July ... 1998

Three Research Questions

What is the age of maximum mean annual increment - as measured by basal area in square feet per acre?

What is the influence of site index on the timing of maximum mean annual increment?

How are these observations useful to the forest manager?

The Data/The Analysis/The Plottings

Individual plot data from the East Texas Pine Plantation Research Project were available for analysis in this study. Each plot consists of two subplots. Each subplot is considered an observation. The analysis was limited to individual observations ages 24 years and older. All observations are unthinned.

For each observation, basal area in square feet per acre was calculated.

Based on these values, MAI (mean annual increment) was calculated.

The values are depicted in graphs on the next twenty eight pages.

Conclusions

From examination of the twenty eight graphs, it appears that maximum MAI tends to occur between 12-17 years.

Site index appears to have no influence on the timing of maximum mean annual increment.

And these observations are useful to the forest manager...The above range of maximum MAI values could be used as possible guidelines for a first thinning, or a possible harvest schedule if short rotations with no thinnings are the management objective.
