NOTICE

The quality of this microform is heavily dependent upon the quality of the original thesis submitted for microfilming. Every effort has been made to ensure the highest quality of reproduction possible.

If pages are missing, contact the university which granted the degree.

Some pages may have indistinct print especially if the original pages were typed with a poor typewriter ribbon or if the university sent us an inferior photocopy.

Reproduction in full or in part of this microform is governed by the Canadian Copyright Act, R.S.C. 1970, c. C-30, and subsequent amendments.

AVIS

La qualité de cette microforme dépend grandement de la qualité de la thèse soumise au microfilmage. Nous avons tout fait pour assurer une qualité supérieure de reproduction.

S'il manque des pages, veuillez communiquer avec l'université qui a conféré le grade.

La qualité d'impression de certaines pages peut laisser à désirer, surtout si les pages originales ont été dactylographiées à l'aide d'un ruban usé ou si l'université nous a fait parvenir une photocopie de qualité inférieure.

La reproduction, même partielle, de cette microforme est soumise à la Loi canadienne sur le droit d'auteur, SRC 1970, c. C-30, et ses amendements subséquents.

ABSTRACT

A study was undertaken to determine the feasibility of developing an engine dynamic signal monitoring and diagnostic system for use on-line in a high volume engine manufacturing plant as well as in a research environment for the development of new engine components. The system will enable rapid and precise diagnostics of the production engine for identifying and locating manufacturing or assembly defects which do not include thermodynamics, combustion / or emission related defects.

Recently published literature on engine noise and vibration monitoring and diagnostic systems is reviewed with special emphasis on the use of noise and vibration for on-line monitoring and diagnosing. A complete bibliography of 175 references is appended, together with the summary chart outlining the subject classified by topics.

The feasibility of using noise and vibration for the detection of engine manufacturing and assembly defects as well as evaluating the effectiveness of component design changes, was originally carried out in the dynamometer laboratory. Here, customer returned engines were evaluated for noise and vibration using three different monitoring systems developed for the same purposes. In these systems accelerometers, microphones and pressure transducers were used in conjunction with both a conventional dynamic signal analyzer and a specially designed eight channel data acquisition system coupled with custom designed computer programs. All these systems are capable of detecting defects in customer returned engines. Detail reviews were carried out emphasizing the advantages and disadvantages of each system. The noise and vibration measurements were then correlated with actual manufacturing and assembly defects. The systems were also tested for evaluating the noise and vibration characteristics of changes in piston design.

With the success in diagnosing customer returned engines, a field study was

undertaken to determine the feasibility of using noise and vibration for detecting missing connecting rod bearings, loose connecting rod nuts, and other related manufacturing/ assembly defects. A modified monitoring system which includes accelerometers and microphones together with a uniquely designed data acquisition system was used to obtain the noise and vibration data. In the initial phase, data was collected from fifteen partially completed engines having different defects. These were then analyzed to set the vibration limits for rejection. The on-line engine monitoring and diagnostic system was implemented and it was observed that in the test of more than 120,000 engines, the success rate in reduction of defective engines was 100 percent.

Thus it was concluded that the monitoring system with a specially designed data acquisition system is capable of on-line monitoring and rapid and precise diagnosing of production engines with manufacturing and / or assembly defects. The system is also well suited for use in evaluating the noise and vibration characteristics of any engine when one or more of its components has undergone design changes.

DEDICATION

This work is dedicated to my wife, JASMIN and our daughter, VEHNIAH.

ACKNOWLEDGEMENTS

The author would like to express his appreciation to Dr. Z. Reif for his guidance, continuous encouragement and tolerance. Thanks are also due to Dr. R. Gaspar, Dr. W. North, and Dr. M. Huynh for their assistance and comments.

The author also wishes to extend special thanks to all the people at the Essex Engine Plant in particular the Managers of the plant and the employees of the Quality Department for making the success of this "Real World" research opportunity possible.

Special thanks are due to the Dynamometer Test Analysts, Layout and Quality Analysis Personnel and Tradesmen for continuous technical assistance and generous contributions to many experiments and prototype machining.

The assistance of Dr. D. Chang, Miss. Sirk-Addis Zena, John Runge and Dave Mathias during the preparation of this study is greatly acknowledged.

NOMENCLATURE

a	distance from piston pin to top of piston skirt
A	acceleration
(A_1)	lateral component of the pin force
(A_2)	the axial component of the pin force
ADC	Analog to Digital Converter
AV	average
b	distance from piston pin to bottom of piston skirt
BDC	Bottom Dead Center
c	distance from piston pin to C.G.
CID	Cylinder Identification
CPU	Central Processing Unit
Da'isp	Data Analysis and Display Software by DSP Development Corporation.
dB	decibel
d_p	piston pin diameter
e	distance from piston center line to piston C.G.
f	distance from piston pin to top ring
F	represents the failure of fault detection
F_1	piston/bore reaction force at top of skirt
F_2	piston/bore reaction force at bottom of skirt
FFT	Fast Fourier Transform
g	acceleration of gravity
HPIB	Hewlett Packard Interface Bus
H'_a	the angular momentum after impact
H(s)	system transfer function
i	the index for vector data points
\bar{l}	sound intensity vector
l_3	mass moment of inertia of piston about piston C.G.
l_{rod}	mass moment of inertia of connecting rod about rod C.G.
ICP	Integral Circuit Piezoelectric
I/O	Input/ Output
ISR	Interrupt Service Routine
J_B	sign coefficient accounting for piston velocity direction and thrust or antithrust contact with the bore at the bottom of skirt
J_p	sign coefficient accounting for relative angular
J_{SB}	sign coefficient accounting for piston contact with thrust or antithrust side of bore at bottom of skirt
J_{ST}	sign coefficient accounting for piston contact with thrust or antithrust side of bore at top of skirt
J_T	sign coefficient accounting for piston velocity direction and thrust or antithrust contact with the bore at the bottom of skirt

J_v	sign coefficient accounting for velocity direction of piston
k	k^{th} mode of the system
KE	Kinetic Energy
kHz	kilo Hertz
m	the number of traces collected
M	moment developed between piston pin and piston due to friction
m_2	mass of piston pin
m_3	mass of piston
m_{eq}	the mass at point 2 of piston pin location
m_{2eq}	the equivalent connecting rod mass located at point 2
m_{rod}	mass of connecting rod
P_H	lateral component of gas pressure load
P_V	axial component of gas pressure load
p	instantaneous pressure
Pa	Pascal
p_k	pole location for the k^{th} mode = $\sigma_k + j\omega_k$
PIP	Profile Ignition Pickup
Q	the offset distance between the piston and crank shaft axis
Q_k	arbitrary scaling constant
r	the index of a particular trace
R	radius of bore
RAM	Random Access Memory
re	References
RPM	Revolution Per Minute
s	distance from crank pin (point 1) to rod C.G.
$s_{1,2}$	the roots of the characteristic equation
S	represents the satisfied fault detection at both TDC and BDC
SB	represents the satisfied fault detection only at BDC
SDOF	Single Degree of Freedom
SPL	Sound Pressure Level
ST	represents the satisfied fault detection only at TDC
T	transpose of the vector
t_d	time delay
t_w	time windows
TDA	Time Domain Averaging
TDC	Top Dead Center
TTL	Transistor-Transistor Logic
u	distance from piston center line to piston pin
$\{U_k\}$	mode shape vector
US	represents the unsatisfied fault detection
v	distance from bore center line to crankshaft axis
v_r	the instantaneous particle velocity
VAR	variance
W	the acoustic power passing through a surface, S
x_2	lateral displacement of piston pin

\dot{x}_2	velocity of the mass m_{eq}
\dot{x}_3	horizontal velocity of the piston
\ddot{x}_2	lateral acceleration of piston pin
\ddot{x}_3	lateral acceleration of piston C.G.
$X(i)$	the i th component of a vector X
\ddot{y}_2	axial acceleration of piston pin
\ddot{y}_3	axial acceleration of piston C.G.
$Y(i)$	the average vector for all traces X
z	damping ratio
$Z(i)$	the i th component of the variance vector
$\dot{\beta}$	the angular velocity of the piston
β'	the new angular velocity
$\ddot{\beta}$	angular acceleration of piston
δ	r differential length
η	loss factor
θ	crank angle
μ	coefficient of friction between piston skirt and bore
μ_p	coefficient of friction between the piston and pin
ρ_o	the density of air
σ	damping factor
$\dot{\phi}$	relative angular velocity of the connecting rod
ϕ_o	the angle of the connecting rod to the bore center line at TDC
$\ddot{\phi}$	angular acceleration of connecting rod
ω	angular velocity
ω_d	damped natural frequency
ω_n	underdamped natural frequency

CHAPTER 1.

INTRODUCTION

Today, achieving higher productivity at the minimal cost is one of the key goals of engine manufacturers. This, coupled with higher standards of customer satisfaction, requires not only innovative concepts in engine design, manufacturing and assembly processes but also the integration of on-line engine monitoring and a diagnostic system which is capable of detecting manufacturing and assembly defects. The implementation of such a system would greatly increase productivity, customer satisfaction and reduce scrap costs.

Hence, it is necessary for engine manufacturers who wish to succeed in the highly competitive market of the future to plan immediately for integration of on-line engine monitoring and diagnostic systems.

A typical engine manufacturer is capable of producing 2000 engines per day which is equivalent to about 3 million dollars daily output. One such manufacturer listens to the voice of the customers through participations in dealer visitations and vehicle assembly plants to better understand its customer needs and concerns. The statistical data of one representative manufacturer indicates that it exchanges 0.05 percent of engine production to its customers. The majority (60 percent) of the engine exchanges are related to excessive engine noise and vibration. Upon examination of the customer return engines, the main concerns involve engine manufacturing and assembly defects.

Thus, one concerned engine manufacturer who is aware of the high cost incurred by these defective engines being received by the customers, decided to develop and implement non-destructive techniques for the on-line detection of manufacturing and assembly defects.

At present, an engine assembly requires the engine to be tested at several stages

of the assembly process. However, it is desirable to detect all the defects in the engine at the earliest possible stage in order to prevent major damage and hence additional repair and assembly cost due to further operation with the defective engine.

A conventional method to detect a missing connecting rod bearing, referred to as the cold test, is to measure the deck height of the piston at top dead center from the cylinder block bank face. However, this method needs to be improved due to its inconsistency in results, long set-up time, prolonged calibration time and problems with maintainability and durability of the gage. Replacement of this dimensional gage with vibration measurement is necessary and an investigation was initiated for this purpose.

One other engine diagnostic method in the automotive industry is auditory assessment by an operator who can infer the mechanical defects causing a particular engine noise. However, the reliability of the judgements is sometimes questionable due to the effect of inconsistency of the physiological condition of the inspector and ambient conditions. Most important of all, the operator's judgment is subjective, especially in the case of defects that are on the borderline of acceptability.

The goal of this research is to develop a viable and cost effective method of diagnosing manufacturing and assembly defects in internal combustion engines using noise and vibration signals.

In view of the above considerations, the following objectives were set for this dissertation:

1. To review the recently published literature on engine signal monitoring and diagnostic methods with an emphasis on various mechanical signature analysis techniques.
2. To determine appropriate transducers for the on-line detection of manufacturing and assembly defects.
3. To develop and implement a viable and cost effective on-line monitoring and diagnostic system for identifying and locating engine manufacturing and

assembly defects by means of vibration and noise measurement and analysis.

4. To develop a practical and cost effective system for use in evaluating the noise and vibration characteristics of an engine component before and after design changes.
5. To recommend areas for future research and development.

CHAPTER 2.

LITERATURE SURVEY

In this chapter, a literature survey was conducted in the area of engine dynamic signal monitoring and diagnostic procedures for use in the dynamometer laboratory as well as in the production cold and hot test stands. First, a review of fault diagnosis for internal combustion engine is presented. It is followed by a summary of the past work on data processing techniques. Finally, different methods of diagnosing engine faults are presented.

2.1 Fault Diagnosis in Internal Combustion Engines

One of the most common procedures followed by the automotive industry to evaluate engine noise during inspection consists of operating the engine on a test stand. Noise level evaluation is based on an auditory assessment by an inspector/operator who, from sound level and frequency variations, can infer the mechanical defects causing the particular noise. Though this method is often simple and fast, the difficulties involved are obvious. The operator judgment is affected by ambient conditions (e.g. noise in the test areas) and by alterations of his physiological condition (fatigue, inurement, etc.). Most important of all, the operator's judgment is subjective and does not necessarily agree with the judgment of another operator, especially in the case of defects on the borderline of acceptability. These considerations show the need for a proper measurement apparatus in order to maintain a constant quality standard.

The main objective of this study is to develop techniques of diagnosing defects in various internal combustion engines. These techniques use the measurement of engine noise and vibration as the primary source of parameters coupled with other data such as pressure, temperature, torque, etc.. Besides being able to detect the presence of a fault,

the techniques must also be capable of diagnosing the types of defect so that cost effective remedial measures may be applied. Virtually all operating conditions of engine produce vibration, and therefore, noise. Hence abnormal operation can be detected from the noise and vibration produced. The use of noise or vibration measurement has great advantages because it is fundamentally non-destructive and non-invasive.

Most of the published technical papers are concentrated on the techniques for condition monitoring of rotating machinery. They include the analysis of vibration data, metallic debris detection and spectrographic oil analysis.

Presently, engine diagnostic equipment is available and is used in automotive industries for on-line testing of internal combustion engines. The systems generally rely upon measurement of parameters from the electrical system and an analysis of small fluctuations in the power output and crankshaft rotation. The fault conditions are deduced from the power output characteristics of each cylinder. This method of detection is not specific. The use of engine noise and vibration measurements generally provide a more specific indication of engine defects such as excessive bearing clearances, piston slap or scuffing, crankshaft imbalance and various assembly defects.

Generally, the current techniques of applying noise and vibration for detecting faults are mainly developed for monitoring and diagnosis of machinery rotating at a constant speed. Rotating machines mainly produce repetitive signals of a more or less periodic nature. Most techniques are oriented toward the description or extraction of such type of signals. Spectral analysis is commonly used because it is based on a decomposition of this class of signal. Another method is the time domain averaging which filters out periodic signals time-locked to such a period.

The dynamic signals of an internal combustion engine can be characterized as "almost periodic" in nature. They are often produced by mechanical systems incorporating some periodic movement, but may also be generated by random effects accompanying friction, fluid flow, impact, etc... Thus, conventional methods of analysis are generally not

effective for reliably detecting faults in internal combustion engines.

The majority of the applications of noise and vibration measurement for fault diagnosis have been concentrated in the areas of gears and bearings [162] . The techniques range from simple measurement of noise and vibration signal levels to more detailed evaluation in the time and frequency domains.

2.2 Analysis Techniques

Applications in the diagnosis of internal combustion engine faults are described by Braun and Seth [22, 23]. The main interest in this project is not the specific methods of measurement, but the way in which the results are processed in order to extract the relevant data and identify the fault. The analysis techniques that need to be applied for the diagnosis of internal combustion engine can be divided into three main sections:

1. Data acquisition
2. Data reduction and processing
3. Algorithms for the diagnosis of engine faults.

The objective of this study is to develop methods of recognizing engine faults applicable in a production cold or hot test environment.

2.2.1 Data Acquisition

The following points must be considered together with the knowledge of the analysis, the diagnostic procedures and the environment:

1. Vibration is strongly related to the distance from the point of measurement to the ultimate source.
2. Vibration is more related to engine operating condition than to noise.
3. Depending upon the microphone position, a measurement of noise will be less biased to a particular part of the machine and the information relating to a particular

aspect of the machine's performance is likely to be scrambled. Noise is also capable of being modified by the acoustic environment.

In production line testing (cold or hot test) the main consideration is to keep the number of connections to the engine to a bare minimum. Hence the relative merits of noise or vibration measurement are listed below:

2.2.2 Noise

Noise is:

1. Capable of providing data on the condition of an engine from a single measurement.
2. A non-contact measurement.
3. The data analysis procedures are generally more complex.
4. Enclosures are sometimes necessary for testing in a production environment.

2.2.3 Vibration

Vibration is:

1. Capable of providing condition data on individual components of the engine.
2. No special enclosures are required in a production environment.
3. Vibration is directly related to mechanical operations within the engine.
4. A large number of transducers may be required, thus generating a lot of data for processing.

2.2.4 Transducers

The most commonly used transducers to measure noise and vibration are discussed in the following sections.

2.2.4.1 Noise

The choice of microphone depends on the required frequency response, durability and cost. Bruel and Kjaer [24] describe in detail the frequency response of different microphone designs.

2.2.4.2 Vibration

The piezoelectric accelerometer is the most commonly used transducer for vibration measurements because of its relatively small size, low cost and measuring stability with a wide frequency range. The use of a scanning laser interferometer is useful when considering the large number of measurement positions on the engine. It is a non-contact device that can be placed alongside the engine. It is even capable of directing the beam onto both sides of the engine using mirrors. At present, the use of a laser interferometer is limited because of its high capital cost. Anderton [5] described the use of a laser doppler velocimeter for measuring surface vibration.

2.3 Data Processing Techniques

The generation of noise and vibration by a faulty engine can be categorized into three areas:

1. Impacts between components associated with incorrect clearance (valve train, gears, connecting rods, pistons and bearings). This results in an impulse generated vibration which occurs at a fixed point in the engine cycle.
2. Imbalance in rotating components (crankshaft, camshaft, gears, balance shafts). The resulting vibration is harmonic at low orders of engine rotation.
3. Abnormal combustion (incorrect ignition timing, incorrect valve opening). The resulting vibration generally causes an increase in the energy above approximately 2 kHz in the firing pulse of the cylinder.

Thus, the noise and vibration generated by a faulty engine are complex in nature. The analysis must decompose the data in such a way that the fault recognition process can be concentrated on those attributes of the signal which are most representative of the faults to be diagnosed, avoiding the inclusion of a contaminated signals.

2.3.1 Frequency Domain Signal Analysis

In general, the harmonic nature of vibration caused by an out of balance crankshaft in an engine can be diagnosed using a narrow band frequency analysis. However, most engine faults such as piston slap, valve knock, are characterized by impulses which contain a particular frequency spectrum. Therefore, it is possible to diagnose some engine faults by identifying their associated frequency components. Both narrow band and 1/3 octave band procedures can be applied on the raw signal, time averaged signal and the signal envelope.

Wallace and Darlow [166] formulated an efficient approach to recovering transient shaft speed information using Fourier Transform techniques. In a similar work, Pischinger [117] described a method of time frequency windows for direct determination of the combustion noise from the airborne noise of a diesel engine. This method shows influences on the combustion noise, particularly where the mechanical noise is predominant. Meier [94-99] used frequency domain signal analysis in detecting engine faults in production test cells. Chung [32], on the other hand, discussed the application of Digital Fourier Transform methods (i.e., coherence and transfer function techniques) to investigate noise generated by an engine. The transfer functions, in these cases, were determined empirically for pinpointing the noise generation of an engine as well as to predict the effect on engine noise of various assumed cylinder pressure wave forms. Bianchi [17] utilized Fast Fourier Transform waveform analysis techniques on engine pressure signals to determine the diagnostic viability.

2.3.2 Power Cepstrum

Power cepstrum is the even or cosine transform of the logarithm of a power spectrum. It is the detection of periodicity within the spectrum of a given signal. Thus, it is commonly used to identify the harmonic and sideband components within a signal, such as that of a gearbox [24, 90]. However, the use of time domain methods in diagnosing engine faults is preferred over power cepstrum because of cost and effectiveness.

2.3.3 Acoustic Intensity Techniques

In recent engine work on acoustic intensity, Thompson [157] described the finite difference approximation errors in acoustic intensity measurements. Pope [118], in a similar work, stated that the cross-spectral method can provide diagnostic data from noise sources that were not previously obtainable. The same method can be used to measure sound power without requiring a special acoustical facility. By using the lead wrapping approach, Crocker [43] measured the sound power radiated from major surfaces of a diesel engine in order to identify the generating noise source. In this work, surface intensity and acoustic intensity were used to measure the sound power.

Acoustic intensity measurements are also used for determining noise sources in engines [40]. Chung [31] developed a cross-spectral method of measuring acoustic intensity at General Motors Research Laboratories. He demonstrated a rapid space time averaging technique, a detailed mapping of noise emission, a noise source ranking and a calculation for total engine sound power. Furthermore, he proved the reasonable accuracy and the effectiveness of the acoustic intensity method. Abe [1], on the other hand, developed digital acoustic intensity techniques in engine noise studies. Using a phased-locked data acquisition, an acoustic power balance was constructed for an engine. These results were shown to correlate well with other methods such as lead covering, average surface vibration level and close microphone.

2.3.4 Time Domain Analysis and Variance Techniques

Braun and Seth [22, 23, 139, 140, 142, 143], in their various work in engine diagnostics, formulated techniques for the decomposition of signals obtained from transducers. The authors proposed that a raw signal from a transducer can be decomposed into three distinct components:

1. A periodic signal
2. A random repetitive signal
3. A residual non-synchronous signal.

A variance analysis technique was developed in which cycle to cycle variability at each point in the engine cycle is calculated. This technique was demonstrated to be particularly useful for detecting faults in both manufacturing and assembly processes. This technique was later extended for evaluating engine noise by changing the piston profile [161].

2.3.5 Finite Element Analysis

As inexpensive computing power is readily available, the finite element method can now be used in an engine noise analysis which is considered to be very computing intensive.

Crocker [44] used an engine structure analysis which involved the finite element method and modal analysis to design a low noise engine. Crocker and Lalor [41], later on, extended the use of the finite element technique to predict engine structure noise and vibration with the objective of optimizing engine structure design for low noise. Challen [28] reviewed the progress in diesel engine noise reduction with emphasis on finite element modelling techniques of engine structures. Finite element analysis can be used in conjunction with experimental modal analysis for predicting the effect of design changes on the structural behaviour of the engine block [21].

2.3.6 Other Techniques

Otte [113], in his recent work, discussed a signal processing technique for verifying the correlation between multiple vibration and acoustical signals. It is based on the principal component analysis, a multivariate statistical analysis technique, and utilizes an eigenvalue decomposition of a covariance matrix. Various forms of spectral density functions (power spectral density, cross spectral density, transfer and coherence functions) and time domain functions (cross-correlation, impulse response, and inverse complex coherence function) can be used in the signal analysis to detect machine defects [49]. The time domain functions are useful for noise source identification (such as determining time delays associated with multiple potential noise sources), to identify important sources and relate the delays to the geometry of structures in order to determine the transmission paths.

Another approach for engine analysis is the pattern recognition techniques which were introduced by Cortina [35]. These techniques were used to reduce complexity and to permit the implementation of Bayes' procedures in a practical field portable equipment. This results in the design of pre-detection filters which can simplify and reduce the measurement equipment required to detect faults in real time. While Carr and Lalor [26] proposed the use of energy methods for predicting and reducing noise from engine covers, Alfredson [3] described the partial coherence technique for source identification on a diesel engine.

2.4 Diagnosis of Engine Faults

The process of engine diagnosis is one of data reduction which results in discrete classification in terms of engine faults. The data is generally reduced in order to extract the characteristics of the engine conditions. The extraction of characteristics permits concentration on those components which are directly related to the specific condition of

the engine. A common method of characteristics extraction is to compare the measured data set with a reference and compute the degree of deviation from the reference. Seth, Stuart and Field [140, 142, 143] formulated the strategy for engine diagnostic algorithms used in production cold test and hot test stands. The use of a selected number of engine characteristics to make a logic based decision was included. The complexity of the logic structure sometimes necessitates a diagnostics program development on the basis of a hierarchy approach.

Although the primary purpose of this study is concerned with the development of analysis techniques for engine fault detection, we need to understand the basic mechanism by which engine faults lead to noise and vibration. Many technical papers have been published on the subject of engine noise and vibration, and a selection of those which are particularly relevant to this study is referenced under the topics of piston noise, gear noise and valvetrain noise in Appendix A. The following describes the common faults associated with different components in an engine. Discussion on detection techniques and noise reduction are reviewed briefly.

2.4.1 Fuel Injector and Fuel Pump Noise

The present stringent legislation restricting gaseous emission in passenger cars creates an increase in world demand for electronically controlled, multiport injection systems for spark ignition engines. These systems are part of an engine that produced objectionable noise in the passenger compartment of a vehicle. Young [175] described the Lucas designed fuel injector which has reduced injector noise emission. Sound power measurements were made to quantify this reduction. The fuel pump is another noise source that needs to be eliminated. Kemmer [78] stated the methods for reducing noise in electrical fuel pump. As a remedy, he recommended having a fairly continuous flow and smooth pressure variations in the pump.

2.4.2 Valve Train Noise

There are many factors which cause valve noise in an engine. They include valve lift, valve bounce, valve tilt, valve seat distortion (mechanical or thermal), and valve insert rigidity [70]. Hanaoka [65] developed a new method of cam design that reduces valve train noise which occurs at the instant the valve opens and closes, and also when the follower is on the cam lobe. Generally, valve noises are caused by impacts, and their sound intensity is proportional to the impact speed. Follower noises are caused by frictional vibrations due to metal to metal contact at points where the oil film thickness becomes zero. Irregular contact surfaces increase these noises, and valve train noises at high speeds are caused by irregular valve dynamic behaviour.

2.4.3 Noise Cancellation Techniques

There are two ways of reducing high levels of structure-borne noise generated, at the engine second order frequency, by the reciprocating imbalance forces. One is a design approach to reduce the magnitude of the vibration generated mechanism, another applies cancellation techniques to reduce the resultant interior vehicle noise. For example, Wood [174] proposed a noise regulator device to achieve cancellation of structure-borne noise in four cylinder vehicles. Cancellation techniques can achieve, in principle, very significant noise reduction, but being essentially 'add-on' methods, they incur a mass penalty.

2.4.4 Passenger Car Interior Noise

Winklhofer [173] described the engine noise contribution towards the interior noise of the car and also gave ways of reducing engine noise in general.

2.4.5 Diesel Engine Noise Reduction

To improve passengers' comfort, various attempts are made by commercial vehicle manufacturers to reduce the dominant vehicle noise which is the engine. This is particularly true with diesel engines as they are much noisier than the gasoline counterpart. Windett [172] described various methods of improving diesel engine noise which could be carried out in a production process without major re-design of the basic engine. Watanabe [168], in a similar work, analyzed the transient noise characteristics of diesel engines and proposed methods of measurements. Russell [128-134] offered three approaches to control diesel engine noise. This is achieved by:

1. Control at source, of all major sources:
 - i) Smooth cylinder pressure development
 - ii) Elimination of timing drive impacts
 - iii) Minimum piston slap impacts.
2. Quiet structures, either:
 - a. Vibration isolation of external surfaces from all sources.
 - b. Combination of treatments of thin section surface areas of structures:
 - i) Crankcase/cylinder block resonances tuned to frequencies at which excitation is minimum.
 - ii) Vibration damping treatments to sump, valve gear covers, etc., when made of flexible sheet materials.
 - iii) Vibration isolation of sump, valve gear covers, pulleys, etc., when made of flexural stiff.
3. Enclosures, either:
 - a. Closely fitting enclosures made from flexible, damped, material which does not radiate sound efficiently, supported from the engine via vibration-isolating mounts. Little or no acoustic absorbent in the small gap between the engine and enclosure,

or

- b. Ventilated sound-proof "tunnel" around the engine and gear box, lined with acoustic absorbent.

2.4.6 Gear Noise

Gear noise is one of the major concerns for engine manufacturers. Substantial research in the areas of gear noise was carried out by Welbourn [171]. He described the causes of gear noise and provided references on various topics related to gear noise. In a similar work, Watanabe [168] identified gear tooth characteristics that minimize noise generation (excitation). A new "maximum-conjugacy" tooth form employed these characteristics to reduce gear noise to about 15% of that of conventional gear quality class 9 or better, including all automotive gearing.

Externally measured vibrations can be associated with dynamic loads due to wear [159]. Thus the degree of vibration can provide an indication of wear and useful life. Shmutter [146, 147] described a method of identification of gear noise associated with conjugate errors and nicks. He also presented an original and practical method applicable to torsional and gear related systems. There is a potential of 10-20 dB reduction in gear noise by using coated gears [126] even at relatively low rpm. Nivi [105], in his work, indicated that the presence of gear nicks on the rear axle carrier may be detected by measuring its torsional vibration. This detection method was incorporated in an in-process rear axle test stand with reasonable success. Galotto (59) described a gear noise control device for quality inspection (detection of gear defects) in a production line.

2.4.7 Combustion Noise

Another major source of engine noise is the combustion process. Warren and Hanley [170] outlined a study on combustion and diesel engine noise. They concluded

that the diesel engine cylinder pressure spectrum was dominated by cycle to cycle variations in the cylinder pressure, not by repeatable, periodic process. Volkswagenwerk [165] published several technical papers which detailed the combustion processes that generate noise and vibration in engines. Various methods for detecting knocks due to combustion were also mentioned. The quantitative measurement of spark knock, the relationship with composition and knock resistance of gasoline and the detection of knock, are described in detail in references [10, 11, 14]. Anderton [6] showed that for a given engine speed and bore, there is a very large variation in the overall noise, of the order of 25-30 dBA, and that this variation is associated with a particular combustion system. Furthermore, he clarified that it is possible to design lower noise engines, even using conventional structures, provided that the maximum speed is limited and an intrinsically quieter combustion system is used.

2.4.8 Engine Balance

Balancing the automotive engine is one of the best ways of reducing noise and vibration in an engine. Various balancing methods are discussed in detail by Thomson [160] and in the General Motors Corporation Manual [60].

2.4.9 Piston Noise

Ross and Ungar [127] showed that piston slap is initiated when the side thrust changes direction. This occurs under two conditions: when the force in the connecting rod changes from tension to compression and vice versa, or when the component of the connecting rod force normal to the cylinder axis changes direction as a result of changes in the sign of the angle between the connecting rod and the cylinder axis. The latter condition always occurs at the top and bottom dead center; the former condition is realized when the total inertia force contribution to the side thrust just balances the resulting force from the

gas pressure. In practical engines, one always encounters piston slap at the top and bottom dead center, but mid-stroke slaps may be suppressed at low speed operating conditions where the aforementioned force balance cannot be attained.

Takiguchi [156] stated that an optimum piston design for noise reduction includes changing the piston profile to reduce friction and increase lubrication. Under most running conditions, there are six slaps per combustion cycle, the first and by far the largest of which occurs around TDC firing, when the piston moves rapidly from the non thrust to the thrust face of the bore [124]. For the conditions under which piston slap in gasoline engines is particularly intrusive, that is at low to medium speeds and loads, there are invariably six slaps per cycle. In this mode, the excitation given to the block by the primary slap is much greater than by the other five so that, it has been found possible to concentrate only upon the effects of this impact when assessing piston slap noise.

By measuring the cylinder wall strain, a block vibration or radiated noise from an engine, Richmond and Parker [125] were able to assess piston slap noise. A knowledge of the relative movement of the piston in the cylinder is important in understanding piston slap noise. A simulation model [103, 109] was created for this purpose. In his paper, Lalor [88] made three conclusions:

- (a) speed is the most important parameter controlling the mechanical noise of all sizes of engine throughout their speed range,
- (b) mechanical clearance is also an important parameter for small engines at low speed, and throughout the speed range for large engines,
- (c) reciprocating mass is also an important parameter for small engines at high speed.

A further improvement in piston design can also be made to reduce noise. This can be accomplished by reducing the impact of the top land and skirt [76].

The maximum influence on piston design manifests itself in the structural vibration signals, measured on the cylinder liner, in the frequency range between 4 and 8 kHz. Haddad and Pullen [64] stated that piston slap appears to be of major importance in producing the

resultant engine vibration and noise, especially at lower engine speeds. Hodgett and McDonald [71] proved both experimentally and theoretically that the piston forces transmitted to the main bearings and to the engine mounts are increased by the resonances of crankshaft vibrations. In his paper, Fujimoto [58] concluded that the effect of oil film on the motion of the piston within the clearance is considerable, particularly on the lower part of the piston skirt.

2.4.10 Combustion Knock

Combustion knock is caused by irregular combustion which generates pressure oscillations in the cylinder. It is controlled in the early stage of engine design and by proper fuel selection. The placement and design of valves, spark plugs, fuel injection ports and the additive contents in engine fuel are factors causing the existence of combustion knock.

Ferraro [52] developed a knock intensity meter based on a criterion correlating knock intensity and kinetic energy associated with knock-typical pressure oscillations.

2.4.11 Engine Valve Cover, Sumps, Shields, and Enclosures

Sung and Lalor [154] discussed the use of shields and partial enclosures for engine noise reduction. Carr and Lalor [26] showed that the vibrational energy of a valve cover was usually lower when center fixing rather than when edge bolting is used. Using a damped steel sump reduced sump vibrational energy by increasing the damping without significantly affecting the energy transfer. Using a damped steel sump generally reduced crankcase vibrational energy. They also showed that the energy transfer was highest when the modal characteristics of the cover flange were similar to that of the engine component to which the flange was attached.

2.4.12 Engine Sound Quality

Quietness and better sound quality bring a more comfortable feeling to driver/passengers, as well as better handling and performance. Kuroda and Fujii [87] indicated that superior engine sound quality can be achieved by increasing the counterweights and stiffness of a crankshaft and, also, by optimizing the spark advance and improving the vibration characteristics of various engine parts. Crocker [39] described the use of digital signal processing techniques used to assess engine noise quality for a variety of engine types and conditions. Furthermore, he identified the causes and solutions for subjective unpleasantness.

2.4.13 General Vehicle Noise and Vibration

Flower and Ford [54, 55] described the optimization of engine mount design for improving vehicle noise, vibration and ride qualities.

CHAPTER 3.

THEORY

Different aspects of engine behaviour are governed greatly by the transverse and rotational movement of a reciprocating piston within the cylinder bore. As the horsepower and torque rating of an engine increase, the piston skirts become shorter thereby permitting a greater angle of piston to bore inclination. Hence, in this chapter, these influences are discussed in detail and potential engine design improvements are taken into consideration.

3.1 Dynamics of Piston- Crank Mechanism

During one cycle of engine running, the piston, connecting rod and crankshaft mechanism are exposed to three different categories of primary exciting forces, namely: a) combustion force, b) inertia force and c) a combination of both combustion and inertia forces. The separation of vibration signals between the contribution of these exciting forces is one of the main problems in this study.

When one or a combination of these forces move the piston and crankshaft with respect to their bearings, the mechanical clearances between components cause excitation upon impact. Especially when the piston is moving from compression to the expansion stroke, side force reversal causes the greatest impact to the respective components.

In this section, kinematic and dynamic relationships of the piston are derived to understand the mechanism of the engine vibration generation. These are compared to the vibration signals which are obtained during both cold and hot test of the engines.

3.1.1 Piston Kinematics

For the piston-slider crank mechanism shown in Figure 3.1, the displacement of piston can be derived using kinematics as follows:

$$y = Y_o + r(1 - \cos \theta) + L \left[1 - \sqrt{1 - \left(\frac{r}{L}\right)^2 \sin^2 \theta} \right] \quad (3.1)$$

where

y = location of the piston from the top dead center

Y_o = the distance from the top of block deck to top of piston at TDC

r = radius of the crank

θ = crank angle

L = length of the connecting rod.

If λ is defined as the ratio of radius of the crank to the length of the connecting rod, i.e.,

$$\lambda = \frac{r}{L}$$

and Φ is defined as

$$\Phi = \sqrt{1 - \left(\frac{r}{L}\right)^2 \sin^2 \theta} = \sqrt{1 - \lambda^2 \sin^2 \theta} \quad (3.2)$$

then, by substituting these relationships into Equation (3.1), the piston location becomes

$$y = Y_o + r(1 - \cos \theta) + L(1 - \Phi) \quad (3.3)$$

Now the velocity, V , and acceleration, A , of the piston are the first and second time derivatives of the piston displacement, i.e.,

Figure 3.1 : Piston Slider Crank Mechanism without Offsets

Figure 3.2 : Piston Slider Crank Mechanism with Offsets

$$V = y' = r\omega \sin \theta \left(1 + \frac{\lambda \cos \theta}{\phi} \right) \quad (3.4)$$

and

$$A = y'' = r\omega^2 \left[\cos \theta + \frac{\lambda(\cos 2\theta + \lambda^2 \sin^4 \theta)}{\phi^3} \right] \quad (3.5)$$

In a practical engine design, the piston pin and/or crank shaft axis are offset from the bore center line as shown in Figure 3.2 and this offset must be taken into account in the analysis. The geometry of the connecting rod system with offset is shown in Figure 3.3.

In Figure 3.3, the piston displacement from the top deck to the top of piston at any crank angle, θ , is given by

$$y = Y_o + (r + L) \cos \phi_o - L \cos \phi - r \cos \theta \quad (3.6)$$

where ϕ_o is the angle of the connecting rod to the bore center line at TDC.

Furthermore

$$\cos \phi_o = \frac{\sqrt{(r + L)^2 - Q^2}}{r + L} \quad (3.7)$$

and

$$\cos \phi = \sqrt{1 - \left(\frac{r}{L} \sin \theta - \frac{Q}{L} \right)^2} \quad (3.8)$$

If γ is the ratio of the offset distance between the piston and crank shaft axis to the length of the connecting rod, i.e.,

Figure 3.3 : Connecting Rod System with Offset.

$$\gamma = \frac{Q}{L} \quad (3.9)$$

and ϕ is defined as

$$\phi = \cos \phi = \sqrt{1 - (\lambda \sin \theta - \gamma)^2} \quad (3.10)$$

where Q is the offset distance between the piston and crank shaft axis.

The velocity and acceleration expressions now become:

$$V = y' = r\omega \sin \theta \left(1 + \frac{\lambda \cos \theta}{\phi} \right) - \frac{r\omega \gamma \cos \theta}{\phi} \quad (3.11)$$

and

$$A = y'' = r\omega^2 \cos \theta + \frac{L\omega^2}{\phi^3} \left[\phi^2 \left(\cos^2 \theta - \sin^2 \theta + \frac{\gamma}{\lambda} \sin \theta \right) + (\gamma \cos \theta - \lambda \sin \theta \cos \theta)^2 \right] \quad (3.12)$$

For the special case of zero offset, i.e., $\gamma = 0$ and Equations (3.11) and (3.12) reduce to Equations (3.4) and (3.5).

3.1.2 Connecting Rod Dynamics

The types of piston motion which affect the piston slap impulse are:

- 1) piston translation with friction in the cylinder space, and
- 2) angular motion of the piston.

As it is difficult to calculate the impact to the cylinder wall due to the piston motion, an

approximate method which replaces the distributed mass of the connecting rod with an equivalent two-mass system is used for piston dynamics calculations. The dynamics of the connecting rod are formulated in a similar manner.

For the rigid connecting rod shown in Figure 3.4, its equivalent two mass system is illustrated in Figure 3.5. For this system to be dynamically similar to the original system the following conditions need to be satisfied:

a) inertial equivalent,

$$I_{rod} = m_1 s^2 + m_2 (L - s)^2 \quad (3.13)$$

b) mass equivalent,

$$m_{rod} = m_{1eq} + m_{2eq} \quad (3.14)$$

c) moment equivalent,

$$m_{2eq}(L - s) - m_{1eq}s = 0 \quad (3.15)$$

where

m_1 is the big-end mass of the connecting rod,

m_2 is the small-end mass of the connecting rod

I_{rod} is the mass moment inertia of the original connecting rod

The moment of inertia of the equivalent connecting rod is calculated as:

$$I_{eq} = m_{1eq}s^2 + m_{2eq}(L - s)^2 = m_{rod}s(L - s) \quad (3.16)$$

Using this approximation, there is an error in estimating the inertia of the rod. This error is $I_{rod} - m_{rod}s(L - s)$. Therefore, in order for the two mass system to be dynamically equivalent to the original connecting rod, a corrective torque T must be applied about the big end. This torque is

$$T = I_c \ddot{\phi} \quad (3.17)$$

Figure 3.4 : Connecting Rod Geometry.

Figure 3.5 : Equivalent Connecting Rod.

where

$$I_c = I_{rod} - m_{rod}s(L - s) \quad (3.18)$$

and $\ddot{\phi}$ = the rotational acceleration of the connecting rod.

The angular velocity of the connecting rod is,

$$\dot{\phi} = \frac{d\phi}{dt} = \frac{r\omega \cos \theta}{L \cos \phi} \quad (3.19)$$

where $\omega = \dot{\theta}$ = angular velocity of the crank shaft.

Differentiating the velocity with respect to time gives the angular acceleration

$$\ddot{\phi} = \frac{-rL\omega^2 \sin \theta \cos \phi + rL\dot{\phi}\omega \cos \theta \sin \phi}{(L \cos \phi)^2} \quad (3.20)$$

$$\ddot{\phi} = \frac{L\dot{\phi}^2 \sin \phi - r\omega^2 \sin \theta}{L \cos \phi} \quad (3.20a)$$

3.1.3 Piston Dynamics

As stated in the previous section, the mass and moment of inertia of the piston are the most important factors which control the dynamic behaviour of the systems. However, the dynamics of the connecting rod has to be considered due to its large share of the total mass in the piston mechanism. A typical percentage of the total mass distribution of the piston and the connecting rod is shown in Figure 3.6. For the piston/rod assembly geometry shown in Figure 3.7, the coordinate system and the sign convention are as shown. The following is a description of the notation:

- 1) The positive x-coordinate is directed to the right from the piston (and bore) center line.
- 2) The positive y-coordinate is directed downward from the top of the piston skirt.
- 3) The rotation of the piston (β) is positive clockwise.
- 4) The crank rotation (θ) is also positive clockwise.

Total Oscillating Mass = 100%

Figure 3.6 : Distribution of the Oscillating Masses.

Figure 3.7 : Piston Sign Convention.

- 5) The connecting rod rotation (ϕ) is positive counterclockwise.
- 6) The thrust side of the piston is on the left and the antithrust side is on the right.
- 7) The location of the piston pin, crank axis, piston C.G., etc. are defined in the x-y coordinate system.

The piston lateral displacement (x) is zero when the center of the piston is located at the center of the bore. The piston axial location (y) is zero when the piston is at its highest point (TDC). The piston rotation (β) is zero when the piston position is vertical. Crank rotation is zero (360° and 720°) when the crank position is vertically upward. A crank angle of 0° corresponds to the top of the power stroke. The connecting rod rotation (ϕ) is also zero when the rod is vertical. Points 1, 2, 3, T and B are denoted as the center of the crank pin, the center of the piston pin, the piston C.G., the top of the piston skirt and the bottom of the piston skirt, respectively. The point designations are used as subscripts in specifying the piston motion and its properties. For example, the mass of the piston is denoted as m_3 and the mass moment of inertia of the piston about the piston C.G. is denoted as I_3 . The lateral acceleration of the piston pin is denoted as \ddot{x}_2 and axial acceleration of the piston C.G. is \ddot{y}_3 .

The geometry of the piston and the forces acting on it are shown in Figure 3.8. Taking moments about the crank pin (point 1) for the piston and connecting rod loads gives

$$\begin{aligned}
& -P_V(L_2 + u) + P_H(L_1 + f) + F_1(L_1 + a) + F_2(L_1 - b) \\
& + J_T \mu F_1(L_2 + u + x_2 + J_{ST}R) + J_B \mu F_2(L_2 + u + x_2 + J_{SB}R) \\
& - m_3 g(L_2 - e + u) + m_3 \ddot{y}_3(L_2 - e + u) - m_3 \ddot{x}_3(L_1 + c) \\
& - m_2 \ddot{x}_2 L_1 + m_2 \ddot{y}_2 L_2 + m_{rod} s^2 \ddot{\phi} \\
& - I_3 \ddot{\beta} + I_{rod} \ddot{\phi} = 0
\end{aligned} \tag{3.21}$$

Figure 3.8 : Piston Geometry and the Associated Forces.

Summing moments about the piston pin (point 2) for the piston loads gives

$$\begin{aligned}
 & - P_V(u) - P_H(f) + F_1(a) - F_2(b) \\
 & + J_T \mu F_1(u + x_2 + J_{ST}R) + J_B \mu F_2(L_2 + u + x_2 + J_{SB}R) \\
 & + m_3 g(e - u) - m_3 \ddot{y}_3(e - u) \\
 & - m_3 \ddot{x}_3(c) - M - I_3 \ddot{\beta} = 0
 \end{aligned} \tag{3.22}$$

The terms used in Equations (3.21) and (3.22) are defined as follows:

a = distance from piston pin to top of piston skirt.

b = distance from piston pin to bottom of piston skirt.

c = distance from piston pin to C.G.

e = distance from piston center line to piston C.G.

f = distance from piston pin to top ring.

g = acceleration of gravity.

m_2 = mass of piston pin.

m_3 = mass of piston.

m_{rod} = mass of connecting rod.

s = distance from crank pin (point 1) to rod C.G.

u = distance from piston center line to piston pin.

v = distance from bore center line to crankshaft axis.

x_2 = lateral displacement of piston pin.

\ddot{x}_2 = lateral acceleration of piston pin.

\ddot{x}_3 = lateral acceleration of piston C.G.

\ddot{y}_2 = axial acceleration of piston pin.

\ddot{y}_3 = axial acceleration of piston C.G.

F_1 = piston/bore reaction force at top of skirt.

F_2 = piston/bore reaction force at bottom of skirt.

I_3 = mass moment of inertia of piston about piston C.G.

I_{rod} = mass moment of inertia of connecting rod about rod C.G.

J_B = sign coefficient accounting for piston velocity direction and thrust or antithrust contact with the bore at the bottom of skirt.

J_T = sign coefficient accounting for piston velocity direction and thrust or antithrust contact with the bore at the bottom of skirt.

J_{SB} = sign coefficient accounting for piston contact with thrust or antithrust side of bore at bottom of skirt.

J_{ST} = sign coefficient accounting for piston contact with thrust or antithrust side of bore at top of skirt.

$L_1 = L \cos \phi$

$L_2 = L \sin \phi$

M = moment developed between piston pin and piston due to friction.

P_H = lateral component of gas pressure load.

P_V = axial component of gas pressure load.

R = radius of bore.

μ = coefficient of friction between piston skirt and bore.

$\ddot{\beta}$ = angular acceleration of piston.

$\ddot{\phi}$ = angular acceleration of connecting rod.

The motion of the piston C.G. $(x_3, \dot{x}_3, \ddot{x}_3, y_3, \dot{y}_3, \ddot{y}_3)$ is related to the motion of the piston pin $(x_2, \dot{x}_2, \ddot{x}_2, y_2, \dot{y}_2, \ddot{y}_2)$ and to the piston rotation $(\beta, \dot{\beta}, \ddot{\beta})$ in the following manner

$$x_3 = x_2 + c\beta \quad (3.23)$$

$$\dot{x}_3 = \dot{x}_2 + c\dot{\beta} \quad (3.24)$$

$$\ddot{x}_3 = \ddot{x}_2 + c\ddot{\beta} \quad (3.25)$$

$$y_3 = y_2 + (e - u)\beta \quad (3.26)$$

$$\dot{y}_3 = \dot{y}_2 + (e - u)\dot{\beta} \quad (3.27)$$

$$\ddot{y}_3 = \ddot{y}_2 + (e - u)\ddot{\beta} \quad (3.28)$$

Substituting Equations (3.25) and (3.28) into Equation (3.21) and rearranging terms gives

$$H_1 F_1 + H_2 F_2 + H_3 \ddot{x}_2 + H_4 \ddot{\beta} + H_5 = 0 \quad (3.29)$$

where

$$H_1 = L_1 + a + J_T \mu (L_2 + u + x_2 + J_{ST} R) \quad (3.30)$$

$$H_2 = L_1 - b + J_B \mu (L_2 + u + x_2 + J_{SB} R) \quad (3.31)$$

$$H_3 = -m_3(L_1 + c) - m_2 L_1 \quad (3.32)$$

$$H_4 = m_3(L_2 - e + u)(e - u) - m_3(L_1 + c)(c) - I_3 \quad (3.33)$$

$$H_5 = (I_{rod} + m_{rod} s^2) \ddot{\phi} - P_V(L_2 + u) - P_H(L_1 + f) \quad (3.34)$$

$$- m_3 g(L_2 - e + u) + m_3 \dot{y}_2(L_2 - e + u)$$

$$+ m_2 \ddot{y}_2 L_2$$

Substituting Equations (3.25) and (3.28) into Equation (3.22) and rearranging terms gives

$$H_6 F_1 + H_7 F_2 + H_8 \ddot{x}_2 + H_9 \ddot{\beta} + H_{10} = 0 \quad (3.35)$$

where

$$H_6 = a + J_T \mu (u + x_2 + J_{ST} R) \quad (3.36)$$

$$H_7 = -b + J_B \mu (u + x_2 + J_{SB} R) \quad (3.37)$$

$$H_8 = -m_3(c) \quad (3.38)$$

$$H_9 = -m_3(e - u)^2 - m_3(c^2) - I_3 \quad (3.39)$$

$$H_{10} = -P_V(u) - P_H(f) + m_3 g(e - u) - m_3 \ddot{y}_2(e - u) - M \quad (3.40)$$

Equations (3.29) and (3.35) are two of the equations required to solve for the four unknowns $(F_1, F_2, \ddot{x}_2, \ddot{\beta})$. The other two equations can be developed once the mode of the piston motion is specified.

The four modes of the piston motion (relative to the cylinder) which are used to describe the behavior of the piston are shown in Figure 3.9. They are as follows:

- Mode 1. No horizontal movement is present. Both the top and the bottom of the skirt are in contact with the bore, either diagonally or vertically.
- Mode 2. Piston is rotating about the top of the skirt.
- Mode 3. Piston is rotating about the bottom of the skirt.
- Mode 4. Piston is free in the bore, translating and rotating according to the net transverse force and turning moment applied to it.

Each type of motion can be defined by a particular set of equations from which the subsequent behavior of the piston may be determined. In order to derive these equations the following simplifying assumptions are made:

1. The angular acceleration of the crankshaft is zero.
2. The angular velocity of the connecting rod is independent of the transverse motion of the piston.

Assumption 2 simplifies the calculations by eliminating the coupling of the

Mode 1 : Both top and bottom of piston skirt are in contact with the cylinder bore, either vertically or diagonally.

Mode 2 : Top of piston skirt in contact with one side of cylinder bore.

Mode 3 : Bottom of piston skirt in contact with one side of cylinder bore.

Mode 4 : Piston free in cylinder bore.

Figure 3.9 : Basic Modes of Piston Motion.

differential equations. The justification here is that, although the transverse piston motion may alter the angular acceleration of the connecting rod, the time for which such acceleration occurs is too short to influence the angular velocity significantly.

The equations of motion for each regime are derived below:

a) In Mode 1, where there is no lateral movement of the piston, we have

$$\ddot{x}_2 = 0 \quad (3.41)$$

$$\ddot{\beta} = 0 \quad (3.42)$$

and therefore,

$$H_1 F_1 + H_2 F_2 = -H_5 \quad (3.43)$$

and

$$H_6 F_1 + H_7 F_2 = -H_{10} \quad (3.44)$$

from which we obtain

$$F_1 = \frac{-H_5 H_7 + H_2 H_{10}}{H_1 H_7 - H_2 H_6} \quad (3.45)$$

$$F_2 = \frac{-H_1 H_{10} + H_5 H_6}{H_1 H_7 - H_2 H_6} \quad (3.46)$$

b) In Mode 4, where there is no piston contact with the bore, we have

$$F_1 = 0 \quad (3.47)$$

$$F_2 = 0 \quad (3.48)$$

and therefore,

$$H_3 \ddot{x}_2 + H_4 \ddot{\beta} = -H_5 \quad (3.49)$$

and

$$H_8 \ddot{x}_2 + H_9 \ddot{\beta} = -H_{10} \quad (3.50)$$

from which we obtain

$$\ddot{x}_2 = \frac{-H_5 H_9 + H_4 H_{10}}{H_3 H_9 - H_4 H_8} \quad (3.51)$$

$$\ddot{\beta} = \frac{-H_3 H_{10} + H_5 H_8}{H_3 H_9 - H_4 H_8} \quad (3.52)$$

c) In mode 2, where the piston rotates about the top of the skirt as shown in Figure 3.9, we have

$$F_2 = 0 \quad (3.53)$$

$$\ddot{x}_2 = -\alpha \ddot{\beta} \quad (3.54)$$

and therefore,

$$H_1 F_1 + (-H_3 \alpha + H_4) \ddot{\beta} = -H_5 \quad (3.55)$$

and

$$H_6 F_1 + (-H_8 \alpha + H_9) \ddot{\beta} = -H_{10} \quad (3.56)$$

from which we obtain

$$F_1 = \frac{-H_5(-H_8 \alpha + H_9) + (-H_3 \alpha + H_4) H_{10}}{H_1(-H_8 \alpha + H_9) - (-H_3 \alpha + H_4) H_6} \quad (3.57)$$

$$\ddot{\beta} = \frac{-H_1 H_{10} + H_5 H_6}{H_1(-H_8 \alpha + H_9) - (-H_3 \alpha + H_4) H_6} \quad (3.58)$$

d) In Mode 3, where the piston rotates about the bottom of the skirt as shown in Figure 3.9, we have

$$F_1 = 0 \quad (3.59)$$

$$\ddot{x}_2 = b \ddot{\beta} \quad (3.60)$$

and therefore,

$$H_2 F_2 + (H_3 b + H_4) \ddot{\beta} = -H_5 \quad (3.61)$$

and

$$H_7 F_2 + (H_8 b + H_9) \ddot{\beta} = -H_{10} \quad (3.62)$$

from which we obtain

$$F_2 = \frac{-H_5(H_8 b + H_9) + (H_3 b + H_4) H_{10}}{H_2(H_8 b + H_9) - (H_3 b + H_4) H_7} \quad (3.63)$$

and

$$\ddot{\beta} = \frac{-H_2 H_{10} + H_5 H_7}{H_2(H_8 b + H_9) - (H_3 b + H_4)H_7} \quad (3.64)$$

3.1.4 Piston/Piston Pin Friction Forces

The moment (M) developed between the piston and the piston pin cannot be determined until the pin force (A) is known. The direction of the moment depends on the relative angular velocity of the piston ($\dot{\beta}$) and of the connecting rod ($\dot{\phi}$). An iterative approach is used to determine the lateral component of the pin force (A_1) and the axial component (A_2).

The piston contact forces (F_1 and F_2) and the piston accelerations (\ddot{x}_2 and $\ddot{\beta}$) are determined from the moment relationships derived in the previous section by initially setting the friction moment (M) equal to zero. Then, summing the piston forces in the lateral (x) direction and axial (y) direction provides the two equations necessary to solve for A_1 and A_2 . From the free body diagram of the piston, Figure 3.10, we can derive :

$$A_1 + J_p \mu_p A_2 - F_1 - F_2 + m_3 \ddot{x}_3 + P_H = 0 \quad (3.65)$$

$$A_2 - J_p \mu_p A_1 + J_v \mu (F_1 + F_2) + m_3 \ddot{y}_3 - P_v - m_3 g = 0 \quad (3.66)$$

where

μ_p = coefficient of friction between the piston and pin.

J_p = sign coefficient accounting for relative angular velocity of piston and connecting rod.

J_v = sign coefficient accounting for velocity direction of piston.

Rearranging terms in Equation (3.65) and (3.66), one obtains

Figure 3.10 : Pin Forces Acting on Piston.

$$A_1 + C_1 A_2 = C_2 \quad (3.67)$$

$$C_3 A_1 + A_2 = C_4 \quad (3.68)$$

where

$$C_1 = J_p \mu_p \quad (3.69)$$

$$C_2 = F_1 + F_2 - m_3 \ddot{x}_3 - P_H \quad (3.70)$$

$$C_3 = -J_p \mu_p \quad (3.71)$$

$$C_4 = -J_v \mu (F_1 + F_2) - m_3 \ddot{y}_3 + P_v + m_3 g \quad (3.72)$$

Solving for A_1 and A_2 gives

$$A_1 = \frac{C_1 C_4 - C_2}{C_1 C_3 - 1} \quad (3.73)$$

$$A_2 = \frac{C_2 C_3 - C_4}{C_1 C_3 - 1} \quad (3.74)$$

The friction moment M can be determined from A_1 and A_2 as follows:

$$M = J_p \frac{\mu_p d_p}{2} \sqrt{A_1^2 + A_2^2} = J_p \frac{\mu_p d_p}{2} A \quad (3.75)$$

where d_p = piston pin diameter.

This moment is now used to determine new contact forces and piston accelerations. New values for A_1 and A_2 are determined from Equations (3.73) and (3.74). The process is repeated until convergence of M is achieved. In all tested cases convergence was achieved.

3.1.5 Piston Motion and Impacts

The piston accelerations (\ddot{x}_2 and $\ddot{\beta}$) can be determined at every crank angle throughout a four stroke cycle. The lateral velocity and location of the piston are calculated by integrating \dot{x} and $\dot{\beta}$ over a specified range using the appropriate time step.

The location of the top and bottom of the piston skirt is continually monitored so that the mode of the piston motion can be determined at each crank angle. In the case when the piston impacts the cylinder bore, the kinetic energy of the piston at impact is determined for that location.

To model the impact between the piston skirt and the cylinder bore the following assumptions are made:

- 1) The velocity of a point on the piston at which impact occurs is reduced to zero, i.e., rebound does not occur.
- 2) If the piston is free in the bore prior to impact, then the angular velocity of the piston after impact is determined according to the principle of conservation of angular momentum.

The piston angular velocity after impact may be determined as follows. Consider a system consisting of piston and cylinder (Figure 3.11) just prior to impact, with the piston having a horizontal velocity \dot{x}_3 and angular velocity $\dot{\beta}$. The equivalent mass at point 2 (piston pin location) m_{2eq} is :

$$m_{2eq} = m_2 + m_{2eq}$$

where m_2 = mass of piston pin, and

m_{2eq} = the equivalent mass of connecting rod.

The mass m_{2eq} has a velocity \dot{x}_2 . The angular momentum just before impact with respect to the contact point P (see Figure 3.11) is given by

$$H_a = m_3 \dot{x}_3 (b + c) + I_3 \dot{\beta} + m_{2eq} \dot{x}_2 b \quad (3.76)$$

Figure 3.11 : Piston Impact with Cylinder Bore.

After impact the velocity of the impact at P is zero and the piston rotates about the point of contact at the new angular velocity $\dot{\beta}'$. Thus the angular momentum after impact is given by

$$H'_a = m_3 \dot{x}'_3 (b + c) + I_3 \dot{\beta}' + m_{eq} \dot{x}'_2 b \quad (3.77)$$

but, from Figure 3.11, we have

$$\dot{x}'_2 = b \dot{\beta}' \quad \text{and} \quad \dot{x}'_3 = (b + c) \dot{\beta}' \quad (3.78)$$

Then

$$H'_a = I_3 \dot{\beta}' + m_{eq} b^2 \dot{\beta}' + m_3 (b + c)^2 \dot{\beta}' \quad (3.79)$$

Applying the principle of conservation of angular momentum,

$$H_a = H'_a \quad (3.80)$$

and

$$\dot{\beta}' = \frac{m_3 \dot{x}_3 (b + c) + I_3 \dot{\beta} + m_{eq} \dot{x}_2 b}{I_3 + m_3 (b + c)^2 + m_{eq} b^2} \quad (3.81)$$

Equation (3.81) defines the angular velocity of the piston after impact.

To quantify the impact, the change in kinetic energy of the piston during impact is calculated as follows:

$$\text{Kinetic Energy lost} = KE_1 - KE_2$$

where

$$KE_1 = 0.5[m_3\dot{x}_3^2 + m_3\dot{y}_3^2 + m_{eq}\dot{x}_2^2 + I_3\dot{\beta}^2] \quad (3.82)$$

= kinetic energy of piston before impact

$$KE_2 = 0.5[m_3\dot{x}_{3a}^2 + m_3\dot{y}_{3a}^2 + m_{eq}\dot{x}_{2a}^2 + I_3\dot{\beta}_a^2] \quad (3.83)$$

= kinetic energy of piston after impact

where the subscript "a" refers to the velocities after impact.

A computer program was used to predict the piston motion (lateral and rotational).

Figure 3.12 shows the typical specifications of an engine used in the experiments.

Initially, the locations of the piston pins with respect to crank angles were calculated. Sudden alternations of piston pin locations in the lateral direction which might cause piston slaps were observed as illustrated in Figure 3.13. The cyclic change in displacement of the piston pin with respect to the crank angle was also seen in the axial direction, as indicated in Figure 3.14.

The velocity and acceleration of the piston pin were obtained by the first and second derivatives of the piston pin displacement equations. Figures 3.15 to 3.18 illustrate the plotted output.

By taking moments about the piston pin, as depicted in Equation 3.22, the piston / bore reaction forces were calculated and plotted as shown in Figures 3.21 to 3.26. Finally, the kinetic energy loss at impact was calculated and it is illustrated in Figure 3.27.

3.2 Modal Analysis

Competition, government regulations, inflation and many other factors are putting pressure on the automotive industries to build products which weigh less, and operate more reliably with less noise and vibration than in the past. In order to effectively solve noise and vibration problems, engineers must have a good understanding of the dynamics of mechanical structures and of the influence of the proposed design modifications may have on the overall engine performance.

The primary objective of this section is to provide the detailed dynamic characteristics of the engine components.

It is important to know the modes of vibration of the structure as they provide the frequencies at which the structure can be executed into resonance and the predominant wave-like motion at the resonant frequencies. This information is useful for determining the optimized locations of sensors for automated engine data acquisition and diagnostic system.

Modal Analysis is a process of characterizing the dynamics of a structure in terms of vibration. It involves identifying the eigen-values and eigen-vectors of the equations of motion corresponding to the frequencies at which the structure is more likely to vibrate in a predominant, well identified, wave-like deformation. The amplitudes of this wave motion in the structure are specified by the corresponding eigen-vectors. (When the eigen-values are complex, they also describe the damping of the modes of vibration). Each mode of vibration, then, is defined by an eigen-value (resonant frequency and damping) and its corresponding eigen-vector (mode shape).

In this work, modal analysis is applied on engine components so as to obtain the global structural properties i.e. the modal mass, stiffness and damping. The following section gives a detailed description of the structural response of the engine assembly. This information is useful in optimizing the location of sensors in the design of automated engine data acquisition and diagnostic systems.

3.2.1 Modes of Vibration

Physically, modes of vibration are the so called "natural frequencies" at which the predominant motion of a structure occurs as a well defined waveform as shown in Figure 3.28. Mathematically, modes of vibration are defined by certain parameters of a linear dynamic model. As illustrated in Figure 3.29 each mode of vibration is defined by a resonant frequency, a damping factor and a mode shape. It should be noted that a structural dynamic model can be completely defined in terms of its modal parameters. Hence, the purpose of modal testing is to artificially excite a structure so that the frequencies, damping and mode shapes of its predominant modes of vibration can be identified.

3.2.2 Modal Testing Methods

In general, there are two fundamentally different methods of modal testing of structures: the normal mode and the transfer function methods. The normal mode method is the classical method of experimentally extracting modal parameters. This requires a large number of exciters "tuned" to excite the structure in a single desired mode of vibration. The forcing function is sinusoidal and only one mode is excited at a given time. This method however is difficult, time consuming and expensive to implement because of the following:

- 1) It is difficult to find the best location for the shakers on the structure without some prior knowledge of the modes of vibration
- 2) It is extremely difficult to excite closely coupled modes, one at a time
- 3) The structure must be completely instrumented with enough transducers and signal conditioning equipment so that the mode shape for all desired degrees of freedom can be measured at once.

Figure 3.28 : Modes of Vibration ¹

Figure 3.29 : Modes of Vibration Definition ¹

¹ Adapted from Structural Analysis Seminar Notes by Ken Ramsey and Mark Richardson of Structural Measurement Systems

However, the normal mode method is suitable for use to analyze large structures where large energy input is required. It also has good signal to noise characteristics.

The Transfer Function method is rapidly gaining wide recognition mainly due to the recent developments in computer hardware. This method is based on the use of digital signal processing techniques and the Fast Fourier Transform algorithm to measure frequency response functions between various points on the structures. Modal parameters (natural frequencies, damping and characteristic mode shapes) are identified by performing further computations (curve fitting) on the above frequency response functions.

The major differences between the Normal Mode Method and the Transfer Function Method are summarized in Figure 3.30.

The Transfer Function Method was selected for use in the investigation of modal characteristics of engine components.

MODAL TESTING METHODS

NORMAL MODE METHOD	TRANSFER FUNCTION METHOD
Multi-Shaker	Single Point Excitation
Sinusoidal	Broadband
One Mode at a Time	Many Modes at a Time
Analog Instrumentation	FFT-Based Digital Instrumentation

Figure 3.30 : Modal Testing Methods.

3.2.3 Theoretical Modal Models

In order to gain insight into the dynamics of engine structures, it is necessary to provide basic knowledge of structure modelling. Modal Analysis is based on three fundamental assumptions concerning the nature of the structure. These are:

- i) The structure is linear. This means that the response of the structure to a combination of forces, simultaneously applied, is the sum of the individual responses to each of the forces acting alone.
- ii) The structure is time invariant
- iii) The analytical equations used to describe the structure must use parameters that are measurable. It means that the input-output measurements contain enough information to generate an adequate behavioural model.

Consider the Single Degree of Freedom System (SDOF) shown in Figure 3.31 consisting of spring, mass and damper.

Figure 3.31 : A Single Degree of Freedom Model

The equation of motion for the system is:

$$\sum F = ma \quad (3.84)$$

$$M\ddot{x} + C\dot{x} + kx = F \quad (3.85)$$

Taking the Laplace transform of Equation (3.85)

$$(Ms^2 + Cs + k)X(s) = F(s) \quad (3.86)$$

Let

$$B(s) = Ms^2 + Cs + k \quad (3.87)$$

Then, Equation (3.86) becomes,

$$B(s)X(s) = F(s) \quad (3.88)$$

or

$$X(s) = \frac{F(s)}{B(s)} \quad (3.89)$$

A transfer function $H(s)$ can be defined as

$$H(s) = \frac{1}{B(s)} \quad (3.90)$$

By combining (3.89) and (3.90)

$$X(s) = H(s)F(s) \quad (3.91)$$

Substituting Equation (3.87) into Equation (3.91),

$$H(s) = \frac{X(s)}{F(s)} = \frac{1}{Ms^2 + Cs + k} \quad (3.92)$$

$$\therefore H(s) = \frac{\frac{1}{M}}{s^2 + \frac{C}{M}s + \frac{k}{M}} \quad (3.93)$$

where

$$s^2 + \frac{C}{M}s + \frac{k}{M} = 0 \quad (3.94)$$

is the "characteristic equation".

The roots of the characteristic equation can be found by using the quadratic formula

$$s_{1,2} = \frac{-\frac{C}{M} \pm \sqrt{\left(\frac{C}{M}\right)^2 - 4\left(\frac{k}{M}\right)}}{2} \quad (3.95)$$

$$s_{1,2} = -\frac{C}{2M} \pm \frac{1}{2}\sqrt{\left(\frac{C}{M}\right)^2 - 4\left(\frac{k}{M}\right)} \quad (3.96)$$

or

$$s_{1,2} = -\frac{C}{2M} \pm \sqrt{\left(\frac{C}{2M}\right)^2 - \left(\frac{k}{M}\right)} \quad (3.97)$$

When $\left(\frac{C}{2M}\right)^2 - \frac{k}{M}$ is greater than zero, the system is said to be overdamped. When it is less than zero, underdamped. When exactly equal to zero, the system is said to be critically damped.

Underdamped systems are oscillatory in nature and best represent the majority of structural systems.

Critical damping

$$\left(\frac{C}{2M}\right)^2 = \frac{k}{M} \quad (3.98)$$

$$C_c = 2M\sqrt{\frac{k}{M}} \quad (3.99)$$

underdamped natural frequency ω_n

$$\omega_n = \sqrt{\frac{k}{M}} \quad (3.100)$$

$$\therefore C_c = 2M\omega_n \quad (3.101)$$

Define the Damping ratio, z , as

$$z = \frac{C}{C_c} \quad (3.102)$$

and the Loss factor as $\eta = 2z$ (3.103)

From Equations (3.97), (3.102) and (3.103)

$$\begin{aligned} s_{1,2} &= -\frac{C}{2M} \pm \sqrt{\left(\frac{C}{2M}\right)^2 - \frac{k}{M}} \\ &= -\frac{zC_c}{2M} \pm \sqrt{\left(\frac{zC_c}{2M}\right)^2 - \omega_n^2} \\ &= -z\omega_n \pm \sqrt{z^2\omega_n^2 - \omega_n^2} \\ \therefore s_{1,2} &= (-z \pm \sqrt{z^2 - 1}) \omega_n \quad (3.104) \end{aligned}$$

The damping factor σ is defined as the real part of each root i.e.

$$\sigma = z\omega_n \quad (3.105)$$

Damped natural frequency ω_d is defined as the imaginary part of each root

$$\omega_d = \omega_n \sqrt{1 - z^2} \quad (3.106)$$

When the value of the radical in Equation (3.97) is negative, the roots of the system characteristic equation will be complex. A graphical presentation of the roots of the characteristic equation is conveniently accomplished by the use of a Laplace-plane or, simply, s-plane.

Figure 3.32 illustrates the mapping of s_1 and s_2 onto the s-plane.

Thus the simplified equation for the roots of the characteristic equation is

$$s_{1,2} = -\sigma \pm j\omega_d \quad (3.107)$$

The roots of an underdamped system will be conjugate pairs as the imaginary part of each root is the only parameter that changes

Let

$$p = \sigma + j\omega_d \quad (3.108)$$

$$p^* = \sigma - j\omega_d \quad (3.109)$$

where * denotes conjugation.

The system transfer function can now be written as

Figure 3.32 : The mapping of S_1 and S_2 onto the S-Plane

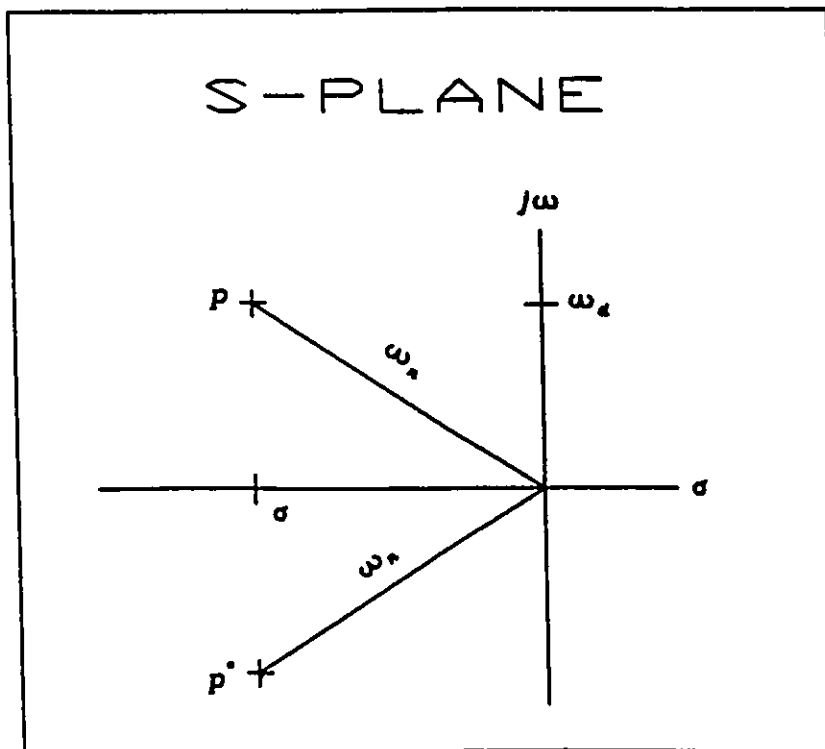

Figure 3.33 : The S-Plane Mapping

$$H(s) = \frac{\frac{1}{M}}{(s-p)(s-p^*)} \quad (3.110)$$

The s-plane mapping of Equation (3.110) is shown in Figure 3.33.

Hence, the fundamental definitions and relationships for an SDOF system have been established. These properties must now be linked to physically measurable parameters to make them useful for measurement applications.

Performing partial fraction on (3.110)

$$H(s) = \frac{c_1}{(s-p)} + \frac{c_2}{(s-p^*)} \quad (3.111)$$

and evaluating at $s=p$

$$c_1 = \frac{\frac{1}{M}}{2j\omega_d} \quad (3.112)$$

Evaluating at $s = p^*$ gives

$$c_2 = -\frac{\frac{1}{M}}{2j\omega_d} \quad (3.113)$$

The constant c_1 and c_2 are conjugates of one another.

Let

$$A = C_1 = \frac{\frac{1}{M}}{2j\omega_d} \quad (3.114)$$

$$A^* = C_2 = -\frac{\frac{1}{M}}{2j\omega_d} \quad (3.115)$$

Thus Equation (3.111) can be written as

$$H(s) = \frac{A}{(s-p)} + \frac{A^*}{(s-p^*)} \quad (3.116)$$

In order to construct a standard form of transfer function, we define a slightly different version of the complex amplitude which is called the complex residue

$$R = 2jA \quad \text{and} \quad R^* = -2jA \quad (3.117)$$

or

$$R = \frac{\frac{1}{M}}{\omega_d} \quad \text{and} \quad R^* = -\frac{\frac{1}{M}}{\omega_d} \quad (3.118)$$

Thus the standard form of the single degree of freedom transfer function now becomes

$$H(s) = \frac{R}{2j(s-p)} - \frac{R^*}{2j(s-p^*)} \quad (3.119)$$

So far Laplace transform does not lend itself for hardware implementation because it is a three dimensional domain: Frequency, Damping and Amplitude.

Structural analysis makes use of the fact that Fourier analysis, with its many types of hardware implementation, can be used to extract the frequency and amplitude data.

Damping can then be extracted by a variety of curve fitting techniques.

The system frequency response is defined as the system transfer function evaluated along the $j\omega$ -axis. This is the same as putting the system damping to zero. ($\sigma = 0$)

$$H(j\omega) = H(s) |_{s=j\omega} = \frac{R}{2j(j\omega - p)} - \frac{R^*}{2j(j\omega - p^*)} \quad (3.120)$$

or

$$H(j\omega) = \frac{1}{2} \left[\frac{R}{(\omega_d - \omega) + j\sigma} - \frac{R^*}{(-\omega_d - \omega) + j\sigma} \right] \quad (3.121)$$

This expression can now be used directly for measurement with modern dynamic signal analyzers. In addition, the Inverse Fourier Transform of the system frequency response function (i.e. Equation 3.121) is the impulse response of the system assuming all initial conditions are set to zero.

In practice, there are very few systems that can be accurately modelled by a single degree of freedom system. For the case of an n-degree of freedom system, it can be shown that the system transfer function can be expressed as

$$H(s) = \sum_{k=1}^n \left[\frac{R_k}{2j(s - p_k)} - \frac{R_k^*}{2j(s - p_k^*)} \right] \quad (3.122)$$

The next step is to link the equations of motion of the theoretical model to real structures. The mode shape (or eigen vector) of a system is defined as a vector which represents the motion of a given structure when excited at resonance (natural mode of vibration). The vector consists of a series of complex displacements which describe the amplitude and direction of deflections at each point on the given structure. In fact, these

are the system residues. By taking advantage of the symmetry inherent in the residue matrix ($h_{ij} = h_{ji}$, known as reciprocity), one can form an expression for a mode shape vector $\{U_k\}$

$$[R]_k = Q_k \{U_k\} \{U_k\}^T \quad (3.123)$$

where

Q_k = Arbitrary scaling constant

$k = k^{\text{th}}$ mode of the system

T = transpose of the vector

Obviously the mode shape vectors have different magnitudes for a given residue matrix depending on the value of Q_k . The scale factor Q_k is generally shown as one of several standard scaling methods such as the Unit Scale Factor (Q_k), Modal Mass = 1 and $Q_k = \frac{1}{\omega}$, etc.

Generally, it is unusual to make measurements on an SDOF system. Thus it is necessary to handle a situation where an arbitrary number of points and directions on a structure is selected for study and only a limited number of modes are of concern. Thus Equation (3.122) may be rewritten as

$$h_{rc}(s) = \sum_{k=1}^n \left[\frac{R_{rc}(k)}{2j(s - p_k)} - \frac{R_{rc}(k)^*}{2j(s - p_k^*)} \right] \quad (3.124)$$

where

r = row of transfer matrix $H(s)$

c = column of transfer matrix $H(s)$

n = total of modes to be studied

k = current mode number

p_k = pole location for the k^{th} mode = $\sigma_k + j\omega_k$

R_{rc} = residue of $h_{rc}(s)$ for the k^{th} mode.

Note that each term in the summation expression of Equation (3.124) is an $n \times n$ matrix which represents the contribution of each mode, k , to the transfer matrix.

For each identified shape vector, a hypothetical SDOF system can be constructed using the derived modal parameters such as the modal mass, modal stiffness and modal damping. These are related to the pole locations as follows:

$$M_k = \frac{1}{Q_k \omega_k} \quad (3.125)$$

$$K_k = (\sigma_k^2 + \omega_k^2) M_k \quad (3.126)$$

and

$$C_k = 2\sigma_k M_k \quad (3.127)$$

3.2.4 Modal Parameter Extraction Techniques

So far the discussion has focussed on how modal parameters can be combined to determine the spatial deflection of structures. However, it is useful to address how these parameters are obtained from vibration measurements on the structure. An estimate of the natural frequencies of specific modes can be made simply by determining the frequency peaks in the frequency response function. This concept works very well for simple systems that have few modes, light damping, wide separation of modes, and minimal measurement noise.

The damping ratio can be obtained by finding the upper and lower frequencies

(ω_u, ω_l) on either side of the damped natural frequency which display amplitudes of 3 dB below the peak of the frequency response magnitude. Thus the expression:

$$\approx \frac{1}{2} \left(\frac{\omega_u - \omega_l}{\omega_d} \right) \quad (3.128)$$

can be used to obtain the damping ratio.

The residue can now be determined by using the following approach.

From Equation (3.121)

$$H(j\omega) = \frac{1}{2} \left[\frac{R}{(\omega_d - \omega) + j\sigma} - \frac{R^*}{(\omega_d - \omega) + j\sigma} \right]$$

At resonant $\omega = \omega_d$, $H(j\omega)$ becomes

$$H(j\omega_d) = \frac{1}{2} \left(\frac{R}{j\sigma} - \frac{R^*}{-2\omega_d + j\sigma} \right) \quad (3.129)$$

A convenient approximation can be made for $H(j\omega)$ in cases where the damped natural frequency is much larger than the damping factor, i.e.,

$$H(j\omega_d) \approx \frac{1}{2} \left[\frac{R}{j\sigma} \right] \quad (3.130)$$

This equation is valid for lightly damped structures which exhibit damped natural frequencies that are much greater than their associated damping factors.

In Equation (3.130), $H(j\omega_d)$ is purely imaginary, thus:

$$\text{IMAG}\{H(j\omega_d)\} \approx \frac{R}{2\sigma} \quad (3.131)$$

$$\text{REAL}\{H(j\omega_d)\} \approx 0 \quad (3.132)$$

Rearranging Equation (3.131)

$$R = 2\sigma \text{IMAG}\{H(j\omega_d)\} \quad (3.133)$$

Recalling that

$$\sigma = z\omega_n$$

and, when $z \ll 1$,

$$\omega_n \approx \omega_d$$

Hence

$$\sigma \approx z\omega_d \quad (3.134)$$

It is important to note that Equation (3.128) permits z to be determined and Equation (3.134) can be used to find σ . The residue (and ultimately the mode shape) can be obtained from Equation (3.133) because the value of the imaginary part of the frequency response function at ω_d can easily be determined from the Fourier analyzer.

The technique mentioned above is called quadrature peak picking. It is applicable to frequency response functions that are noise free, with light damping, and have enough data points to enable accurately estimate:

- a) the damped natural frequency,
- b) the 3 dB down points and

c) the magnitude of the imaginary part of the frequency response function. In addition, the modes must be widely spaced otherwise the skirt of any one mode can cause large errors in the parameter estimation.

3.2.5 Frequency Response Functions

There are six different forms transfer functions for mechanical system as shown in Figure 3.34. In general, all these transfer functions contain the same information. The decision to use one or a combination of these transfer functions depends on the capability of the equipment, the frequency range of interest, the types of transducers etc.. In this study, accelerometers, force transducers and a dynamic signal analyzer were used to obtain the "Accelerance" transfer functions.

$\frac{\text{DISPLACEMENT}}{\text{FORCE}}$	=	DYNAMIC COMPLIANCE	$\frac{\text{FORCE}}{\text{DISPLACEMENT}}$	=	DYNAMIC STIFFNESS
$\frac{\text{VELOCITY}}{\text{FORCE}}$	=	MOBILITY	$\frac{\text{FORCE}}{\text{VELOCITY}}$	=	MECHANICAL IMPEDANCE
$\frac{\text{ACCELERATION}}{\text{FORCE}}$	=	ACCELERANCE	$\frac{\text{FORCE}}{\text{ACCELERATION}}$	=	DYNAMIC MASS

Figure 3.34 : Summary of the Different Forms of Transfer Functions for Mechanical Systems.

3.3 Sound Intensity

The sound intensity vector, \vec{I} , is the net rate of flow of energy per unit area at a given position. Thus the acoustic power, W , passing through a surface, S , is defined as:

$$W = \int_s \vec{I} d\vec{S} \quad (3.135)$$

The usefulness of the sound intensity concept is primarily due to this fundamental relationship. In a medium without flow (i.e. without bulk movement of the medium), the time averaged intensity vector, \vec{I} , is equal to the product of the instantaneous pressure, p , and the instantaneous particle velocity \vec{v} , at the same point, i.e.,

$$\vec{I} = \overline{p\vec{v}} \quad (3.136)$$

where the long horizontal bar denotes a time average. Hence the intensity vector in a given direction r is estimated to be,

$$\vec{I}_r = \overline{pv_r} \quad (3.137)$$

p is the sound pressure at the measuring position

v_r is the particle velocity at the measuring position in the direction r

3.3.1 Finite Difference Approximation

The particle velocity, \hat{v}_r , in a particular direction r , can be closely approximated by integrating over time the difference in sound pressure at two points, A and B, separated by a distance Δr . Mathematically:

$$\hat{v}_r = -\frac{1}{\rho_o} \int \frac{(p_B - p_A)}{\Delta r} dt \quad (3.138)$$

where ρ_o is the density of the air, and $p_B - p_A$ is the pressure difference. In practical applications, the Bruel and Kjaer sound intensity system may be used to measure p_A and p_B .

The signals are frequency analyzed in parallel in real time and the sum and difference of the two signals for each frequency band are calculated, $p_B + p_A$ and $p_B - p_A$. The difference is integrated over time and divided by the distance between the two microphones of the probe to yield the particle velocity \bar{v}_r . The sum divided by two, (i.e. the sound pressure mid-way between the microphones), is then multiplied by the particle velocity to yield the sound intensity vector component, \bar{I}_r , according to Equation (3.137).

It should be noted that the magnitude of the measured intensity component depends on the orientation of the probe; a maximum is measured when the probe's axis of symmetry is pointed towards the sound source and a minimum is measured when the probe is perpendicular to the line joining the probe to the source.

Intensity measurements are extremely susceptible to phase differences in the two channels of the measuring instrument. This phase mismatch comprises of:

- 1) the phase mismatch between the two microphones.
- 2) the phase mismatch between the two channels of the analyzer.

The phase mismatch is worst at low frequency for a given distance between the acoustical centers of the two microphones Δr . Hence phase mismatch limits the lowest usable frequency for a given Δr , i.e., large Δr is to be preferred at low frequency while small Δr is best at high frequency.

CHAPTER 4.

EXPERIMENTAL DETAILS

In this study, a number of V-6 engines were tested in two distinct ways i.e. externally driven (Cold Test) and Hot Test or Dynamometer Test. Vibration signals were captured and analyzed. They served as a primary parameter for monitoring the engine conditions. The engine noise and cylinder pressure were also monitored. However they served as secondary parameters. A number of experiments were performed, each of different nature and function. These were:

1. Modal analysis of the engine
2. Cold test of engines
3. Hot test of engines
4. Dimensional measurements.

The following sections will describe the experimental measurement procedures and the associated equipment used.

4.1 Modal Analysis of Engine

The vibration mode analysis of an automotive internal combustion engine block was performed in order to achieve two main objectives;

- 1) to study the dynamic response of the engine block and its components; and
- 2) to determine the proper mounting location for the vibration transducers used in the cold test diagnostic system.

Figure 4.2 shows the schematic of the modal analysis system and the equipment used in this experiment is shown in Figure 4.1.

Experiment Tasks	Equipment
Dimensional measurements of engine components	LK Micro Four Coordinate Measuring Machine
FFT Analysis	B&K 2032 Signal Analyzer
Impact Testing	PCB Model 086B05 Modally Tuned Impact Hammer
Sensor	PCB 303A02 Accelerometer
Modal Analysis	SMS Version 6.01 Structural Measurement System
Signal Analysis	Hewlett Packard HP 9000 Model 320 with Motorola 68020 Processor

Figure 4.1 : Experimental Apparatus for Modal Analysis

In this experiment, the modal analysis of an engine block was carried out by the impulse-frequency response technique which measured the response of an impulsive force applied to the engine block as schematically illustrated in Figure 4.2.

The signals from the accelerometer and load cell on the hammer were passed through anti-aliasing filters before analog to digital conversion. The amplitude and phase angle at each point on the engine block (at natural frequency) can be evaluated by modal analysis software, SMS structural measurement systems. The major steps in the modal analysis for a given engine are:

1. The impact point and the number and location of response sites are selected.
2. The geometry of the measurement points is defined and serial numbers are marked on the engine block.
3. Dimensional measurements are carried out and recorded in a written log.
4. Frequency responses are captured through the B&K 2032 FFT analyzer and transferred to the HP 9000 computer.
5. Curve fitting of the data governing frequency, damping and residues is performed.
6. Mode shapes are evaluated and plotted. These are displayed in animated forms.

Figure 4.2 : Layout of Modal Analysis System

4.2 Cold Test of Engine

One of the conventional methods to detect a missing connecting rod bearing, in a so called "B" test (also known as cold test), is the measurement of the deck height of the piston at the location of TDC from the cylinder block deck. Decisions of pass, fail or repair will be based on the results of these tests. However, the deck-height measurement method is required to be improved due to its inconsistency in results and durability of gage. As an attempt to replace this dimensional gaging by a more reliable method, vibration and noise measurements were assessed. The following experiments were carried out as part of this effort.

4.2.1 Sound and Vibration Measurements

The vibration of the engines, both normal and defective, was monitored when the engine was driven at the speeds of 250 RPM and 420 RPM by an electric motor. To measure vibration, two PCB 308M86 transducers were mounted on the pan rail of the engine and the output was captured with the use of the Nicolet 440 Waveform Analyzer and PEC68K Data Acquisition System. The locations of the accelerometers were carefully selected from the results of a modal analysis of the engine block. The location of the microphone was determined by trial and error as shown in Figure 4.3.

More details of the data acquisition and processing equipment are discussed in the following section. The full schematic of the B-Test stand hardware is illustrated in Figure 4.4.

The Nicolet 440 Waveform Analyzer was used in conjunction with the built-in PEC68K Data Acquisition System. It has an ability to store 260K data points per sweep in its random access memory (RAM) which can then be analyzed on the oscilloscope or saved on a Bernoulli hard disk. Every sweep of the Waveform Analyzer was triggered at the same crank angle by utilizing a position sensor. The feature of the autocycle function of

Figure 4.3 : B-test stand showing locations of accelerometers and Microphone.

Figure 4.4 : The Full Schematic of Cold Test Stand Hardware

the system enabled the data acquisition and storage to be obtained with a minimum loss of time domain history due to data processing.

The overall test cycle involving the test stand is represented by the flowchart in Fig. 4.5. The solid line elements of the chart signify the additions proposed for the vibration test. The vibration test was executed as a substitution of the conventional deck height test. The detail flowcharts of the vibration test of the current production system and the development system are found in Appendix B.

Each test was executed as a module. The overall test cycle was initiated by a PLC (Programmable Logic Controller) bit indicating that the engine was fully clamped and that all the sensors were in position. As depicted in the flowchart, the modules were executed in the following order:

- 1) Breakaway Torque (60 Nm low limit and 110 Nm high limit),
- 2) Running Torque (13 Nm low limit and 24 Nm high limit) and
- 3) Vibration Test (Variance $0.25 g^2$ at 250 rpm, $0.71 g^2$ at 420 rpm).

At the completion of each test, the result of the test was checked and the remainder of the test sequence was aborted if there was a reject.

4.2.2 Data Acquisition

Once the encoder interrupts were enabled, data acquisition began. The vibration data was acquired in the ISR's (Interrupt Service Routine) for each accelerometer. When the ADC indicated that a conversion was completed, the Motorola 68000 microprocessor executed an ISR based on the multiplexer channel selected. The ISRs for both accelerometers stored the result of the conversion, and accumulated the sum of all the vibration measurements taken. The sums were later used to calculate the mean of the signal.

The ISRs for the accelerometers were not the same. However, when an encoder interrupt occurred, on either rising or falling edge, both accelerometer outputs have to be

Figure 4.5 : Flowchart of Overall Test Cycle.

sampled. To accomplish this, a "glitch" in the ADC (Analog to Digital Converter) was exploited. Whenever the ADC was read, another conversion was initiated and, when it was completed, another interrupt was triggered. In other tests, this was avoided by turning the ADC interrupt off prior to reading the result of the conversion of accelerometer #1, then the multiplexer channel was changed to accelerometer #2. Reading the output of the ADC at this point resulted in another conversion being initiated. Like ISRs for the other tests, the ISR for accelerometer #2 disabled the ADC interrupt prior to reading its value. The ADC was then read, and the multiplexer was set back to the channel for accelerometer #1. The next encoder interrupt then reenabled the ADC interrupt and the process was repeated.

Because the ADC was not a simultaneous sample and hold device, the accelerometers were not read at exactly the same time. There was a time differential between readings of 25 microseconds (the conversion time for the ADC). However, the conversion time did not affect the performance of the test because this period is short compared to the time span for the highest frequency response of the signal.

Vibration was sampled in the above manner for eight revolutions. The storage location of the sampled data was reset when sample #2047 was obtained. This indicated the last sample for each revolution.

In the initial acquisition of data, reference signals were captured from a normal engine. Thereafter, the engine was checked dimensionally in the standard room and proved within engineering specifications. Subsequently, the engine was operated with missing or defective parts in piston No. 1. These were repeated for every piston with missing or defective parts, by the firing order. The characteristics of the defective engine components were as follows:

1. Missing connecting rod bearings
2. Unbalanced crank
3. Nick on balance shaft gear
4. Loose connecting rod nuts

5. Reversed bearing cap
6. Mismatched bearing cap
7. Cylinder bores defective machining
8. Tight piston pin
9. Missing main bearings
10. Loose main bearing bolts.

The results of these tests will be discussed in Chapter 6.

4.3 Hot Test or Dynamometer Test of Engine

In the automotive industry, a hot test is performed to measure engine performance capability to pre-established minimum acceptance criteria in the dynamometer laboratory. Vibration, noise, and cylinder pressure measurements were carried out during the hot test and the results were compared to that of the cold test. The general procedure used for this test and equipment is described in this section.

4.3.1 Engine Test Stand, Dynamometer and Control System.

The schematic of an engine test stand is illustrated in Figure 4.6. It consists of

- a) a T-slotted base plate on isolated foundation
- b) engine mounts
- c) a drive shaft
- d) the engine
- e) a dynamometer and control system
- f) the test stand control and data acquisition system.

The test engine was mounted on a separate base plate to that of the

Figure 4.6 : A Schematic Diagram of an Engine Test Stand

dynamometer. This set-up was desirable so that any motion of the engine frame would not cause any detrimental effect to the engine itself and would not transmit any vibration to the adjacent area. The connection of the test engine and the dynamometer was through a special elastic drive shaft which allowed an axial mis-alignment and reduced variations in the torque and running speed.

In this study, the eddy current dynamometer shown in Figure 4.7 was used for measuring the engine torque and speed. The system is an assembly of four different components:

- a) Rotating eddy current machine
- b) Cradle
- c) Torque measuring equipment
- d) Speed measuring equipment.

The eddy current dynamometer is easily controlled by a d.c. input. Its main advantages include high power absorption, high speed capabilities and relatively low cost.

The d.c. flowing through the exciting coil, which is fixed to the dynamometer casing, produces a magnetic field which counteracts the rotary motion because the dynamometer casing is connected to the torque measuring equipment (load cell) through a lever arm. The moment of reaction is indicated as a force for a definite length of lever arm. To determine the power output it is essential to measure the speed: a proximity sensor senses the slots in a toothed disc at the shaft end of the dynamometer and produces voltage impulses. These impulses are converted into a speed-dependent voltage which is used for speed indication and control.

The standalone independent data acquisition and control system is coupled with the dynamometer to provide a complete engine test system. The system is based on a Digital Equipment Corporation PDP 11/73 computer and peripherals and the software using DEC's RSX-11M Plus operating system. The system was designed to ensure

Figure 4.7 : A Block Diagram of a Complete Test Cell

ease of use by laboratory test personnel and to provide the power and flexibility necessary to run various test procedures. The block diagram of a complete test cell is illustrated in Figure 4.7.

The software for the test system is structured to provide two distinct levels of interaction: operation level and configuration level. The operation level provides the function needed to start and stop a test procedure, display data print data and operate the safety shutdown system. The configuration level provides various menu-driven interactive programs that allow a user to adjust the system to specific requirements.

A sample of the parameters measured and displayed in typical engine operating conditions is shown in Figure 4.8.

4.3.2 Data Acquisition System for Hot/ Dynamometer Test

The data acquisition for the Hot/Dynamometer test was divided into three different systems. Each system had its advantages and disadvantages and these will be summarized in the analysis of the engine test data.

4.3.2.1 System No. 1: Data Acquisition System Using Dynamic Analyzer

The block diagram in Figure 4.9 illustrates the interaction of the equipment in the complete measurement system. The basic components are the trigger box, transducers, dynamic signal analyzer, computer and its control system.

The trigger system consists of the signal inductive pick-up and a conditioning box. The conditioning box converts the spark plug signal to a TTL (Transistor-Transistor Logic) compatible voltage signal that is suitable for the external trigger of the dynamic signal analyzer.

The data acquisition system contains a computer with software, analyzer, a

programmable filter and transducers. The signal passes through the filter where aliasing frequencies are removed. After triggering, the data is collected by digital sampling in the HP 3561A analyzer. The computer is programmed to control the analyzer, filter, mass storage and printer functions. The typical menu is shown in Figure 4.10. The programs are written in HP BASIC for both the data acquisition and analysis. The listings of these programs are found in Appendix C.

4.3.2.2 System No. 2: Data Acquisition System Using Nicolet 440

The schematic in Figure 4.11 shows the system which uses the Nicolet 440 Benchtop Waveform Acquisition System which is a four channel, 12 bit, 10 mega samples per second system. This system digitizes and stores the signals in memory and shows them on the display screen. The displayed waveforms can then be used to measure time and voltage values, manipulate the waveform either internally (which has a 260 k data points sweep capability) or send it to an external computer.

Six transducer bases were glued down on the engine block (centre line of the pistons) and B&K 4384 transducers were mounted. The signal was amplified through a B&K 2635 Charge Amplifier and then captured by a Benchtop Waveform Data Acquisition System. Modal analysis was performed earlier in the experiment to determine the location of the transducers to avoid the vibration nodes of the engine block.

The vibration signal was captured at the time of number 1 engine spark plug firing. This was made possible by using the external trigger signal generated by the induction of the #1 engine spark plug cable. The crank angle at the firing of the spark plug was recorded. Twenty five engine cycles of traces of vibration data, which represented 50 revolutions of the crank shaft, were swept in the oscilloscope and then saved to a built-in data storage system as one set of data. Forty sets of data were acquired for different engine operation conditions. Figure 4.12 is a sample of the data acquisition system set-up.

4.3.2.3 SYSTEM NO.3 : 8 Channel Data Acquisition System

The block diagram of the 8-channel data acquisition system is illustrated in Figure 4.13. The heart of the system consists of Motorola 68020 CPU (Central Processing Unit), 1 Megabyte of RAM (Random Access Memory), interrupt control, serial port, I/O (input/output) interface. The data acquisition box is connected to six transducers, a magnetic pick-up, Engine PIP (Profile Ignition Pickup) and CID (Cylinder Identification) signals from the Electronic Engine Controls and finally a personal computer with programs to handle the data acquisition and analysis. The flowchart of the data acquisition programs for both the Box and the personal computer can be found in Appendix D.

Figure 4.13 : System No. 3, 8-channel Data Acquisition System.

4.4 Sound Pressure and Sound Intensity Measurements

The Bruel and Kjaer Type 3360 Sound Intensity Analysis System consists of the Sound Intensity Analyzer Type 2134, the Display Unit Type 4715, the Sound Intensity Probe Type 3519 and Remote Indicating Unit ZH 0250. The 3360 can measure the vector quantity sound intensity level in real time 36 third-octave bands with center frequencies from 3.2 Hz to 10 kHz and in the 12 octave bands with center frequencies from 4 Hz to 8 kHz. The results are displayed on the separate, calibrated Display Unit Type 4715 where not only the sound intensity level can be measured but also the direction of the incident sound intensity can be inferred.

The 2134 and 4715 combination can also be used as a digital frequency analyzer in real time for measurements of sound pressure levels and in a wide variety of analyses of acoustical, vibrational and other signals. For sound pressure measurements, a real-time analysis is performed in the 42 third-octave bands with center frequencies from 1.6 Hz to 20 kHz and the 14 octave bands with center frequencies from 2 Hz to 16 kHz.

For both modes of operation, i.e., sound pressure level mode and the sound intensity level mode, the input signal may be A-weighted in the input amplifier before displaying the resulting spectrum.

4.4.1 Sound Intensity Analyzer Type 2134

The Type 2134 is a digital frequency analyzer with two input channels primarily designed for sound intensity measurements. Either channel can be used for sound pressure measurements and both channels are employed simultaneously when the Type 2134 is used to measure sound intensity. The sound pressure and sound intensity modes of operation are push-button selectable on the front panel.

4.4.2 Calibration

The probe can be calibrated, one microphone at a time, by means of a known sound pressure level such as that provided by the Pistonphone Type 4220 (which provides 124 dB re 20 μ Pa sound pressure level at 250 Hz with an accuracy of ± 0.15 dB). A calibrated barometer is provided with the pistonphone to determine the necessary correction due to the atmospheric pressure.

It can be shown that when calibrating the system for use in the sound intensity mode only half the atmospheric pressure correction (which is indicated on the barometer in dB) must be applied to each microphone.

The reference for the sound pressure is 20 μ Pa and the reference intensity for sound intensity level is $1 \text{ pW} / \text{m}^2$. These reference values have been chosen so that, for a freely propagating plane wave, the intensity level, IL, is practically equivalent to the sound pressure level, SPL. The actual relationship is:

$$IL = SPL - 0.16 \text{ dB.}$$

Therefore with pressure calibration, the intensity levels are 0.16 dB too high, which can be allowed for, if desired, by adjusting the sensitivity control. This calibration with a known sound level automatically calibrates the system for sound intensity level and the sound intensity levels on the display unit are given in dB re $1 \text{ pW} / \text{m}^2$.

4.4.3 Sound Intensity Vector Component Calculations

The Bruel and Kjaer 2134 contains four, front panel selectable programmes to calculate the sound intensity vector component, I_r , for the four permissible combinations of spacer, δr , and microphone (i.e. for $\delta r = 6$ mm or 12 mm with the 1/4" microphones or for $\delta r = 12$ mm or 50 mm for the 1/2" microphones). Before performing a measurement, the optimum probe configuration range should be chosen for a particular application by considering the probe size, probe sensitivity and frequency range.

4.4.4 Display Unit Type 4715

Measurement results are displayed on the Display Unit Type 4715 in the form of a bar-graph in third octave or octave bands. For sound pressure measurements the bars on the display all have the same brightness. For sound intensity measurements however, there are two different levels of brightness for the bars on the display unit; "grey", "normal" brightness columns for the sound intensity which is incident on the front probe (referred to as "positive" intensity); "white" columns for the sound intensity which is incident on the rear of the probe.

4.4.5 Remote Indicating Unit ZH 0250

In very confined spaces or where the quantity of information presented by the Display Unit is more confusing than helpful, it can be preferable to use the probe in conjunction with the Remote Indicating Display Unit ZH 0250. The small, hand-held ZH 0250 enables a single channel, either octave or third octave, of either sound pressure level or sound intensity level to be read out from the 2134 in the form of a bar graph. The unit can also initiate integrations and can operate up to 50 m from the 2134.

4.5 Transducers and Accessories

There are several transducers and their supporting equipment used in this study. The specifications and functions are discussed in the following sections.

4.5.1 Bruel and Kjaer Type 4384 Accelerometer

The active elements of this accelerometer consist of a piezoelectric disc loaded by seismic masses and held in position by a clamping ring. When the accelerometer is subjected to vibration, the combined seismic mass exerts a variable force on the

piezoelectric element. This force then produces a corresponding electric charge due to the piezoelectric effect. The key specifications are listed in Figure F.1 (Appendix F). This accelerometer is also supplied with calibration chart and measured frequency response curve.

4.5.2 Bruel and Kjaer Type 2635 Charge Amplifier

This is a portable low noise charge amplifier for use with piezoelectric accelerometers. Accurate three digit conditioning networks allow dial-in of exact sensitivity to give amplifier output rating between 0.1 to 1000 mV/unit. The major specifications of this unit are outlined in Figure F.2.

4.5.3 PCB Model 302A21 Accelerometer

This is low impedance quartz accelerometer designed for operation in high (400° F) temperature environment. The accelerometer operates from low cost power unit and connects directly to some FFT analyzers equipped with ICP (Integral Circuit Piezoelectric) current source. The major characteristics are tabulated in Figure F.3.

The accelerometer is also supplied with an individual NBS (National Bureau of Standards) traceable calibration certificate.

4.5.4 PCB Model 308M86 Accelerometer

The accelerometer is built with a proven, quartz element and advanced microelectronic circuit capable of withstanding dirty factory environment. The specifications are outlined in Figure F.4.

4.5.5 PCB Model 408D06 Power Supply

This power supply is used with ICP (Integrated Circuit Piezoelectric) transducers. Its functions include powering the transducer electronics, amplifying the signal, debiasing the output signal and indicating normal or faulty system operation. The main specifications are listed in Figure F.5.

4.5.6 Bruel and Kjaer Type 4249 Calibration Exciter

This accelerometer calibrator is completely self-contained, pocket-sized, vibration reference source for laboratory and field applications. It is designed to produce a reference acceleration level of 10 ms^{-2} rms at a frequency of 159.2 Hz ($\omega = 1000 \text{ rads}^{-2}$) and is intended for rapid calibration of vibration measurement, monitoring and recording systems utilizing piezoelectric accelerometers. The main specifications are outlined in Figure F.6.

4.5.7 Bruel and Kjaer Laser Velocity Transducer Set Type 3544

The Laser Velocity transducer set consists of the Laser Velocity Transducer and Power Supply. By attaching a small piece of retroreflective tape to the surface of the vibrating object (or painting the surface with reflective liquid), vibration velocity at that point can be measured by aiming the Laser on the object.

It is designed for use in all those applications where an accelerometer cannot be used. Such applications includes measurement on:

- a. hot surfaces of structures (e.g. engine exhaust)
- b. light structures (such as disk drive head) and
- c. rotating surfaces (sides or ends of shafts)

The specifications of this equipment are summarized in tabular form on Figure F.7.

4.5.8 PCB Model 086B05 Impulse Force Hammer

The hammer consists of an integral, ICP, quartz force sensor mounted on the striking end of the hammer head. It is structured with rigid quartz crystals and a built-in microelectronic unity gain, isolation amplifier. The hammer sensitivity is outlined in Figure F.8.

4.5.9 PCB MODEL 303A02 Accelerometer

This miniature ICP (Integrated Circuit Piezoelectric) accelerometer is designed specifically for high frequency response. The size makes it ideal for structural measurement where the effect of the accelerometer on the structure is critical. The specifications and calibration specifications are tabulated in Figure F.9.

4.5.10 PCB Model 112A Pressure Transducer

A standard spark plug is modified to mount a miniature quartz pressure transducer in a spark ignition engine for measuring combustion pressures. The specifications for this transducer are tabulated in Figure F.10.

4.5.11 Bruel and Kjaer Type 4155 Microphone

This is a free field, half inch condenser microphone used for general and low sound level measurements. The free frequency response from 4 Hz to 16 kHz is $\pm 2dB$. The sensitivity is 50 mV/Pa. The influence of 1 ms^{-2} axial vibration is typically 60 dB equivalent sound pressure level. The influence of relative humidity is 0.004 dB/% RH while the influence of static pressure is -0.001 dB/mbar.

4.5.12 Bruel and Kjaer Type 2231 Sound Level Meter

The Bruel and Kjaer Type 2231 is a precision hand held sound level meter. With Microphone type 4155, it has a measuring range of 24 dB to 153 dB. The availability of interchangeable application modules allow measurement of acoustical parameter of wide range of acoustical parameter. The other main specifications are summarized in Figure F.11.

4.5.13 Rockland Model 2783 Signal Processing Filter

Rockland Model 2783 is a high pass/ low pass filter/ signal conditioner with near-ideal passband and stopband characteristics. It has the following main features;

- 1) 3 digit resolution from 0.1 Hz to 110 kHz
- 2) 8 pole/8 zero Elliptic response
- 3) differential inputs with low noise amplifier to handle signals from 1 mV to 31.6 V full scale.
- 4) selectable bipolar or unipolar output swing to suit all A to D converters.
- 5) overload indicators to avoid signal distortion.
- 6) opto-isolated GPIB and RS 232 interfaces.

The detailed specifications are outlined in Figure F.12.

4.6 Time and Frequency Domain Analysis Equipment

4.6.1 Bruel and Kjaer 2032 Dual Channel Signal Analyzer

The Bruel and Kjaer 2032 analyzer is a two channel Fast Fourier Transform (FFT) analysis system having 801 lines of resolution. It is fast because of its high real time frequency of 5 kHz. It has a fully instrumented front-end and user defined calibration. The full specifications are listed in Figure F.13.

4.6.2 Hewlett Packard HP3561A Dynamic Signal Analyzer

The Hewlett Parkard HP3561A is a single channel narrow band dynamic signal analyzer with a frequency range of 100 kHz. It weighs only 16 Kilograms. The analyzer is equipped with a bubble memory capable of storing more than 100 time traces and frequency spectra. The analyzer measures input signals from 22.39V rms to 2.82 mV rms. The 80 dB dynamic range of this equipment allows measurement of signal of interest exists in the presence of large unwanted signals. The signal processing capabilities include rms averaging, rms exponential weighting averaging, and time averaging. It also has software for mathematical operations which can be applied to measurement data for additional processing. The A-weighting filter is available for acoustic measurements. The Integrated Circuit Piezoelectric (ICP) current source is available for powering ICP accelerometers.

Most important of all in automated measurement, this analyzer is equipped with the Hewlett Packard Interface Bus so that it can be controlled remotely by a computer. Since measurement data can be remotely input or output, it is possible to extend, with a computer, the basic measurement capability of this instrument. The detailed specifications are summarized in Figure F.14.

4.6.3 Nicolet 440 Benchtop Waveform Acquisition System

Vibration data during an engine test was captured in the Nicolet 440 Benchtop Waveform Acquisition System which is a four channel, 12 bit, 10 megasamples per second system. This system digitizes analog input signals, stores the digitized signals in memory and shows them on the display screen. The displayed waveforms can then be used to measure time and voltage values, manipulate the waveforms either internally in the system or send it to an external computer, Which has a 260K data points sweep capability. The detailed system specifications are outlined in Figure F.15.

4.7 Data Presentation

The acquired data and results obtained were presented, with the use of various computer programs developed and DADiSP. The computers and peripherals used include the following:

1. IBM PS/2 Model 90 computer,
2. Hewlett Packard 9000 Model 360 computer,
3. Hewlett Packard HP 7550 plotter,
4. Hewlett Packard Laserjet III printer and
5. Hewlett Packard Thinkjet printer.

4.8 Engine Teardown Analysis

The test engine is mounted on the engine teardown stand for complete dimensional and torque measurements. Typical torque and dimensional measurements of the engine are shown in Figures 4.14 and 4.15, respectively.

Figure 4.15 : Dimensional Measurement Data

4.8.1 Piston to Bore Clearance

The air gages with electronic column readout are calibrated with the masters. Before measurements, the piston and the cylinder bore were thoroughly cleaned and were free of oil residue. The piston to bore clearance was then measured using the air gage system shown in Figure 4.16.

4.8.2 Offset Piston Skirt with respect to Ringland

In the production environment, any dimensional measurement has to be performed in an effective and reliable manner. The measurement of the runout of the piston skirt with respect to ringland number 1 is accomplished using the gage shown in Figure 4.17.

Using Figure 4.18 as a guide, the measurement procedure for the runout of the piston skirt with respect to the ringland is as follows:

- i) Orient the piston as shown.
- ii) Push the piston against a stop at indicator base.
- iii) Zero the indicator.
- iv) Rotate the piston 180° .
- v) Record the measurement AC (including sign).
- vi) Similarly BD can be measured by zeroing the indicator at B and measuring at D.
- vii) The offset is thus calculated using the formula.

$$\text{Offset} = \sqrt{(AC)^2 + (BD)^2}.$$

4.8.3 Concentricity of Ringland with respect to Skirt

This measurement is performed in the laboratory where the environment (temperature, humidity, and cleanliness) is controlled. This is done using a special Coordinate Measuring Machine. After positioning the piston skirt, the measuring head

Figure 4.18 : Measurement Guide for Concentricity of Piston Ringland to Skirt

was programmed to sweep through the ringland and measure the coordinates of 1500 points on the ringland. Typical results of the measurement are shown in Figure 4.19.

This measurement is far more accurate than the production gage. The correlation between these measurement methods is shown in Figure 4.20. The correlation R is equal to 0.957 which indicates a "strong" linear relationship between the production gage measurement and the CMM measurement.

4.8.4 Piston Skirt Ovality and Taper Measurement

The Adcole Model 910 auto inspection gage (computer controlled) shown in Figure 4.21 is used to measure the piston skirt ovality and taper measurement. In this measurement, the piston is chucked in the headstock machine while a carbide follower records the movement as the piston rotates. The piston skirt profile is shown in Figure 4.22. The skirt ovality is summarized in Figure 4.23.

CHAPTER 5.

DATA ANALYSES

The important variables which are related to the combustion and mechanical impacts to be monitored are as follows:

- 1) Vibration signals, either acceleration or velocity,
- 2) Noise signals,
- 3) Cylinder pressure of engine and others.

As a set-up guide, a preliminary measurement of vibration, noise and cylinder pressure signals was made to observe the engine characteristics. It was found that the vibration, noise and pressure signals are deterministic in nature. In addition, there was a distinct increase in the amplitudes of the vibration signals when the engine was running with defective engine components. Therefore, the descriptor which is able to represent these distinct characteristic changes when the defective engine runs will be meaningful and effective in this engine diagnosis study. Vibration signals were selected as the primary signals while noise and cylinder pressure signals were used to verify the results.

In this study, data analyses were carried out as follows:

1. The vibration signals obtained from the engine operations were analyzed in the time and frequency domains. Appropriate methods of analysis in the two domains were derived, separately, through visual inspection of the time-amplitude vibration signals and the frequency spectra obtained.
2. Time domain averaging and variance analysis were then performed with respect to the time datum or location datum of the data.
3. Four statistical descriptors were selected and calculated for the time domain analysis, namely: mean, standard deviation, skew, kurtosis.
4. In the frequency domain analysis, peak value of the frequency spectrum was used.

5.1 Time Domain Averaging

A typical vibration signal from normal engines is shown in Figure 5.1. In this research, a time domain averaging (TDA) technique was used to analyze the vibration signal. It is accomplished by simply averaging desired time traces. Even though simple to implement, it is a powerful technique for extracting periodic components from a raw signal. It is also useful for detection of any fault that is consistently regular, but not if transient or irregular [2]. Therefore, the time domain signal averaging technique is employed in this research. It is accomplished by simply averaging desired time traces.

A typical vibration signal from one engine cycle as shown in Figure 5.2 can be separated into periodic and semi-periodic components as illustrated in Figures 5.3 and 5.4, respectively. In the separation procedure, the periodic components are determined by time domain averaging of 15 engine cycles of vibration signals, and the semi-periodic components are derived by subtracting the periodic components from the composite (original) signal.

As an attempt to relate these time traces to the history of the piston movement, in terms of crank angle, each time record is initiated at a common trigger point in both the hot and cold tests. After a sufficient length of time sweep, a new trace of time series is triggered at the same crank angle. A mathematical description of the TDA (including its properties as a filter in eliminating non-cycle linked signals), is provided in reference [22].

Figure 5.4 : Semi-Periodic Components of Vibration Signals

5.2 Statistical Parameters

In this study, three statistical descriptors were selected to describe the overall amplitude characteristics of the signals, such as its spread/dispersion, symmetry, and peakedness. They are:

1. Variance (a measure of spread)
2. Skew (a measure of symmetry)
3. Kurtosis (a measure of peakedness)

To calculate these statistical descriptors, vibration signals were first grouped according to amplitude classes. The most obvious advantage of performing computations on the grouped data is the significant reduction in the computation speed. In the grouping process, the amplitude scale was divided into classes of equal interval and the number of times data values fall in each class was tallied. As such resultant grouped data (or frequency distribution) is known as the amplitude distribution of the signal.

5.2.1 Variance Analysis

Dispersion can be defined as the degree of spread of observations about the mean. This characteristic of the distribution can be measured by either the variance (second order central moment, M_2) or the standard deviation σ , (the square root of variance).

In the last section time domain averaging was described. Time domain averaging allows the extraction of periodic components which are always present in the signal. Other components, which are not always present but occur at specific positions in a cycle, are termed semi-periodic. These types of signal can be valuable in detecting faults such as bearing defects, piston slap, etc.. The mathematical development of the variance method can be found in references [22, 23] and examples of its use are presented in references [139, 143]. The basic equations needed to perform this analysis are briefly described as follows:

$$AV(X(i)) = Y(i) = \frac{1}{m} \sum_{r=0}^{m-1} X(i) \quad (5.1)$$

$$Z(i) = VAR(X(i)) = (X(i) - Y(i))^2 \quad (5.2)$$

where

m = the number of traces collected

i = an index for vector data points

r = the index of a particular race

$X(i)$ = the i th component of a vector X

$Y(i)$ = the average vector for all traces

$Z(i)$ = the i th component of the variance vector

In these computations, the removal of the periodic function is accomplished and, by squaring the result, the semi-periodic function information is exaggerated. This exaggeration protects the semi-periodic information from being filtering out, while at the same time noise components converge to a specific constant value over the whole variance vector. Figure 5.5 shows a typical variance of the vibration signals from a normal engine during a hot test and the waterfall plots of the variance of each engine cycle, are shown in Figure 5.6.

5.2.2 Measurement of Central Tendency and Asymmetry

Observations of the tendency to center or group themselves around a central value and the peakedness of the distribution of the vibration signals were also observed.

However, no noticeable trend in data analyses was observed.

Figure 5.5 : Variance of Vibration Signals from Normal Engine during Hot Test

Figure 5.6 : Running Variance of Vibration Signals from Normal Engine during Hot Test

5.3 Frequency Domain Analysis

The HP3561A FFT analyzer includes an anti-aliasing device that samples at 2.56 times the highest frequency of interest and the resulting transformed data (frequency spectrum) is represented by a set of 400 sampled values. Figure 5.7 shows a typical frequency spectrum of a vibration signal when the engine is running at 2000 rpm. Even though the engine is excited at all frequencies from 0 to 20 kHz and the measuring system response is linear within the same range, in this research only components in the range from 0 to 5 kHz were considered in the analysis. This is due to the fact that most mechanical components in engines do not respond readily to frequencies greater than 5 kHz.

Figure 5.8 illustrates a typical frequency spectrum of the engine vibration signal with a component defect, such as a reversed piston skirt taper. It was observed that, for different engine defects, the amplitude of the frequency spectrum was different. Therefore, the global peak value of the spectrum was chosen as one of the descriptors.

Figure 5.7 : Frequency of a Normal Engine.

Figure 5.8 : Frequency Spectrum of an engine with Reversed Taper Piston #2.

CHAPTER 6.

RESULTS AND DISCUSSIONS

In this chapter, the experimental results of monitoring defective engine conditions with the use of vibration, noise and cylinder pressure signals are presented. The modal analysis of the engine block is dealt with at the beginning. This is followed by the results of the cold and hot test of the engine with different parameters and different methods. Next, the effects of the location of transducers to the corresponding amplitudes are discussed. Finally, the determination of optimum parameters to monitor the defective engine condition is also discussed.

6.1 Modal Analysis of an Engine

The vibration mode analysis of an automotive internal combustion engine block was performed in order to achieve two objectives;

- 1) to study the dynamic response of the engine block and its components, and
- 2) to determine the proper mounting locations for the vibration transducers.

Initially, 19 points on the oil pan rail surface of the engine assembly (Figure 6.1), including proposed mounting locations of two accelerometers, were selected for the frequency response function measurements. The dynamic behaviour of the oil pan rail (Figure 6.2) at different resonance frequencies is depicted in Figures 6.3 to 6.8. The corresponding frequency response functions for points #1 and #2 are shown in Figures 6.9 and 6.10.

By examining the dynamic behaviour of the oil pan rail in detail, it was observed that the first mode of the engine block appeared at the frequency of 460 Hertz with the nodal points of the structure at locations #5 and #15 respectively (Figure 6.3). A second mode of the structure appeared at a frequency of 730 Hertz with the nodal

points also at locations #5 and #15 (Figure 6.4). Finally, the sixth mode of vibration was observed at the frequency of 1349 Hertz (Figures 6.8, 6.9 and 6.10).

In light of these results, points #9 and #18 were selected as the locations of the two accelerometers in the cold test. This selection was made essential for sensing the highest vibration response and avoiding the nodal points.

6.2 Effects of Data Processing

The effects of different signal processing methods for the defective engine monitoring are discussed in this section. Initially, different data triggering methods are discussed followed by an assessment of the different processing systems used. The results from different methods are compared and finally, optimum procedures for this study are discussed.

6.2.1 Effect of Triggering Methods

Time domain signals from an engine reflect the instantaneous motion of the various components. As the dynamic motion of the engine is cyclic (due to combustion characteristics), the time domain signals need to be examined cycle by cycle. To achieve this objective, the engine signals need to be acquired from a reference relative to the angular position of the crankshaft. However, different triggering algorithms in the data acquisition process may lead to different results in the analysis. To test this hypothesis, two different triggering methods were used in the experiments and the results will be compared in the following section.

Initially, data was captured when the acquisition system was triggered by TTL (Transistor-Transistor Logic) signals which were generated by an induction voltage at the #1 spark plug firing. The number of data points (for one engine cycle) was determined by the time period per cycle and the data sampling rate, as follows:

$[\text{Data points}] = [\text{sampling rate}] * [\text{period of one engine cycle}]$.

Figure 6.11 shows the trace of a typical data set which was acquired by the use of time locked triggering method. In this figure, the upper trace represents the time domain engine signal while the lower trace represents a combination of the header signal and time locked triggering signal. The data points for one cycle were set at 1024 points which was determined by the sampling rate at a specified engine speed. However, when the engine speed is varying, the 1024 data points do not exactly cover one engine cycle. Thus any fluctuation in the speed of the engine causes difficulty in capturing exactly one cycle of engine data. Figure 6.12 shows the variation of the engine vibration signals which were captured by means of the Nicolet 440 Digital Data Acquisition System (System No. 2) when the engine speed was controlled at 1500 rpm (± 5 rpm). Although there are fluctuations in the amplitude with the cycles, the location of the peaks is consistent at approximately 390 degree of crank angle. However, when the engine speed was oscillated between 1500 rpm to 1800 rpm, the locations of distinct peaks were scattered, as shown in Figure 6.13.

Similar experiments were repeated with a different data acquisition system. Figure 6.14 shows a variance of the time domain vibration which was captured by the HP3561A Dynamic Signal Analyzer (System No. 1) at 1500 ± 5 rpm while Figure 6.15 was acquired at 1500 to 1800 rpm. These results showed similar behaviour to that obtained by means of the Nicolet 440 system..

To overcome the disadvantage of time locked triggering, position locked triggering was employed to acquire the data. In this method, the signals for triggering the trace are from the pulses generated from a custom designed encoder attached to the crankshaft.

For this set of tests, the results indicated that the location of the peak amplitudes is consistent for both constant and varying engine speeds (Figure 6.16 and Figure 6.17). After testing, the engine was disassembled for mechanical and visual inspections to

Figure 6.17 : Vibration Analysis of an Engine with Defective #5 Piston using System No. 3, i.e. Position Locked Triggering Method (1500 to 1800 rpm)

identify the defective components.

After performing more than 100 engine tests using the position locked triggering method, it was found that the results were repeatable and reliable. Thus, this method is selected for the triggering mechanism for subsequent data collection.

6.2.2 Effect of Signal Processing

In this section, the effect of signal processing on the detection of faults is analyzed. In the experiments, three different vibration data acquisition systems - HP3561 Dynamic Signal Analyzer, Nicolet 440 Digital Signal Analyzer and the custom made 8 Channel Data Acquisition System were employed. The data were evaluated to select the most effective system to monitor the defective parts in engines.

Initially, the Hewlett Packard Dynamic Signal Analyzer was employed to capture the vibration and noise signals. This system captures 1024 data points for each sweep and the time and/or frequency records are compressed to 399 data points for display. As an illustration of the typical results of this method, the variance of the vibration signals versus crank angle is plotted in Figures 6.18 and 6.19. It should be noted that the firing order of the six cylinder engines used in this study was 1, 4, 2, 5, 3, 6. In these results, it was observed that the distinct vibration amplitudes were originated from number 2 cylinder in the engine. This distinct noise was identified as well by the experienced stethoscope operator at number 2 cylinder.

There is a drawback with this system. As the data collection and processing were carried out serially, there will be a gap in the recorded trace. This gap creates difficulty in analyzing the data as illustrated below.

Figure 6.20 shows a sample result of variance of random vibration signals from a customer returned engine. According to the average variance of the signal, as shown in Figure 6.21, it is evident that there are certain occurrences of excessive vibration at every 120 degrees span. However, non-periodic random amplitudes are also observed in the

Figure 6.18 : Vibration Variance of an Engine with Defective #2 Piston with Accelerometer on Location 2.

Figure 6.19 : Vibration Variance of an Engine with Defective #2 Piston with Accelerometer on Location 6

Figure 6.20 : Vibration Running Variance of an Engine with Defective #6 Piston

Figure 6.21 : Vibration Average Variance of an Engine with Defective #6 Piston

waterfall plot due to the discontinuity in the measured vibration signals. A check with a stethoscope indicated that the noise source was from piston number 6, and the audible ticking noise was perceived at every piston pin reversal point. A subsequent engine teardown analysis showed that the defect was an oversized ringland diameter of piston number 6. Thus there is a possibility of misdiagnosis of the engine defect with this method especially if the defect is associated with a random vibration. To overcome this problem, it is necessary to use a system which is capable of capturing and storing time data continuously.

Therefore, a custom designed eight channel data acquisition system was employed to monitor the engine conditions. In this study, however, only six of the channels are used.

Vibration data was captured with the eight channel data acquisition system when the engine was running at 2000 rpm. All the transducers were calibrated before being installed on the engine and the vibration signals for 64 revolutions of the engine were monitored. The variations of the vibration signals were then analyzed and plotted as shown in Figures 6.22 to 6.24. Distinct amplitudes of variation can be observed at the crank angle of 385 degree, which is equivalent to the top dead center of piston number 5. In order to assess the efficiency/ effectiveness of the defect detection method, the following are to be considered:

- a) the effect of location of transducers on the amplitude of variance and
- b) consistency of the amplitudes of variance between engine cycles.

Considerable differences in amplitudes of variance exist, depending on the location of transducers. As shown in Figures 6.22 to 6.24, the results from three channels exhibit distinct amplitudes at the same location in each cycle. However, their magnitudes are different depending on the location of transducers. Especially the amplitudes from channel number 5, (with the transducer located on the defective cylinder), are considerably higher than others. From these experiments, it is concluded

Figure 6.22 : Vibration Variance of an Engine with Defective #5 Piston at Location of the Accelerometer on Cylinder Wall #4

Figure 6.23 : Vibration Variance of an Engine with Defective #5 Piston at Location of the Accelerometer on Cylinder Wall #5

Figure 6.24 : Vibration Variance of an Engine with Defective #5 Piston at Location of the Accelerometer on Cylinder Wall #6

that:

- 1) Multi channel data acquisition systems are required to compensate for the inconsistency of amplitudes due to the location of the transducers.
- 2) An optimum engine speed for data acquisition has to be determined in order to achieve the minimum data processing time and to compensate for the inconsistency of amplitudes between cycles.

6.3 Cold Test of Engine

The vibration and noise of engines were monitored when driven at the specified speeds of 250 and 420 rpm by an electric motor for both normal and defective engines. Higher speeds were avoided to prevent possible damage of engine due to insufficient lubrication.

To measure vibration, two accelerometers were mounted on the pan rail of the engine block. The outputs were captured using a six channel data acquisition system through an Allen-Bradly Portable Programming Terminal.

To measure noise, a Bruel and Kjaer Type 4150 microphone was used with the sound level meter Type 2231.

In the data acquisition, reference vibration and noise signals were initially captured from a normal engine whose components were within engineering specifications. The vibration and noise signals from defective engines were then recorded from two accelerometers or a microphone. The details of the measurement will be considered in the next section

6.3.1 Vibration Measurements

Vibration signals from the engine which was driven by an electrical motor, were acquired through two accelerometers. Data was obtained for a time period of 0.24

seconds which is equivalent in duration to 8 revolutions of the crankshaft when the engine is running at 250 rpm. The number of data points was reduced to 1024 points per revolution to minimize the data processing time. Experiments were repeated for 35 engines with different defective characteristics. A position locked encoder signal, which was modulated to generate 5 volts TTL signal at a particular location (10 degrees before TDC of the piston) of the crankshaft, was used to trigger the data acquisition system to capture the vibration signals.

Figures 6.25 and 6.26 show composite vibration signals from a normal engine during a cold test. It can be seen that the vibration response from a normal engine is low and consistent. These measurements were compared to the vibration signals from engines with missing or defective engine parts in piston #1. This was repeated for every piston in the firing order sequence and for 35 engines. Figures 6.27 and 6.28 show the vibration signals (of two different channels) from a defective engine during the cold test. A normal engine has low and consistent amplitude distribution whereas the defects produce large and distinct peaks.

In the experiment it was observed that the amplitudes of vibration are dependent upon the location of the accelerometer as illustrated in Figures 6.27 and 6.28. Higher engine speed also causes the vibration signal to increase as shown in Figures 6.29 and 6.30.

Once captured, the signals were analyzed by means of time domain averaging, variance, and frequency analysis which will be discussed in the next section.

6.3.1.1 Time Domain Averaging and Variance Analysis of Vibration Signals

The averaging of vibration waveforms was performed for 15 engine cycles for a normal engine. No significant differences were observed in signal amplitudes as shown in Figure 6.31. However, for defective engines, distinct spikes appeared in the trace (Figure 6.32). These spikes correspond to the location of side force reversals in the

Figure 6.25 : Channel 1 Raw Vibration Data for Normal Engine

Figure 6.31 : Average Waveform of a Normal Engine During Cold Test

Figure 6.32 : Average Waveform of a Defective Engine (#1 Cap Bearing Omitted) during Cold Test

piston.

Better results were obtained when the variance analysis was performed on the raw signals. This is illustrated by the waterfall plot of variance of vibration signals for seven engine cycles during a cold test of a defective engine (with the cap bearing of #1 piston connecting rod missing). Distinct amplitudes are present at TDC and BDC of #1 piston. Because of the success, this test was repeated for different defective parts on different pistons of the engine.

6.3.1.1.1 Detection of Missing Connecting Rod Bearings

With the test configuration discussed previously, the engine was operated with a missing connecting rod bearing in piston #1. Measurements were then taken and the process was repeated in turn for every piston of the engine with a missing bearing. Figure 6.32 shows a sample of a TDA signal from an engine with a missing rod bearing cap on #1 piston. The distinct peaks appeared at crank angles of 20 and 220 degrees which are slightly off the TDC and BDC of the piston. Similar results were observed for engines with different defects as shown in Figures 6.33 to 6.40. After reviewing these results, the following conclusions are drawn:

1. the vibration levels measured for the normal engine are very low and consistent,
2. there are two vibration pulses per revolution for each missing bearing and
3. the pulses occur over a finite period which is relatively short in duration.

A summary matrix of performance factors was devised to indicate the feasibility of this vibration measurement procedure for detection of any defective engine components. Table 6.1 shows a sample matrix of obtained results when the engine was running with one missing connecting rod bearing cap on each piston in turn and on four engines. It can be seen that all of the faults were detected satisfactorily with this

procedure. Table 6.2 shows the same level of success when the engine speed is increased to 420 rpm. Although higher speed produces better result, low speed is preferred so as to avoid damaging crankshaft when a rod bearing is missing. For the case where the connecting rod bearing is missing, Table 6.3, similar results were obtained.

6.3.1.1.2 Detection of Miscellaneous Defective Components

The same procedure outlined in section 6.3.1.1 was repeated for an engine with different defective components. The results summarized in Table 6.4 indicate the feasibility of using this method to detect a missing rod bearing cap, a missing rod bearing, and loose connecting rod nuts. However, the remaining of the defective conditions, i.e., mismatched bearing cap, missing main bearing and unbalanced crankshaft, were not detected consistently.

2. US = detection with inconsistency
3. F = failure to detection.

Table 6.4 : Performance Matrix of Defective Engine Test Utilizing Vibration Measurements.

6.3.1.2 Frequency Analysis of the Noise Signals

To determine the frequency characteristics of noise signals from defective engines, noise signals were first obtained from a normal engine, whose components were thoroughly inspected. The signal characteristics were then examined. This was followed by an equivalent evaluation of the noise signals from a defective engine with a missing cap rod bearing. Figure 6.41 shows a typical time domain noise signal

RANGE: -51 dBV STATUS: PAUSED

Figure 6.41 : Frequency Spectrum and Time Domain Trace for a Normal Engine

and the frequency spectrum from a normal engine while the corresponding results of the defective engine are shown in Figure 6.42. By comparing these, it was observed that there was no distinct differences in amplitudes of the spectra that would allow us to discern the defective engine from a normal engine.

6.3.2 Noise Measurements

Noise measurements were also carried out during engine running in the cold test stand utilizing a sound level meter. The same set of engine defective conditions were also used in the noise measurements.

Two different sizes of microphones, 1/2 inch and 1/4 inch diameters, were used to monitor the noise signals from the engine. It was found that the noise measurements using 1/2 inch microphone gave a larger amplitude and less noise than the 1/4 inch microphone. Therefore, the 1/2 inch diameter microphone was employed for subsequent noise measurements.

To ensure the feasibility of noise measurement as one of the monitoring methods of defective engines, noise and vibration signals were captured simultaneously. Figures 6.43 and 6.44 show the variance of the vibration signal, while Figures 6.45 and 6.46 depict that of the noise signal. As shown in these figures, for defective engines, both noise and vibration analyses portray similar characteristics in terms of amplitude distributions of the variances.

Experiments were repeated for the different defective engine components and also for defects at different locations. The results from the testing of 25 engines indicated that the noise measurements showed the same characteristics as the vibration measurements. As shown in Table 6.5, missing rod bearing, missing rod bearing cap and loose connecting rod nuts were entirely detected with the measurements of engine noise during cold engine motoring while reversed rod bearing caps, mismatched bearing caps and missing main bearings are partially detected.

6.4 Hot Test of Engine

A variety of engines, normal or with different defective conditions were tested at the dynamometer laboratory. Vibration, sound, and cylinder pressure of the engines were measured. The induced TTL signal from #1 spark plug wire or PIP (Profile Ignition Pickup) signal from the electronic engine control system was used as an external triggering signal to start the signal sweep at the same crank angle, i.e. 10 degrees before top dead center of

the piston. Teardown analysis of the engines was subsequently performed by dimensional and visual inspection of the engine components. Correlations were made between the processed signal characteristics of each pistons and their dimensional characteristics. These will be discussed in the following sections.

6.4.1 Vibration Measurements

Vibration signals from more than 250 engines were monitored utilizing different data acquisition systems at engine speeds of 1500 to 2000 rpm. Operating conditions of the engine, i.e., engine speed, inlet and outlet engine coolant temperatures and applied load to the engine, were monitored and controlled. The acquired vibration signals were analyzed in terms of variance, time domain averaging and running variance.

6.4.1.1 Variance and Time Domain Averaging Analysis

The vibration signal (in the time domain) from a defective engine (Figures 6.48) can now be compared to that from a normal engine (Figure 6.47). There are differences, but it is difficult to distinguish the difference which is attributed to the defective conditions. To improve this, a new method of signal analysis was used. In this method, the time domain averaging was first performed for 15 engine cycles of vibration signal and no significant differences were observed in six group of amplitudes as illustrated in Figure 6.48. The time domain average signal was then subtracted from the composite (raw) signal. Distinct pseudo-random signals were found which were observed to correspond to the location of the side force reversals in the piston, as shown in Figure 6.49. Similar results were found in the variance of the signal plot of the same engine (Figure 6.50). However, the peaks in this case are more pronounced than in the previous case.

Figure 6.47 : Vibration Signals from Defective Engine During Hot Test - One Engine Cycle

Figure 6.48 : Time Domain Average Signals from Defective Engine During Hot Test

Figure 6.49 : Random Repetitive Component of Vibration Signals

Figure 6.50 : Variance of Signatures from Defective Engine During Hot Test

Figure 6.51 shows a waterfall plot of the variance of signals, from a defective engine (customer complaint). Distinct amplitudes of variance are also observed at piston #1. A remark can be made here that the signature introduced by the defect in the piston, while being repetitive, is not truly periodic. This is clearly illustrated by observing Figures 6.47 and 6.48 which are relatively similar. From the results, it can be concluded that the variance function (Figure 6.51) clearly shows the effects of defective conditions and can certainly be used for diagnostic purposes.

Similar experiments were repeated for more than 250 engines. The amplitudes of variance were observed and then they were related to the defective components in the cylinder. To confirm the cause of the high magnitude vibration level, engine teardown analysis was later performed.

6.4.1.2 Frequency Analysis of Vibration Signals

The objective here is to determine the feasibility of using frequency analysis for detecting engine faults. In the frequency analysis, vibrations were first monitored from a defective engine which had a reversed skirt taper piston in cylinder #5. The defective piston was then replaced by a good (within specifications) piston and vibration signals were recorded from the same engine. Figure 6.52 shows a typical time domain vibration signal from the defective engine while that from a normal engine is shown in Figure 6.53. Frequency characteristics of both signals were analyzed. In the frequency spectrum of the defective engine, as shown in Figure 6.54, distinct amplitudes are observed in the frequency range of 2700 to 3500 Hz. However, these distinct amplitudes are not visible in the frequency spectrum of a normal engine as illustrated Figure 6.55. Repeatable results were observed in additional experiments, as shown in Figure 6.56 and 6.57.

The results from this method are promising, however, the reliability of this method in on-line defective engine monitoring is questionable because of some exceptions.

Figure 6.51 : Variance of Signatures from Defective Engine During Hot Test - Waterfall Plot

Figure 6.56 : Frequency Spectrum of Defective Engine
(Concentricity of Piston Ringland to Skirt
Out of Specification)

Figure 6.57 : Frequency Spectrum of the Same Engine
(Barrel Shape Skirt Profile Piston)

Figure 6.58 shows a running variance of the vibration signal from a defective engine which has oversized ringland in piston #6. The corresponding frequency spectrum is shown in Figure 6.60. These are compared to the time and frequency domain signal from a normal engine as illustrated in Figures 6.59 and 6.61 respectively. No significant differences in the frequency spectra were observed which indicates that the detection of a fault is not effective.

6.4.2 Engine Teardown Analysis

After vibration, sound and pressure measurements were accomplished, the dimensional characteristics of the engine components - piston taper, piston skirt to ringland concentricity, piston to cylinder bore clearance and piston ringland diameters - were measured, as shown in Table 6.6. Further measurements such as piston skirt ovality, skirt profile were also performed. These were then compared to the analyzed vibration signals and correlations were made.

6.4.2.1 Effect of Piston Skirt Off-set with Respect to Ringland

As described earlier in the experimental details of a teardown analysis, the piston ringland offset with respect to the piston skirt was measured in two directions. For the sign convention of the readout in A-C axis, the negative sign represents the (piston ringland) offset to the major thrust side while the positive sign represents that of the minor thrust side. The amplitudes of vibration signals from 35 engines, in terms of variance, were plotted against the measured piston skirt offset in the A-C axis (See Figure 4.19 for illustration).

As shown in Figure 6.62, the variance in the signal is high when the offset is less than -0.2 mm . As the offset in the thrust direction approaches -0.100 mm, the variance is consistently low. Thus it can be concluded that the piston ringland offset to the

minor thrust side is not the major cause of high level vibration signals. The offset to the major thrust side, however, is the main contributor to piston noise and vibration. The offset in question (0.100 mm) is within the current blue-print specifications of the production piston. Steps were immediately taken to retarget the machining operation so as to reduce the off-set as much as possible. The target zone for the machining operation is shown in Figure 6.63. As illustrated in this figure, all of the engine noise complaints resulting from high levels of vibration are concentrated outside the target zone which clearly indicates that this zone is effective in eliminating piston noise caused by concentricity of the piston skirt to ringland.

Further attempts were made to correlate vibration signals to the component dimensions obtained in the engine teardown analysis (such as piston skirt taper, piston ringland diameters and piston to cylinder bore clearance). The results obtained from a study of more than 50 customer return engines indicate that as long as all these characteristics are within specifications (whether at the minimum or maximum), the piston does not generate vibration and noise levels that are objectionable to the customers.

6.5 Feasibility of Vibration Analysis Method in On-Line Monitoring

According to the statistics of one engine manufacturer, missing or misassembled components during assembly, and customer engine noise complaints are the major roadblocks in achieving higher productivity and customer satisfaction. Thus, it is important to find effective ways to detect these defects. In this section, the feasibility of vibration analysis in defective engine monitoring is discussed. It is mainly focused on the results of the cold test of engines as being one solution to the problem of releasing defective engines to the final assembly process and finally to the customer.

6.5.1 The Use of Preliminary Threshold Level of Vibration Variance

The determination of the threshold level to detect a defective engine in the cold test will be discussed in this section. An Analysis of the vibration signals obtained from engines indicates the following characteristics:

1. There are two vibration pulses per revolution during the cold test when the defective condition is a missing bearing, as shown in Figures 6.64 and 6.65.
2. The generated vibration pulses are a combination of signals from two cylinders which have the same piston movement (with respect to the top dead center of the pistons). The matching cylinder pairs are as follows: cylinders 1 & 5, 2 & 6, 3 & 4. It is assumed that the output amplitudes from matching cylinders during the cold test are similar.
3. The acquired vibration amplitudes from normal engines are very low compared to those that from defective ones. This facilitates the signal processing of the vibration from defective engines.
4. There is a discontinuity or fluctuation in the vibration amplitudes between the cycles, as shown in Figures 6.66 and 6.67.
5. There are differences in amplitudes of vibration signals from two accelerometers.
6. The duration of the signal peak (which can be attributed to the defective part) is relatively short compared to the engine cycle (see Figure 6.66).

From the above considerations, it is possible to divide the one revolution of the engine into a number of intervals (or windows) of equal spacings. Such a window would contain only a set of variance peaks which is attributed to a specific engine defect. In this study, on an engine revolution is divided into 6 identical windows as shown in Figure 6.65 and Table 6.7. Now, the next task is to determine the threshold level.

The initial threshold level for rejecting defective engines was set up using the average variance value of 15 defective engines (e.g. with missing rod bearings). The

Figure 6.64 : Accelerometer #1 Raw Vibration Data for Defective Engine (#2 Rod Bearing Omitted)

Figure 6.65 : Accelerometer #2 Raw Vibration Data for Defective Engine (#2 Rod Bearing Omitted)

Figure 6.66 : Accelerometer #1 Vibration Running Variance for Defective Engine (#2 Rod Bearing Omitted)

Figure 6.67 : Accelerometer #2 Vibration Running Variance for Defective Engine (#2 Rod Bearing Omitted)

operating threshold value was defined as the minimum value of the vibration measured at different locations on the engine with a missing rod bearing. These values were then adjusted by trial and error until no defective engine was passed. A typical result of this monitoring method is shown in Table 6.8.

LOCATION	POSITION WINDOW
0° - 60°	1
61° - 120°	2
121° - 180°	3
181° - 240°	4
241° - 300°	5
301° - 360°	6

Table 6.7 : Position Windows Associated with Crank Angle.

Possible Location of faults (piston #)	Window No. Where Signal is Greater Than Threshold Level
1 & 5	1 and 4
2 & 6	2 and 5
3 & 4	3 and 6
4 & 3	3 and 6
5 & 1	1 and 4
6 & 2	2 and 5

Table 6.8 : Possible Results of Missing Connecting Rod Bearing

In this table, row 1 for example, if the measured vibration signal is greater than threshold level in window no. 1 and 4, then it is possible that the defect is either at piston #1 or #5.

Reliable and consistent results are being obtained using the above algorithm for identifying missing rod bearing on the cold test.

6.5.2 Implementation of Production Cold Test Stand

The vibration measurements were taken when the partially assembled engine is first driven at 250 rpm (low speed) and then 420 rpm (high speed). Threshold variance amplitudes of the rejected defective engines were determined by a trial and error method. This was achieved by sending selected defective engines to the system, exercising the reject procedure and applying different threshold variance amplitudes. Experiments were repeated until the system achieved 100 percent success in rejecting defective engines.

When the vibration (variance) exceeds a target limit of $0.25 \sigma^2$ (equivalent to 100 units)

at low speed, the engine is rejected without going through the 420 rpm (high speed) test cycle thus eliminating the possibility of damaging the engine. The limit for the high speed test is $0.71 g^2$ (equivalent to 300 units).

Typical frequency distributions of the variance data for both accelerometers 1 and 2 at low and high speeds are illustrated in Figure 6.68 to Figure 6.71. The percentage of rejects due to high vibration at the high speed test ranges from 0.04 to 0.34%. For a daily production of 2000 engines, that translates to, from 1 to 7 engines per day.

The percentage of rejects due to high vibration at the low speed test ranges from 0.21 to 0.29 which translates to, from 4 to 6 engines per day.

For practical reasons, the limits for the threshold were set based on approximately 120,000 engines tested without having an incident of abnormal engine passing the vibration test. The rejected engines are moved to the reject bay area where they are repaired and then sent to be retested.

6.6 Dynamometer Test

From the results of the vibration signal analysis and the related teardown investigation, it is evident that the piston ringland offset with respect to skirt has a major role in generating high amplitude vibration signals. In other words, vibration analysis, in terms of variance analysis, is one of the very effective methods for identifying and isolating defective engine components during the combustion process. To verify the feasibility of this method, vibration was measured after swapping or replacing the noisy piston of a customer-complaint engine.

Figure 6.72 shows typical vibration signals from a noisy engine in terms of variance. Distinct vibration amplitudes are observed from piston #5 as indicated by the location of the maximum amplitude in the vicinity of the firing of cylinder #5.

After the vibration signals were monitored, a teardown analysis was performed and

dimensional characteristics of piston and cylinder #5 were investigated. As shown in Table 6.9, the maximum piston skirt offset in the negative direction was observed at piston #5.

Piston #5 was then swapped with piston #6 and the vibration was measured at the original engine operating conditions. As it can be seen from Figure 6.73, the distinct vibration from piston #5 disappeared and new peaks exist at the location of piston #6 firing.

Additional verifying experiments were carried out by replacing the noisy piston with a new piston. When the vibration was then measured at the same engine operating conditions, it was practically eliminated, as shown in Figure 6.74. These experiments were repeated for three more engines after swapping and replacing the faulty pistons. Conclusive results were consistently obtained.

6.7 Sound Pressure and Sound Intensity Analysis of Engine

The feasibility of using sound pressure and sound intensity measurements to detect defective engines is discussed in this section.

6.7.1 Sound Pressure and Sound Intensity Mapping

A sound intensity mapping was performed on an engine with a faulty piston #6 and the results are shown in Figure 6.75 for the left hand side and in Figure 6.76 for the right hand side of the engine. These figures illustrate (a) the sound intensity data mapping, (b) the mapping of equal intensity contours and (c) the 3-Dimensional plot of the intensity. Figure 6.77 shows the main frequency components of the same engine.

The results (Figures 6.75 and 6.76) indicate that the highest intensity level occurs between cylinder number 5 and cylinder number 6. Thus it is concluded that the approximate physical location of the engine noise source can be determined. However,

it is not possible to determine the exact defective component or the exact time / location (within the cycle) when it occurs. Therefore this method was not considered for use in the monitoring procedure.

6.7.2 Gated Sound Intensity Analysis

The gated sound intensity technique is used for analyzing repetitive non-stationary signals in different applications. The sound intensity from a source is measured using a two-microphone sound intensity probe. The detailed explanation of the technique is found in Appendix G. In this study, gated sound intensity measurements were performed in an attempt to locate and define the noise source of a defective engine that was analyzed in the previous section by sound intensity mapping.

Figures 6.78 to 6.83 are the noise intensity plots from one point in space about two inches from the wall of the cylinders, from cylinder number one to six respectively. The three axes in the 3 dimensional plot are the frequency axis, the sound intensity level axis and the crank angle of engine rotation from 0 degrees to 720 degrees. The engine was running at 1500 rpm and at 100 Nm of torque.

It is shown in these previous figures that this method of analysis can approximately identify the frequency of occurrence of the noise as well as the approximate crank angle. However these results cannot distinctly differentiate the normal versus the abnormal cylinders.

6.8 Cylinder Pressure Measurement

One of the main difficulties in measuring vibration and noise is to differentiate the noise and vibration signals which are generated by the normal engine from those produced by combustion knocks. To investigate the mechanical defects in engines by measurement of vibration and noise, it is essential to eliminate the combustion knocking

phenomenon.

According to Groschel [165], the astonishingly high sensitivity of the human ear for detecting knock cannot be achieved by electronic means, because of the complicated signal processing capability of the ear. Therefore, most of the engine knocking occurrences were detected by experienced operators. These results were confirmed by measurement of the cylinder pressure which enabled these engines to be excluded from the process of identification of engine defects by means of vibration signature analysis.

Figure 6.84 shows a typical cylinder pressure signal which was measured by the PCB type 112A pressure transducer from a normal engine. However, distinct patterns of pressure signals are observed when the pressure was measured for the knocking engine, as shown in Figure 6.85 and its waterfall running variance plots are shown in Figure 6.86. Similar results were obtained by Groschel and Douaud (165) as illustrated in Figures 6.87 and 6.88.

The observed knocking signal patterns in this study were similar to the previous researches so that, measurement of the cylinder pressure was used for identifying combustion knocking engines. This process was used to ensure that the engine vibration obtained from all operating engines, is mainly due to imperfections in the manufacturing and assembly processes.

CHAPTER 7.

CONCLUSIONS

The following conclusions have been reached after examining the results of this study.

1. The vibration signature analysis techniques, in terms of time domain averaging and variance analysis, provide sufficient data for the development of a program for identifying and isolating manufacturing and assembly defects in engines.
2. A noise analysis during the motoring of an engine also indicates reliable results in monitoring missing components. However, the problem of maintenance of microphones in hostile manufacturing environments makes this method impractical. Hence, accelerometers are used in this application.
3. The selection of a proper triggering method in monitoring vibration, noise and pressure signals is critical. The position locked TTL triggering signal provided satisfactory data acquisition. This avoids signal drift due to varying engine speeds in all experiments.
4. The variance analysis of vibration signals can be used to identify the location of defective components in the engine. Using this method, almost 75 percent of teardown analysis time is saved in finding defective components in customer returned engines due to noise. The offset of piston ringland with respect to skirt is found to be a major contributor of engine noise generation. However, there is no evidence that the piston skirt taper, piston to bore clearance are the cause of major noise generation.
5. Engines with defects caused by manufacturing and assembly processes can be identified in terms of their frequency components. However, a large number of engines with special defects cannot be detected by using this method. Hence the reliability and consistency of this method does not warrant application to on-line engine signal monitoring and diagnostics.
6. Successful results in identifying and isolating defective engines have been obtained for

thousands of engine assemblies in an on-line engine monitoring system.

7. Based on this study, two systems were launched simultaneously in the engine manufacturing facility. One system was successfully implemented in June, 1992 for on-line monitoring and diagnosing of partially completed engines with a capability of testing 3000 engines daily. The second system was launched in May of 1992 for diagnosing warranty field-returned engines and evaluating the noise and vibration characteristics of engines before and after design changes. The projected annual cost saving is estimated to exceed 500,000 dollars. This is derived from the reduction in the number of defective engines going to the final phase of assembly or to the customer, a reduction in time required for diagnosing faults, and finally providing design and testing tools for development work.

7.1 Contributions

The major contributions of this research can be summarized as follows:

1. A unique automated engine test and diagnostics system was developed for rapid detection and diagnosis of various manufacturing and assembly defects, resulting in increased productivity and quality, and reduced manufacturing cost.
2. A new eight channel data acquisition system for the evaluation of noise and vibration characteristics and component development testing was designed and implemented in the dynamometer laboratory of an engine manufacturing plant.
3. A new approach in engine noise and vibration data reduction and interpretation was also proposed. This approach has been successfully applied in determination of the root cause of engine noise and in engine component development work.

CHAPTER 8.

RECOMMENDATIONS

The following recommendations represent enhancements of the present work as well as of future research, with emphasis on the successful implementation of complicated online engine monitoring and diagnostic systems.

1. Further investigations have to be carried out using a laser velocimeter as a non-contact transducer.
2. The currently available diagnosing programs using the acoustic intensity method need to be improved for use in locating noise sources in the engine.
3. The development of a more advanced engine dynamic signal monitoring and diagnostic system capable of identifying, isolating and rejecting multiple defects in completely assembled engines, has to be immediately established. This work is currently under way in one of the engine manufacturing facilities and its expected date of completion is May of 1993.
4. Application of the already developed systems is to be extended to the diagnosing of engine noise in the vehicle. This enhances the capability of the automotive mechanics involved in the diagnosis of a vehicle.

APPENDIX C

C. COMPUTER PROGRAMS LISTING FOR SYSTEM NO. 1

DATA ACQUISITION PROGRAM FOR SYSTEM NO. 1

The computer code listed below is the data acquisition program written for the HP300 workstation and the HP3561A analyzer. The code is very analyzer specific and therefore only a brief explanation of what each section of the code does will be of any value.

This first section of code initializes variables to a default condition and initializes communications between the analyzer and the computer. The variables which are defaulted in the section tell the analyzer how much data to sample, when to sample and where to store the resulting data.

```

1   CONTROL CRT,21;1
10  OPTION BASE 1
20  DEG
21  OUTPUT 2 USING "#,-K";CHR$(255),CHR$(75)

104 Asroot$=""

```

The following is the main menu and controls the execution of the program. The menu allows access to subroutines to change default acquisition settings and also is the gateway to the actual acquisition portion of the program. After completion of any acquisitions or parameter change the program returns to this section and waits for any further actions.

This portion of the program stores the data in a Standard Data Format is first stores header information in a header file which includes scaling factors for the raw data which is stored in binary format. It includes analyzer setting which are also used to help reconstruct the data into real numbers. It also stores the actual data in a 16 bit binary format engine cycle by engine cycle. It then stores in a third file text which describes the test and problems which may have occurred.

DATA ANALYSIS PROGRAM FOR SYSTEM NO. 1

Data analysis techniques were developed by use of a user-interactive program on the HP300 workstation. The program code for this program is listed and commented below.

The following module is the main menu. Its functions are:

- 1) determine which type of analysis will be applied to acquired data
- 2) send control of the program to the subroutine which handles the type of analysis the user has requested
- 3) after analysis is completed regains control of the program to allow the user to enter another analysis technique or to plot results to a graphic device

```

APPENDIX F

F. MEASUREMENT EQUIPMENT SPECIFICATIONS

Accelerometer B&K Type		4384
Weight	grams	11
Charge Sensitivity	$\mu\text{C}/\text{ms}^{-2}$	$\pm 2\%$
Voltage Sensitivity	mV/ms^{-2}	≈ 0.8
Mounted Resonance	kHz	42
Frequency Range	5% Hz	0.2 - 9100
Capacitance	pF	1200
Max. Transverse Sensitivity	%	<4
Transverse Resonance	kHz	15
Piezoelectric Material		PZ23
Construction		Delta Shear
Typical Base Strain Sensitivity (in base plane at $250\mu\epsilon$)	$\text{ms}^{-2}/\mu\epsilon$	0.02
Typical Temperature Transient Sensitivity (3 Hz LLF, 20 dB/decade)	$\text{ms}^{-2}/^{\circ}\text{C}$	0.4
Typical Magnetic Sensitivity (50 Hz - 0,03T)	ms^{-2}/T	4
Typical Acoustic Sensitivity Equiv. Acc. at 154 dB SPL (2-100Hz)	ms^{-2}	0.01
Min. Leakage Resistance at 20°C	$\text{G}\Omega$	20
Ambient Temperature Range	$^{\circ}\text{C}$	-74 to 250
Max. Operational Shock (\neq Peak)	kms^{-2}	200
Maximum Operational Continuous Sinusoidal Acceleration (Peak)	kms^{-2}	60
Max. Acceleration (Peak) with Mounting Magnet	kms^{-2}	1.5
Base Material		Titanium ASTM Gr.2

Figure F.1 : Specification for Type 4384 Bruel and Kjaer Accelerometer

Resolution: Δ T Ch. A \rightarrow B: Delay between start of channel A and channel set in seconds from 0 to 9999 s. Resolution: Δ T</p> <p>AVERAGING: Exponential: The number of averages indicated in the measurement setup determines the effective averaging time Linear: Equal weighting. Stops in reaching the selected number of averages. A true average is always displayed and the number of averages is indicated on the display Peak: (Single channel only), the maximum level occurring in each channel is held</p> <p>SYSTEM ACCURACY: Frequency Response: \pm0.4 dB at filter centres with DC coupling Amplitude Linearity: \pm0.1 dB or \pm0.01 % of maximum input voltage, whichever is greater, measured in Autospectrum with at least 32 independent averages, in the presence of another in-band signal not less than 20 dB below max. input Dynamic Range: >75 dB, for Autospectrum with at least 32 independent averages. Noise, distortion, and spurious signals at least 75 dB below max. input voltage</p>
<p>ANALYSIS CHARACTERISTICS Frequency Range: 0 to 25.6 kHz. 15 Frequency spans from 1.56 Hz to 25.6 kHz. Digital zoom giving resolution from 1.95 mHz to 32 Hz anywhere in the frequency range, corresponding to zoom factors from 2 to 16 384 in a binary sequence</p>	

Figure F.13 : Specification for Type 2032 Bruel and Kjaer Dual Channel Signal Analyzer

<p>FREQUENCY AND TIME MEASUREMENT MODES: Narrowband: 125 μHz to 100,000 Hz frequency range. Resolution is frequency span/400. All window, trigger and averaging types are available. Phase: Phase spectrum is available with or without triggering. When triggered, phase can be referenced to the trigger. 1/3 Octave: 0.8 Hz to 80 kHz Full Octave: 1 Hz to 63 kHz Time Capture: Time record can be extended from 1k to 40k samples of continuous input data. Up to 40X zoom expansion factor can be applied to this data with variable center frequency. External Sampling: Input sample rate can be externally controlled up to 256 kHz. TTL compatible sample rate input on rear panel. (Note: Some specs may be degraded in external sample mode). FREQUENCY SECTION: 0 to 100 kHz: Measurement is made over the full frequency range of the analyzer with 250 Hz resolution. Define Start or Center: Measurement is made over the selected frequency span. Start or center frequency can be set anywhere in the 0 to 100 kHz range with resolution of 0.25 Hz. Define Span: Measurement frequency spans are provided in a 1, 2, 2.5, 5, 10 sequence. (Other spans exist between these intervals, but are too numerous to list in the space available.) Define Time Length: Measurement time can be set from 0.004 seconds to 651 minutes per time record. Time setting is rounded up to agree with next available span. ACCURACY: Frequency Accuracy: $\pm 0.003\%$ of frequency reading RESOLUTION: Frequency Resolution: Span/400 MEASUREMENT WINDOWS: Windows are weighting functions which are applied to input data to reduce errors caused by leakage. Flat Top: Hanning:</p>	<p>Uniform: Exponential: AMPLITUDE AND INPUT AMPLITUDE: Input Range: The calibrated input range is 27 dBV (+22.4 V) to -51 dB (3 mV) maximum input level (single tone RMS). Range is adjustable in 1 dB (10%) increments. Dynamic Range: Distortion, spurious and alias products ≥ 80 dB below input range Amplitude Accuracy: Full Scale Accuracy at calculated frequency points. Overall accuracy is the sum of absolute accuracy, window flatness and noise level Absolute Accuracy: ± 0.15 dB $\pm 0.015\%$ of input range: +27 dBV to -40 dBV ± 0.25 dB $\pm 0.025\%$ of input range: -41 dBV to 51 dBV Window flatness: Flat top: +0- 0.01 dB Hanning: +0-1.5 dB Uniform: +0-4.0 dB INPUT Input Impedance: 1 MΩ $\pm 5\%$ shunted by 95 pF maximum. Floating Ground to Case Capacitance: < 0.25 μF DC Isolation: Input low may be connected to chassis ground or floated up to 30 volts RMS (42 Vpk). Input Coupling: The input signal may be ac or dc coupled. Low frequency 3 dB roll off < 1.0 Hz for ac. Anti-Alias Filter Roll-Off: Analog and digital anti-aliasing filters roll off at a nominal rate of 130 dB/Octave with a cut-off frequency at 105 kHz nominally. TRIGGER TRIGGER MODES: Free Run: External: TTL signal. Internal: Input: HP-IB:</p>

APPENDIX G

G. GATED SOUND INTENSITY TECHNIQUE

The gated sound intensity technique is used for analyzing repetitive non-stationary signals. The sound intensity from a source is measured using a two-microphone sound intensity probe. The signals from the microphones are fed into the sound intensity analyzer where the sound intensity, \vec{I} , is calculated. The calculated sound intensity goes to the averager which is started and stopped synchronously with the source.

The signal to be analyzed using the gating technique is assumed to be repetitive with a cycle of T , i.e.

$$\vec{I}(t) = \vec{I}(t + T) \quad (G.1)$$

The variation within one cycle is analyzed in time windows with the length of t_w by averaging the signal within that window:

$$\vec{I}_w = \frac{1}{t_w} \int_0^{t_w} \vec{I}(\tau) d\tau \quad (G.2)$$

The time window can be offset relative to the trigger point by introducing the time

delay t_d :

$$I_w(t_d) = \frac{1}{t_w} \int_{t_d}^{t_d+t_w} \bar{I}(\tau) d\tau \quad (G.3)$$

In order to minimize the statistical uncertainty each window is averaged for a number of cycles, N :

$$I_w(t_d) = \frac{1}{N} \sum_{n=1}^N \left[\frac{1}{t_w} \int_{t_d}^{t_d+t_w} \bar{I}(\tau + (n-1) \cdot T) d\tau \right] \quad (G.4)$$

using the assumption in (1), that the time signal is repetitive with the period, T . By using a real time analyzer, $I(t_d)$ may be presented as a power spectrum.

The synchronization is done by the desktop calculator, using the service request line of the Hewlett Packard Interface Bus (HPIB) for triggering.

A tachometer signal is generated once per cam revolution of the noise source, by using an inductive pickup attached to the spark plug number 1 wire. This trigger is delayed a time t_d , after which a time window with length t_w is opened. Within this time window, the sound intensity is averaged. After time t_w the averager is stopped. In the next revolution, the averager proceeds with the averaging in the period t_w . This process is repeated for a number of revolutions, N , after which the averaged sound intensity is transferred from the analyzer to the computer. The averager is reset, a new delay, t_d , is selected and the process is repeated.

By measuring with a number of different time delays, t_d , the noise coming from the various parts of the rotational cycle of the engine can be analyzed.
