-survival as well as in inactive pro-apoptotic proteins above domains form together a hydrophobic pocket which binds BH3 motif of pro-apoptotic molecule by electric and hydrophobic interactions (BORNER 2003; PETROS *et al.* 2004; HOSSINI, EBERLE 2008). Evolutionary conserved amino acid residues – Gly¹⁴⁵ and Arg¹⁴⁶ localized in BH1 as well as Trp¹⁸⁸ in BH2 domain of anti-apoptotic proteins play a key role in the communication between the receptor pocket and BH3 domain of pro-death factor. It was indicated that the substitution of Gly145Ala/Glu and Trp188Ala prevented the heterodimerization of Bcl-2 family proteins, suggesting that these residues take part in the binding of hydrophobic cleft to BH3 domain (GURUDUTTA *et al.* 2005).

The *in vitro* tests revealed that both Bax and Bcl-2 proteins were able to form channels permeable for chloride or potassium ions, respectively in the membranes

(BORNER 2003; PETROS *et al.* 2004). The process of pore forming required hydrophobic α -5 and α -6 helices overlapping the BH1 domain and the stretch between BH1 and BH2 regions. Both of them bear a resemblance to toxins produced by some bacterial strains (i.e. *Escherichia coli* or *Corynebacterium diphtheriae*) against others. It is thought that the selectivity of Bcl-2 family protein-forming channel is determined by amino acid sequence and electric charge of molecule(s) engaged in its assembly. Moreover, the chemical composition of the membrane surrounding the protein is not insignificant for its poration activity (CHRISTENSON *et al.* 2008). It has been shown that negatively charged phospholipid – cardiolipin supports the pore-forming activity of Bax whereas cholesterol-rich bilayers inhibit Bax integration into the membranes (CHRISTENSON *et al.* 2008).

BH3 domain is composed of 9-16 amino acid residues highly conserved among all Bcl-2 family proteins. It fulfils the role of ligand binding region which is necessary for both hetero- and homo-dimerization and apoptosis triggering (FREY *et al.* 2008). The BH3 domain of anti-apoptotic proteins is an integral part of hydrophobic cleft built with BH1, BH2 and BH3 in contrast to the BH3 domains of pro-apoptotic factors of this family which are hidden inside the molecules of inactive proteins or are exposed to the outside of the molecules when they are active (BORNER 2003; PETROS *et al.* 2004). Unbound BH3 domain of free pro-apoptotic proteins indicates unorganized structure while after their dimerization with pro-survival partners it forms amphiphatic helix penetrating the hydrophobic pocket (BORNER 2003). It is worth mentioning that the substitution of Asp¹⁶⁰ in BH3 domain of Bad with Arg that facilitates the adoption of α -helical structure widely increased the affinity of BH3 peptide to Bcl-X_L protein (PETROS *et al.* 2004).

In addition, the amino acid sequence of Bcl-2 family proteins plays an important role for this interaction. It has been reported that conserved residues – Leu and Asp occupy the position 1 and 6 of BH3 domain in all Bcl-2 family members, whereas Ala or any hydrophobic amino acid (usually Ile) is situated at position 4 of BH3 domain in anti- or pro-apoptotic proteins, respectively.

BH4 domain is localized in amino terminal region of anti-apoptotic Bcl-2 family members as well as some pro-apoptotic proteins (Bcl-x_s, Bcl-rambo,

Bok/Mtd, Boo/Diva) (HOSSINI, EBERLE 2008). For a long time, it was thought that BH4 domain was responsible for apoptosis inhibiting activity of pro-survival molecules (HOSSINI, EBERLE 2008). However, some anti-apoptotic proteins, e.g. Mcl-1, do not possess the above conserved region, but they all include a helical region – $\alpha 1$. In most of anti-apoptotic proteins this motif is enclosed in the BH4 domain. Currently, it seems that just this helical structure controls pro-survival function of Bcl-2 inhibitors regardless of its amino acid sequence. Similar α -helical region was found in Bax molecule in which it negatively regulates pro-apoptotic function of this protein (CARTRON *et al.* 2004).

Some anti-apoptotic Bcl-2 family members contain a 60-aa regulatory loop between α -1 and α -2 helices that seems to work as a region of autoinhibition (Lin 2004, PETROS *et al.* 2004). Chemical modifications (such as phosphorylation) within a given region result in abolishing the pro-survival potential of anti-apoptotic proteins and conversion of their phenotype.

Most of Bcl-2 family representatives contain a C-terminal 15-20-aa hydrophobic sequence – transmembrane (TM) domain – neighboring positively-charged amino acid residues of Lys or Arg, that enables them to attach to the membranes of mitochondria, endoplasmic reticulum or cell nuclei (PETROS *et al.* 2004; SCHINZEL *et al.* 2004a). Some of the proteins anchor to membranes immediately after their synthesis while others possess a transmembrane domain hidden inside their molecule and require to pass some conformational changes to expose TM on the surface (BORNER 2003; SCHINZEL *et al.* 2004a).

3. BAX PROTEIN – A KEY EFFECTOR IN MITOCHONDRIAL PATHWAY OF APOPTOSIS

Human *Bax* gene is located on long arm of chromosome 19 within the region q13.3-q13.4 (APTE *et al.* 1995). This gene is about 4500 bp long and contains six exons. Alternative splicing of its primary transcript produces several isoforms of Bax (α , β , γ , δ , ω , σ and ψ) (CARTRON *et al.* 2002; DROIN, GREEN 2004). In ischemic rat brain a novel splice variant of Bax, Bax κ , was identified (JIN *et al.* 2001). Main variant, firstly isolated – Bax α is encoded by all exons and has a molecular weight

of 21 kDa (192 aa). Its name – Bax (Bcl-2 associated x protein) is derived from its ability to neutralize and block the function of the main anti-apoptotic protein – Bcl-2 (BORNER 2003). Function of the rest of Bax variants still remains unknown (DROIN, GREEN 2004). The promoter of *Bax* has two canonical E-box motifs that bind c-Myc/Max (*Myc associated factor X*) heterodimers. Moreover, *Bax* is under the control of P53 transcription factor and is involved in P53-mediated apoptosis (CARTRON *et al.* 2002).

Bax protein – an effector promoter of apoptosis is constitutively expressed in the cells. In vital cells the described polypeptide is identified only as an inactive monomer or as the molecule bound to anti-apoptotic partner. Apoptosis-inhibitory proteins have a potential to neutralize the function of pro-death factors (CHIPUK *et al.* 2006; CHIPUK, GREEN 2008). It is accepted that in vital cells Bax is mainly localized in the cytosol, although it can be loosely attached to intracellular membranes (SCHINZEL *et al.* 2004b; SCHLESINGER, SAITO 2006). After activation in response to pro-death signals, Bax undergoes some conformational changes thereby incorporating the mitochondrial membranes persistently, forming pores and inducing OMM permeabilization (CHIPUK *et al.* 2006; CHIPUK, GREEN 2008). In active state this protein indicates diminished sensitivity to alkaline treatment, trypsin digestion as well as decreased susceptibility to proteolysis of $\alpha 5$ and $\alpha 6$ helices (BORNER 2003). In this state a significant increase of N-terminal region of Bax immunoreactivity (6A7 epitope between 13 and 19 amino acids) was demonstrated. However, this feature is thought to be reversible and independent of pro-survival Bcl-2 proteins (BORNER 2003; SHARPE *et al.* 2004). It would seem that the 6A7 epitope exposition on the surface of Bax appears at very early stage of its conformational changes and it precedes protein oligomerization. Therefore, this immunoreactivity elevation can not be strictly identified with Bax activation and apoptosis induction (SHARPE *et al.* 2004). In addition, it is believed that Bax translocation and oligomerization are not enough to induce permeabilization of OMM, although they both are required (SKOMMER *et al.* 2007).

Bax protein shares a strong similarity of its tertiary structure with anti-apoptotic members of Bcl-2 family, such as Bcl-2 and Bcl-X_L (SUZUKI *et al.* 2000;

BORNER 2003; PETROS *et al.* 2004). Above polypeptide contains 9 α -helices. The seven of them surround two centrally-localized hydrophobic α -helical structures. The helix $\alpha 5$ is positioned the most internally in the molecule. Between helices α -1 and α -2 a long flexible loop region can be observed. BH1, BH2 and BH3 domains of the described protein, embraced with α -2, α -3 and α -4 helices, lay in the same orientation as the domains of Bcl-X_L. In living cells they form hydrophobic cleft in analogous manner as anti-apoptotic proteins. It prevents from Bax dimerization under normal conditions (DROIN, GREEN 2004). In contradiction with Bcl-X_L or Bcl-2 proteins, BH3 domain of Bax does not go so deep into the hydrophobic pocket of a protein. Additionally Bax, similarly as anti-apoptotic factors, possesses in C-terminus a transmembrane region responsible for directing of the molecule to the mitochondrial membrane (Fig. 1) (SUZUKI *et al.* 2000; SCHINZEL *et al.* 2004b). However, TM region of Bax, unlike of Bcl-2 or Bcl-X_L, is not exposed to the cytosol. Instead of that, it moves back towards the pocket and binds to it as Bak or Bad proteins bind the hydrophobic pocket of Bcl-X_L (SUZUKI *et al.* 2000; BORNER 2003; PETROS *et al.* 2004). It has been revealed that a hydrogen bond formed by hydroxyl group of Ser¹⁸⁴ side chain and carboxyl group of Asp⁹⁸ is directly involved in the interaction between C-terminus of Bax and $\alpha 4$ region of its hydrophobic pocket (SUZUKI *et al.* 2000). It is also possible that C-terminus of Bax protein takes part in pocket stabilization and plays a role in the regulation of its translocation and oligomerization (SUZUKI *et al.* 2000; CARTRON *et al.* 2004). If the C-terminus of Bax is folded the pocket remains in a stable conformation. While the region is removed out of the hydrophobic cleft, the pocket collapses and the protein structure changes leading to protein dimerization and to its interaction with mitochondrial membrane. It is suggested that a removal of α -9 helical region (TM) is initiated by posttranslational modification of Bax (i.e. phosphorylation of Ser and Thr residues present in that region in large numbers) or some currently unknown factor, from behind of BH3-only subfamily, that competes with Bax for binding of its hydrophobic cleft. Interestingly, Pro¹⁶⁸ can be a direct or indirect linker between N- and C-termini of Bax protein displaying a function in the stabilization of its structure (SCHINZEL *et al.* 2004b). Destruction of this interaction under apoptotic signal(s)

results in the exposition of TM domain and translocation of pro-apoptotic protein to the mitochondria. It is possible that Pro¹⁶⁸ is a target for Pin 1 isomerase activity (peptidylprolyl cis/trans isomerase, NIMA-interacting 1) or a substrate for hydroxylation reactions.

BORNER suggested sequential events that may occur in Bax-like proteins during the apoptosis induction (2003). According to this model Bax-like proteins are present in living cells in the cytosol in the form of monomers or remain loosely attached to OMM. This kind of contact does not lead to remodeling of Bax hydrophobic cleft which is stabilized by interactions with membrane phospholipids or some unidentified inhibitory factors. In the case of Bax the C-terminus of the protein needs to be released from the binding with its hydrophobic pocket. In contrast, Bak doesn't require any extra signals because of its anchoring region that is always exposed outside the molecule. An alternative scenario assumes that the pushing aside $\alpha 9$ helix of the molecule evokes immediate changes in the protein structure: disintegration of hydrophobic cleft and exposition of BH3 domain. However, even then the incorporation of Bax to the membranes cannot be achieved because of the Bcl-2 anti-apoptotic proteins inhibiting BH3 domain of this pro-death molecule. Only in the presence of activated BH3-only proteins there occurs the release of Bax from the interaction with Bcl-2 or Bcl-X_L. As a result of the liberation, Bax $\alpha 5/\alpha 6$ helices can stably incorporate into the mitochondrial membranes. It is also possible that Bax may be auto-activated or cross-activated with already active Bax-like molecules without the participation of BH3-only proteins. The next step of OMM permeabilization is the oligomerization of effector proteins (Bax, Bak, Bok) and pore forming. It is conceivable that this stage can also be stopped by Bcl-2-like proteins if they are overexpressed in the cells (BORNER 2003). Therefore, apoptosis-mediating signals must generate multidirectional response to abrogate the multistage inhibition of anti-apoptotic proteins.

It was thought for a long time that $\alpha 9$ helix of Bax was only one region directing the molecule to the mitochondria. However, in 2004 CARTON *et al.* suggested the presence of additional mitochondrial targeting sequence in $\alpha 1$ helix of that protein and proposed an alternative to Borner's manner of Bax activation and

translocation. In viable cells, $\alpha 1$ helix of inactive Bax protein is situated close to $\alpha 2$ (BH3 domain), $\alpha 5$ and $\alpha 6$ regions and guards against their mitochondrial insertion (GRIFFITHS *et al.* 2001, MOLDOVEANU *et al.* 2006). According to the cited authors (CARTRON *et al.* 2004) the negative regulation of above helix is abrogated by its interaction with BH3 domain of the so-called direct activators from BH3-only proteins, e.g. Bid, Bim or Puma. This interaction leads to the opening of Bax molecule and to the exposure of $\alpha 1$ on the surface of pro-apoptotic protein. It has been established that Asp³³ of Bax and Gly⁹⁴, Met⁹⁷, Arg⁸⁴ of BH3-only protein play a key role in this binding. The hypothesis of CARTRON *et al.* (2004) arouses many controversies (SCHINZEL *et al.* 2004b, MING *et al.* 2006). It has been indicated that mitochondrial localization sequence is preceded by ART (apoptosis-regulating targeting domain) inhibitory domain (SCHINZEL *et al.* 2004b). Only if it was removed from the protein, the sequence would be uncovered. Thus, N-terminus of protein performs a role presumably only in inhibition of Bax activity. Indeed, its elimination from the molecule results in producing more potent pro-apoptotic protein – p18 Bax (CAO *et al.* 2003). Interestingly, during apoptosis N-terminus of Bax may be cleaved by calpains (GAO, DOU 2000). Furthermore, transfection of Bax/p18 fragment into cancer cells targeted this cleaved protein segment to mitochondria, which was accompanied by release of cytochrome c.

It has been demonstrated very recently (GEORGE *et al.* 2010) that Bax contains two functional mitochondrial targeting sequence that may act independently in mitochondrial translocation of Bax. They are located in helices $\alpha 6$ and $\alpha 9$ and uncovering of one of them after conformational changes of Bax, directs the molecule to mitochondrial membrane. It has been revealed that only combined mutations in both of these regions preclude its mitochondrial translocation in HeLa cell line.

4. MECHANISMS OF BAX-INDUCED MITOCHONDRIAL OUTER MEMBRANE PERMEABILIZATION

Bcl-2 family proteins regulate apoptosis via their influence on mitochondrial membrane permeability and efflux of pro-apoptotic factors from intermembrane

space of mitochondria, releasing Ca^{2+} ions from endoplasmic reticulum as well as on redox state in cell resulting from a translocation of cytochrome c to the cytosol, disruption of respiratory chain in mitochondria and production of reactive oxygen species (ROS) (BRECKENRIDGE *et al.* 2003; REED 2008; HANSON *et al.* 2008; HETZ, GLIMCHER 2008).

At present, it is accepted that Bax-mediated permeabilization may run through one of the following models. The most common mode of Bax action is that after homo- or heterodimerization with other pro-apoptotic Bcl-2 family molecules, Bax-like proteins form in outer mitochondrial membrane channels big enough to let pass cytochrome c and/or other pro-apoptotic factors, including procaspase-9 which together with cytochrome c forms apoptosome and initiates apoptosis (KRAJEWSKI *et al.* 1999; SCHLESINGER, SAITO 2006; KUMARSWAMY, CHANDNA 2009).

According to the next hypothesis, supported by experiments with liposome, Bcl-2 family proteins interact with channels that already exist in the membrane, e.g. with voltage-dependent anion channel (VDAC), and create structure permeable for molecules of the size of cytochrome c and even bigger (KUMARSWAMY, CHANDNA 2009).

Importantly, Bax may cooperate with proteolytically truncated BH3-only member Bid (tBid) and Ca^{2+} in permeabilizing the outer mitochondrial membrane and releasing mitochondrial apoptogenic factors (LUO *et al.* 1998; WEI *et al.* 2000; DESAGHER *et al.* 1999; BEDNAREK, KILIAŃSKA 2005; BRUSTOVETSKY *et al.* 2010). Recent data have indicated that Bax and tBid together may induce the formation of a large lipid pore in mitochondrial membrane (TERRONES *et al.* 2004). It has been revealed that both of these proteins destabilize the structure of lipid bilayer and provoke pore formation. tBid protein facilitates lipid pore forming through its CBD domain (cardiolipin-binding domain) that directs pro-apoptotic proteins to cardiolipin-rich membranes (TERRONES *et al.* 2004).

Both, Bcl-2 and Bax proteins seem to be also involved in the regulation of Ca^{2+} release from endoplasmic reticulum (ER). During ER stress followed by accumulation of improperly folded proteins in the ER, overexpression of Bik protein induces Bax/Bak heterodimerization and leads to Ca^{2+} efflux from ER. Increase of

the level of Ca^{2+} in the cytosol may stabilize open conformation mitochondrial megachannel – a large structure embracing both of mitochondrial membranes which, among others, can participate in cytochrome c releasing (CHIPUK *et al.* 2006).

5. REGULATORS OF BAX ACTIVITY

5.1. Activators of Bax protein

The main regulators of pro-apoptotic activity of Bax-like proteins are BH3-only members of Bcl-2 family. They may be divided into two subgroups depending on the way how they reveal pro-apoptotic potential of the so-called effectors (CHIPUK *et al.* 2006; LEBER *et al.* 2007; SKOMMER *et al.* 2007):

- Direct activators (Bid-like proteins) e.g. Bid or Bim – proteins that transiently bind to Bax-like proteins and trigger their activation according to ‘hit and run’ model. They can also neutralize anti-apoptotic members of Bcl-2 family molecules.
- Derepressors or sensitizers (Bad-like proteins) e.g. Bad, Bik, Bmf, Noxa, Puma – proteins that do not exhibit a potential to activate Bax-like proteins directly but are able to release effectors from interaction with anti-apoptotic molecules.

The best known and the first described example of Bcl-2 family effector activation was tBid-dependent rearrangement of Bax molecule (ZAMZAMI *et al.* 2000). It has been established that the interaction of Bax with tBid induces conformational change in pro-apoptotic effector molecule (exposure of 6A7 epitope on the molecule) resulting in protein translocation, incorporation to mitochondrial membranes and eventually their permeabilization.

Importantly, Bax can be also directly activated by factors that do not belong to Bcl-2 family. It has been demonstrated that cytoplasmic form of tumor suppressor protein – P53 induces Bax oligomerization and permeabilization of lipid vesicles at the level comparable to that obtainable with tBid (CHIPUK, GREEN 2004). It appears that a proline-rich region of P53 located between 62. and 91. amino acid residues is required for direct activating of Bax molecule. The deletion of this segment fails to permeabilize the membrane and arrests cytochrome c and other pro-apoptotic molecules inside the mitochondria. Additionally, P53 may also act as a derepressor –

a molecule that binds to anti-apoptotic protein (Bcl-X_L) and releases of Bax from the interaction with its inhibitor.

Recently, several reports have revealed that calpain-activated protein product of *Atg5* (autophagy-related gen 5) gene exhibits potential to activate the members of Bax-like family (CODOGNO, MEIJER 2006, YOUSEFI *et al.* 2006). Its 24 kDa N-terminal region, freed after the calpain-mediated cleavage, translocates from the cytosol into the mitochondrial membrane, thereby inducing apoptosis. Thus, *Atg5* plays a role of autophagy-apoptosis switch. However, the mechanism of *Atg*-mediated Bax activation remains unclear.

Furthermore, CUDDEBACK *et al.* (2001) have reported the Bax-activating action of Bif-1/endophilin B1 (Bax-interacting factor 1) in murine pre-B hematopoietic FL5.12 cell line following IL-3 withdrawal. It has been also revealed that loss of Bif-1 protein inhibits Bax/Bak-mediated apoptosis in HeLa cells treated with siRNA, as well as in Bif-1-knockout mouse embryonic fibroblasts (MEFs), obtained from mouse ES cells through homologous recombination (TAKAHASHI *et al.* 2005). It seems that after apoptosis induction Bif-1 undergoes some posttranslational modification(s) enabling its binding to Bax protein. This association triggers conformational rearrangement in Bcl-2 family molecule and this incident is accompanied by its activation and incorporation into the mitochondrial membrane. Once Bax is activated, complex branches out (CUDDEBACK *et al.* 2001, TAKAHASHI *et al.* 2005). Moreover, it is thought that a failure of Bif-1 may contribute to the development of tumors under *in vitro* as well as under *in vivo* conditions.

In addition, Bax can also interact with P53-dependent protein – ASC (Apoptosis associated speck-like protein containing a caspase recruitment domain) which moves to mitochondria after apoptosis induction and, in this way, facilitates Bax relocation (LEBER *et al.* 2007). Similarly, it has been indicated that histone H1.2 trafficking is a part of events leading to Bcl-2 family pro-apoptotic proteins activation, mitochondrial membrane permeabilization and apoptosis induction upon cell death stimulation (YAN, SHI 2003). It is unclear, however, how exactly H1.2 histone acts to provoke Bax/Bak oligomerization after its release to the cytosol.

It is worth mentioning that under special environmental circumstances, Bax and Bak molecules, can be activated *in vitro* without contribution of any additional proteins e.g. in response to nonionic detergents, pH increase or growth of temperature (BORNER 2003). Nevertheless, it is not known if this kind of Bax activation occurs under physiological conditions.

5.2. Inhibitors of Bax protein

Among Bax regulators, with the exception of Bcl-2-like proteins that neutralize pro-apoptotic function of Bax, Ku70 protein – a component of DNA-PK (DNA-dependent protein kinase), 14-3-3 protein, and some Hsp proteins (Heat shock proteins) (α A and α B-crystalins, Hsp70/dj1 and Hsp70/dj2 complexes) are found (LUCKEN-ARDJOMANDE, MARTINOU 2005; GOTOH *et al.* 2004; SHARPE *et al.* 2004; SCHINZEL *et al.* 2004a). Anti-apoptotic activities of the above factors are probably associated with a sequestering of inactive Bax molecule in the cytosol. It has been revealed that the proteins abrogate apoptosis induced by several agents e.g., UV irradiation or staurosporine treatment, while their removal from the cells enhances cell susceptibility towards apoptosis.

Additionally, ASO (antisense oligonucleotides) strategy showed anti-apoptotic potential of ARC protein (Activity-regulated cytoskeleton-associated protein), a factor, that is highly expressed in cardiac and skeletal muscle cells (LUCKEN-ARDJOMANDE, MARTINOU 2005). It was shown that the silencing of ARC expression contributed to conformational changes in the pro-apoptotic molecule Bax and mediated apoptosis. Bax activation and translocation can be brought to a halt by a new endogenous peptide – humanin, too (ZHAI *et al.* 2005). It was indicated that this 24-aa peptide is able to bind both with Bax and its direct activator – Bid (and tBid) and to inhibit tBid-induced Bax oligomerization.

It has been also suggested that Bax mediated apoptosis can be abolished by hexokinase-mitochondria interaction in a process regulated by Akt/PKB kinase activity (MAJEWSKI *et al.* 2004).

In 1998, XU and REED reported about the new anti-apoptotic protein, BI-1 (Bax inhibitor 1), discovered by functional screening in yeast. Above inhibitor is

highly conserved in animals and plants (XU, REED 1998; HÜCKELHOVEN 2004). It has been well documented that BI-1 protein abrogates apoptosis followed by a large number of apoptotic stimuli, e.g. Bax overexpression, growth factor and cytokine deprivation, drug treatment (etoposide, staurosporine), bacterial pathogens (e.g. *Chlamydia psittacci*) in various cell lines (HÜCKELHOVEN 2004). This protein neutralizes pro-apoptotic function of Bax. However, the mechanism of BI-1 action does not seem to be related to its physical interaction with Bax molecule. These two proteins do not appear to associate with themselves.

The main negative regulators of pro-apoptotic function of Bax are Bcl-2 family proteins. Bax can heterodimerize with Bcl-2, Bcl-X_L, Bcl-w and, perhaps, with Mcl-1 proteins and these interactions prevent apoptosis in live cells (DROIN, GREEN 2004; EWINGS *et al.* 2007). After apoptosis induction, the release of Bax from the complexes with proteins that counteract its function takes place due to the fact that BH3-only proteins indicate approximately 100 times stronger affinity for anti-apoptotic Bcl-2-like members than their affinity for Bax (BORNER 2003). Free Bax molecules multimerize and/or interact with the components which already exist in the mitochondrial membranes forming a large channel permeable for cytochrome c and other pro-death factors. Thus, the cell fate depends essentially on the equilibrium between pro-survival and pro-apoptotic proteins. Indeed, it is well known that disruption of the balance between Bcl-2 family partners in the cells entails serious consequences manifested in the disorder of life-or-death decision and on the one hand, cell accumulation, or on the other hand, excessive cell elimination. Defective apoptosis causes a large number of diseases, including cancers, autoimmune syndromes, neurodegenerative disorders, diabetes, immunodeficiency syndromes, infertility (KILIAŃSKA 2002; PEREZ *et al.* 1997; BORNER 2003; HAYASHI, FAUSTMAN 2003; MOLDOVEANU *et al.* 2006; FREY *et al.* 2008).

6. BCL-2 FAMILY PROTEINS – NEW TARGET FOR THE THERAPY OF DISORDERS WITH DEFECTIVE APOPTOSIS

In viable cells pro-apoptotic proteins co-exist in dynamic balance with anti-apoptotic counterparts from Bcl-2 family (DAY *et al.* 2008). It means that decreased

expression of one of them leads to the reduction in the level of the other one. For example, in viable cells of HEK-293 cell line pro-apoptotic Bak is kept in check by pro-survival Mcl-1 protein, whereas a proper number of B lymphocytes in the body is strictly regulated by Noxa/Mcl-1 ratio in the cells. Admittedly, Bax requires some additional signals for its activation, but after apoptotic stimulation cell fate depends to a high degree on the equilibrium between Bax and its main inhibitor – Bcl-2 (OLTVAI, KORSMEYER 1993). The overexpression of anti-apoptotic protein results in cell accumulation and may conduce to survival of transformed cells (CORY *et al.* 2003). Bcl-2 over-expression has been indicated in leukemias, lymphomas and a large number of human solid tumors and its high level is often associated with unfavorable prognosis (CASTLE *et al.* 1993; CORNBLAU *et al.* 1999; DROIN, GREEN 2004). Correspondingly, *Bax α* gene is mutated in many cancers (e.g. derived from colorectum, stomach, endometrium cells) and its expression level influences on the effectiveness of apoptosis induction (BARGOU *et al.* 1995, WAGENER *et al.* 1996; RAMPINO *et al.* 1997; OUYANG *et al.* 1998; REED 1999; FERREIRA *et al.* 2002). Therefore, Bax/Bcl-2 ratio may reflect susceptibility of neoplastic cells to spontaneous as well as drug-induced apoptosis. For instance, the cellular level of Bax and Bcl-2 proteins in prostate cancer cells is a predictive factor forecasting the result of the therapy based on androgen deprivation and radiation (KHOR *et al.* 2007). It has been also shown that Bax/Bcl-2 rate in chronic lymphocytic leukemia (CLL) inversely correlates with resistance of leukemic cells to cytotoxic drug – chlorambucil *in vitro* as well as with clinical responsiveness (PEPPER *et al.* 1997). Above parameter mirrors the potential of the examined cells to apoptosis induction and its analysis may serve *in vitro* as potential tool for evaluating whether neoplastic cells are drug resistant or not (KOBYLINSKA *et al.* 2006).

Owing to the key role of Bcl-2 family proteins in apoptosis regulation they are an attractive target for modern anti-cancer therapy. There are many therapeutical approaches leading to modification of cellular balance between pro- and anti-apoptotic Bcl-2 family molecules. Most of them are targeted to pro-survival proteins and are based on antisense oligonucleotides (JANSEN *et al.* 1998; KONOPLEVA *et al.* 2000; FERREIRA *et al.* 2002). However, the number of trials aiming at inducing *Bax*

gene in tumor cells is growing all the time (WAGENER *et al.* 1996; LI *et al.* 2001; PIROCANAC *et al.* 2002; FALKE *et al.* 2003). As the introduction of a vector expressing *Bax* gene into cells involves a lot of difficulties associated with putative toxic effect of its protein product on normal cells, it is a great challenge for scientists to cause a cancer cell-directed expression of this gene (SEO *et al.* 2009).

A new engineered artificial transcription factor, 5ZFAV, seems to be a solution to this problem (FALKE *et al.* 2003). It has been revealed that 5ZFAV, containing zinc fingers from mouse *Zif268* and transactivation domain from herpes simplex virus protein, VP16, selectively induces the expression of endogenous *Bax* and efficiently turns apoptosis on in P53-deficient sarcoma osteogenic Saos-2 cells. Interestingly, the impact of the novel molecule on P53 positive osteosarcoma cell line – U-2 OS appears to be much less potent giving the chance for selective pro-apoptotic activity against P53-mutated tumor cells.

The Tet-On inducible system, containing reverse tetracycline transactivator (rtTA) and inducing transcription after the binding with tetracycline and its derivatives, seems to be very helpful in controlling *Bax* gene expression (WAGENER *et al.* 1996, SEO *et al.* 2009). It has been reported that the stable transfectants obtained from DLD-1 colon cancer cells transfected with above system (*pTET-On* and *p-TRE Bax* plasmids) and selected in the medium with geneticin, occur to be more sensitive to various drug-induced apoptosis than the cells without introduced *Bax* gene (KOBAYASHI *et al.* 2000).

On the other hand, it has been discovered that *bax* inactivation in oocytes of mice undergoing treatment with doxorubicine reduced their sensitivity to apoptosis and increased their viability (PEREZ *et al.* 1997). Since it is well known that development of infertility in anticancer drugs-treated women is one of the most common side effect of chemotherapy, the inhibition of *Bax* gene in germinal cells during the chemotherapy of cancer could be interesting strategy of infertility preservation (PEREZ *et al.* 1997).

In conclusion, it seems that overexpression of *Bax* alone in cancer cells does not induce apoptosis but enhances its induction following anticancer treatment. A combination of conventional chemotherapy with gene therapy may be a new, very

potent strategy in cancer treatment. It is conceivable that the better understanding of apoptosis regulation may help to overcome apoptosis deficiency (typical in many cancers) and therapy resistance.
