Author's Declaration of Originality

I hereby certify that I am the sole author of this thesis and that no part of this thesis has been published or submitted for publication.

I certify that, to the best of my knowledge, my thesis does not infringe upon anyone's copyright nor violate any proprietary rights and that any ideas, techniques, quotations, or any other material from the work of other people included in my thesis, published or otherwise, are fully acknowledged in accordance with the standard referencing practices. Furthermore, to the extent that I have included copyrighted material that surpasses the bounds of fair dealing within the meaning of the Canada Copyright Act, I certify that I have obtained a written permission from the copyright owner(s) to include such material(s) in my thesis and have included copies of such copyright clearances to my appendix.

I declare that this is a true copy of my thesis, including any final revisions, as approved by my thesis committee and the Graduate Studies office, and that this thesis has not been submitted for a higher degree to any other University of Institution.

ABSTRACT

The aberrant regulation of cell cycle checkpoints can potentially initiate cellular transformation to an oncogenic state that leads to tumor formation. Many families of cell cycle regulators are present to ensure that normal cellular growth and replication occurs, including the polo-like kinases (Plk). Plk4 (Sak), the newest and most structurally divergent member of the Plks has been implicated to play crucial roles in centrosome dynamics and mitotic progression. Plk4 heterozygous mouse embryonic fibroblasts (MEFs) present a number of phenotypic differences, in comparison to their wild type counterparts that may contribute to the increased incidence of tumor formation observed in heterozygous Plk4 mice. Microarray technology was employed to investigate transcriptional differences between the wild type and heterozygous Plk4 MEFs. Furthermore, transcriptional and protein differences were examined in the Plk4 MEFs in response to DNA damaging agents, to explore a possible role for Plk4 in the DNA damage pathways.

ACKNOWLEDGEMENTS

I would like to thank my supervisor, Dr. John Hudson for giving me the opportunity to pursue a Master's thesis in his laboratory. His guidance was invaluable in my pursuing my Master's thesis.

I am also grateful to my committee members, Dr. William Crosby and Dr. Siyaram Pandey, as well as Dr. Huiming Zhang, my committee chair for taking the time to read my thesis, as well as for their valuable input in my Master's career.

I would like to thank my family and friends for all of their help and support throughout this process.

I would also like to thank Hudson lab member's past and present for all of the good times we had together. It would have been very difficult to get through this process without your help and support. A special thanks to Anna Kozarova for her assistance during my master's project.

Chapter 1

Review of Literature

General Introduction

The progression of the cell cycle is tightly regulated to ensure proper integrity of the DNA information and to provide that the genetic material is passed on to viable, normal daughter cells. The integrity of the genetic material is protected by cell cycle checkpoints (Elledge, 1996). These checkpoints halt the cell cycle if the DNA has been damaged or mutated in response to genotoxic stress. Aberrant regulation or loss of one of these checkpoints can result in errors in DNA replication or in chromosomal segregation, leading to aneuploidy or polyploidy, predisposing cells to genetic instability (Xie *et al.*, 2005). This genetic instability can lead to uncontrollable, rapid cellular proliferation which can eventually form cancerous tumors. The cell cycle is tightly controlled, with built-in redundancies that are designed to ensure fidelity. The focus of my research is on Plk4, a member of the polo like kinase (Plk) family of serine/threonine kinases, which have been shown to control a multitude of events throughout the cell cycle (Xie *et al.*, 2005).

Polo like Kinase Family

The polo like kinases (Plks) are an evolutionary conserved family of cell cycle regulators (Dai, 2005). The founding member of the Plk family, Polo was first discovered in *Drosophila melanogaster* (Sunkel *et al.*, 1988) and was shown to be serine/threonine kinase crucial for mitosis (Glover *et al.*, 1993). Mutations in the Polo gene lead to abnormalities in spindle pole formation leading to abnormal mitotic division (Glover *et al.*,

1998). Subsequently homologues have been characterized in simple single celled organisms such as yeast to more complex organisms such as mammals. The family, as a whole, plays key roles in the regulation of the cell cycle and DNA damage pathways. The budding yeast, *Saccharomyces cerevisiae*, and the fission yeast, *Schizosaccharomyces pombe* (Ohkura *et al.*, 1995), contain one Plk homologue, Cdc5 (Golsteyn *et al.*, 1996), and Plo1 (Ohkura *et al.*, 1995) respectively. *Drosophila* contains two Plk homologues, Polo (Fenton and Glover, 1993) and Plk4 (Lowery *et al.*, 2005), while the nematode, *Caenorhabditis elegans* contains three Plk homologues, Plc1, Plc2 (Ouyang *et al.*, 1999), and Plc3 (Chase *et al.*, 2000). Both *Xenopus laevis* and mammals contain four Plk homologues. In *Xenopus*, Plx1 (Kumagai and Dunphy, 1996), Plx2 (Duncan *et al.*, 2001), Plx3 (Duncan *et al.*, 2001), and Plx4 (unpublished data) have all been identified while in mammals, Plk1 (Golsteyn *et al.*, 1994), Snk/Plk2 (Donohue *et al.*, 1994), Prk/Fnk/Plk3 (Donohue *et al.*, 1995) and Sak/Plk4 (Fode *et al.*, 1994) have been characterized. The increase in number of Plk members in more complex organisms is likely a reflection of the need for tighter controls for cell cycle regulation inherent with multicellularity. Plks possess many unique functions throughout the cell cycle including events critical for cell division, centrosome duplication and maturation, DNA damage checkpoint activation, mitotic onset, bipolar spindle formation, Golgi fragmentation and assembly, chromosome segregation, and cytokinesis (Dai, 2005).

Plk Structure

The Plk family consists of catalytic domain at the N-terminus and a one or two polo box domains at the C-terminus of the protein (Dai, 2005) (Figure 1). The catalytic

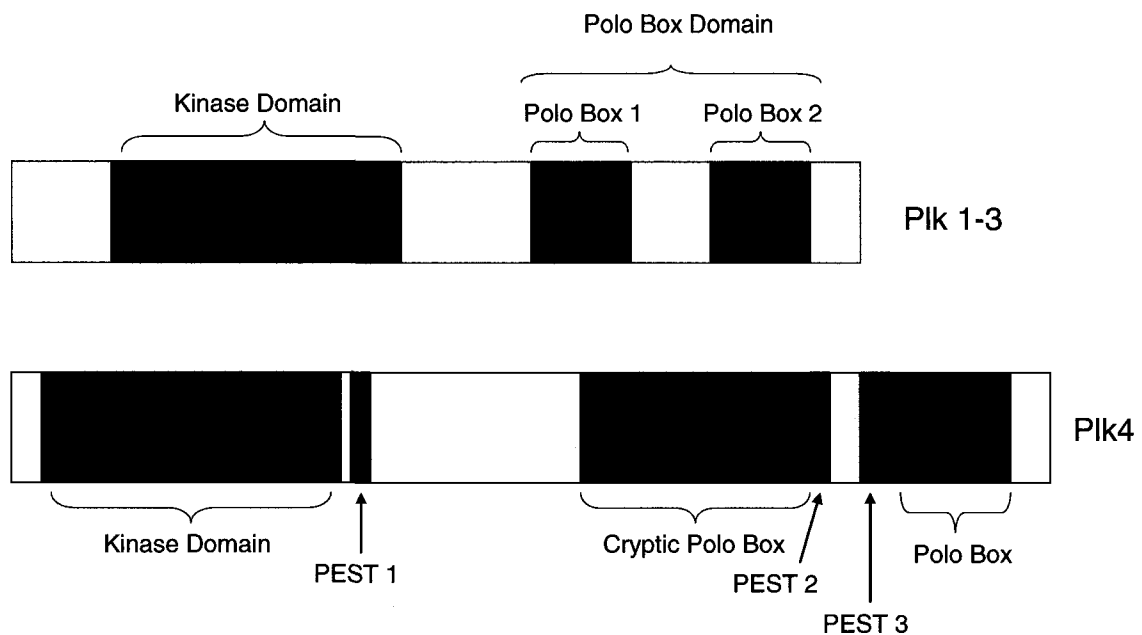

Figure 1: Structural Comparison between Plk4 and of other Plk Family Members

Members of the Plk family all contain a highly homologous kinase domain at the N-terminus and one or two polo box domains at the C-terminus of the protein. Plk4 differs from the other Plks as it contains only one polo box domain. Upstream of Plk4s polo box domain is also a region depicted as the cryptic polo box domain. In addition, Plk4 as contains three PEST sequences associated with reduced protein stability.

domain of the Plks contains their kinase activity and is highly homologous in all Plks. The polo box domain located at the C-terminus of the protein has been shown to regulate cellular functions (Seung *et al.*, 2002), subcellular localization (Elia *et al.*, 2003), and provide a docking site for protein-protein interaction (Reynolds *et al.*, 2003). Plk4 differs from the other Plks in respect to the polo box domain as it contains only one domain. Upstream of the polo box domain, Plk4 contains a cryptic polo box domain, which along with the polo box domain serves as self association domains (Leung *et al.*, 2002). In addition, Plk4 contains 3 PEST sequences which are commonly associated with reduced protein stability and this is the case with Plk4 as it displays a short half life of only two to three hours in non-synchronized cells (Fode *et al.*, 1996) (Figure 1). Though Plk4 contains significant sequence homology to the other Plks in its kinase domain, Plk4 appears to have diverged from a primordial polo-like kinase early in the radiation of metazoans in respect to the rest of its structure (Hudson *et al.*, 2001).

Plk Expression and Localization Profiles

a) Unicellular organisms and invertebrates: The mRNA and protein levels of the Plk family are regulated in a cell-cycle dependent manner. The yeast Plks, Cdc5 and Plo1, in *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* respectively, both localize to the spindle pole bodies, although the timing of localization differs within the cell cycle. Cdc5 localization to the spindle pole bodies occurs in G₁ and persists until late mitosis (Song *et al.*, 2000). Conversely, Plo1 localizes to the spindle pole bodies at the G₂/M transition when Cdc2 is active and subsequently dissociates from the spindle pole bodies during anaphase upon Cdc2 inactivation (Mulvihill *et al.*, 1999). Both yeast Plk

homologues also localize to the cytokinetic ring structures, and play a role in cytokinesis. Cdc5 localizes to the septin ring during G₂ and remains activated until late mitosis (Sakchaisri *et al.*, 2004), whereas Plc1 localizes to the medial ring structures when they are formed (Bahler *et al.*, 1998).

The *Drosophila* Plk homologue, polo localizes to the centrosomes during the G₂/M transition and then associates with the nuclear membrane until its breakdown. During prometaphase, polo localizes to the kinetochores and prior to cytokinesis at the mid-part of the central spindle, a structure essential for cytokinesis (Moutinho-Santos *et al.*, 1999).

In all organisms within the Animal kingdom, Plk homologues follow similar patterns of subcellular localization (Glover, 2005) with localization of the protein a reflection of the different role the respective protein plays throughout the cell cycle. In the following sections I will discuss this for Plks1-3. Plk4 will be discussed in detail individually.

b) Mammalian Plks: In humans Plk1 expression increases from late S phase onward and peaks in mid mitosis at which point Plk1 activity is greatest. Plk1 is then targeted for degradation by the anaphase promoting complex in late mitosis. Plk1 expression levels are high in proliferating tissue such as the testis, spleen and thymus (Golsteyn *et al.*, 1994). Plk1 localizes to many cellular structures throughout the cell cycle, in accordance with the many functions Plk1 performs. Plk1 localizes to the nucleus and cytoplasm during G₂, though its localization is specifically targeted to the centrosomes. In early mitosis, Plk1 is present at the centrosome and kinetochores, while in late mitosis Plk1 localizes to the spindle midbody (Golsteyn *et al.*, 1995). The polo box domain is essential

for targeting Plk1 to these subcellular structures as well as to interacting partners throughout the cell cycle (Elia *et al.*, 2003).

Whereas Plk2 displays significant homology to Plk1, its function and tissue distribution differ greatly. Plk2 has been identified as an early response gene with mRNA levels peaking in response to mitogens. Plk2 primarily functions as a regulator of cell proliferation in G₁ (Simmons *et al.*, 1992). Upon its activation at the G₁/S transition, Plk2 localizes to the centrosomes, indicating a role for Plk2 in centriole duplication (Warnke *et al.*, 2004). A role for Plk2 later in the cell cycle may also be plausible. In response to genotoxic stress causing mitotic spindle damage, Plk2 expression was able to prevent mitotic catastrophe (Burns *et al.*, 2003). Whereas no Plk1 activity was detected in the brain, Plk2 is constitutively expressed in the post-mitotic neurons of the brain indicating Plk2 mediates phosphorylation of proteins within the neurons (Kauselmann *et al.*, 1999).

Similarly to Plk2, Plk3 was identified as an immediate early response gene with mRNA levels peaking after the addition of mitogens (Donohue *et al.*, 1995). Like Plk2, Plk3 also displays a broad distribution of tissue specificity (Holtrich *et al.*, 2000). Plk3 expression is relatively low during mitosis, G₁, the G₁/S transition, and peaks during late S phase and G₂ (Ouyang *et al.*, 1997). Discrepancies have emerged over the localization pattern of Plk3 throughout the cell cycle. Previous work has shown that Plk3 localization is polo-box mediated and that Plk3 localizes to the centrosomes, spindle poles, and the spindle midbody (Jiang *et al.*, 2006). In contrast, Zimmerman and Erikson, 2006 found that Plk3 localized exclusively to the nucleolus and suggested a role for Plk3 in the G₁/S transition. In this study, Plk3 expression was undetectable during mitosis. Similar to Plk2, Plk3 is also expressed in post-mitotic neurons with a possible role in synaptic plasticity

(Kauselmann *et al.*, 1999). Interestingly, Plk3 has also been implicated to have a role in cellular adhesion (Holtrich *et al.*, 2000).

Plks and Mitotic Entry

The transition from G₂ to mitosis is a crucial junction in the cell cycle. Aberrant regulation of this cellular checkpoint can lead to genomic instability and promote oncogenesis. Members of the Plk family play crucial roles at the G₂/M cellular checkpoint to promote entry into mitosis. Plk1 has been implicated to perform numerous functions to promote mitotic entry within the cell. For mitotic entry to occur, the Cyclin B/Cyclin Dependent Kinase 1(Cdk1) complex must become activated. Plk1 promotes mitotic entry by activating cyclin B/Cdk1 at three levels. Firstly, Plk1 is able to phosphorylate Cdc25C in its nuclear export signal sequence promoting its nuclear translocation and activation (Roshak *et al.*, 2000, Toyoshima *et al.*, 2002). Therefore, Cdc25C is able to dephosphorylate Cdk1 promoting the activation of the cyclin B/Cdk1 and mitotic entry (Gauthier *et al.*, 1991). Secondly, Plk1 phosphorylates both Wee1 and Myt1, both CyclinB/Cdk1-inhibiting kinases. In the fission yeast, *Saccharomyces pombe*, Wee1 is known to phosphorylate Thr14 and Tyr15 on Cdc2, the fission yeast homologue of Cdk1. Though in mammals, Wee1 phosphorylation only occurs on Tyr15 (McGowan *et al.*, 1993). Phosphorylation of Wee1 by Plk1 leads to Wee1 enhanced association with the SCF/beta-TrCp E3 ubiquitin ligase, inducing its degradation (Watanabe *et al.*, 2004). Phosphorylation of Thr14 by Myt1 is the additional phosphorylation that serves to inhibit the activity of Cdk1 (Lui *et al.*, 1997). Thirdly, Plk1 phosphorylates cyclin B at the centrosomes in prophase, this being the first site where cyclin B/Cdk1 is actually

phosphorylated. Though discrepancy remains whether this phosphorylation by Plk1 of cyclin B triggers its nuclear import or whether the cyclin B/Cdk1 complex is activated in a different manner.

Plx1, the *Xenopus laevis* homologue of Plk1 is shown to stimulate activation of cyclin B/Cdc2 complex and regulate mitotic entry through a positive feedback loop. Plx1 phosphorylates and activates *Xenopus* polo-like kinase-kinase 1 (xPlkk1). Subsequently, xPlkk1 phosphorylates and activates Plx1 (Qian *et al.*, 1998). Activated Plx1 can subsequently phosphorylate and activate Cdc25C which dephosphorylates Thr14 and Try15 on cdc2 promoting mitotic entry (Qian *et al.*, 2001).

Whereas the role of Plk1 in mitotic entry has been well described, the role of the other Plks at the G₂/M checkpoint remains to be elucidated. As Plk2 primarily regulates G₁/S progression, it doesn't appear to play a role in mitotic entry (Simmons *et al.*, 1992). Although Plk3 does not appear to play a role in mitotic entry, in response to DNA damage Plk3 positively regulates p53 activity to halt progression of the cell from G₂ to mitosis (Xie *et al.*, 2001).

Plks and their Role in Mitotic Exit and Cytokinesis

Plks have been shown to play roles in both exit from mitosis and cytokinesis. For mitotic exit to occur, the inactivation of Cdk1 is required. In budding yeast, inactivation of Cdk1 occurs after the metaphase/anaphase transition, which differs from mammalian cells, where downregulation of Cdk1 occurs at the metaphase/anaphase transition (Clute and Pines, 1999). The downregulation of Cdk1 promotes exit from mitosis, and in budding yeast requires the cooperation of the FEAR (Cdc Fourteen Early Anaphase

Release) (Stegmeier *et al.*, 2002) and MEN (Mitotic Exit Network) pathways (Bardin and Amon, 2001) and Cdc5 plays an important role in regulating both of these pathways. Although the role which Cdc5 plays in regulating has yet to be described, it is assumed that Cdc5 coordinates between the FEAR and MEN pathways via phosphorylating regulatory components in each pathway (Lee *et al.*, 2005). Cdc5 and additional components of the MEN pathway are also required for proper actin ring formation at the mother-bud-neck, the site of cytokinesis (Jimenez *et al.*, 1998).

In fission yeast, Plo1 has been implicated in two events regulating cytokinesis. First, Plo1 localizes to the site of cytokinesis, and this localization is important for the placement and organization of the actin-based medial ring (Bahler *et al.*, 1998). Secondly, Plo1 activity correlates with the initiation of septin formation which regulated by the septin initiation network (SIN) (Gruneberg and Nigg, 2003). The SIN and MEN networks contain structurally related proteins that perform similar functions in each pathway. Like Cdc5, the functional significance of Plo1 role in the SIN pathway has yet to be determined.

In *Drosophila*, polo has also been implicated as having a role in cytokinesis as it directs the function of the Pavarotti-KLP (Pav-KLP) family of motor proteins. This family of proteins plays a role in organizing the central spindle in anticipation of cytokinesis (Glover, 2005). Polo and Pav-KLP interact and both co-localize to the central part of the spindle (Liu *et al.*, 2004). Interestingly, studies have revealed that proteins including Polo, Asp (Wakefield *et al.*, 2001), and γ -TuRC (Sampaio *et al.*, 2001) are involved in the organization of the centrosomes and the early mitotic spindles also

perform roles in cytokinesis. It is hypothesized that Polo may phosphorylate these substrates at both the beginning and conclusion of mitosis (Glover, 2005).

In *Xenopus*, the transition from metaphase to anaphase and therefore exit from mitosis requires the activity of Plx1 since inhibition of Plx1 prevents the metaphase to anaphase transition (Qian *et al.*, 1999). The requirement for Plx1 activity suggests that Plx1 may control the anaphase-promoting complex/cyclosome (APC/C). Three possible mechanisms have been hypothesized; first, Plx1 may activate the APC/C through direct phosphorylation of several APC/C subunits (Kotani *et al.*, 1998). Secondly, Plx1 may regulate the activators or inhibitors of the APC/C (Reimann *et al.*, 2001), or thirdly, Plx1 could activate the APC/C and prevent premature inactivation of the APC/C (Brassac *et al.*, 2000). Additionally, the inactivation of Plx1 may be required for the completion of cytokinesis to occur (Qian *et al.*, 1999).

Like Plx1, Plk1 may be involved both directly and indirectly in the activation of the APC/C. Activation of the APC/C may occur through direct phosphorylation of APC/C subunits along with the phosphorylation of the cyclin B/Cdk1 complex (Golan *et al.*, 2002). Indirectly, Plk1 is responsible for activating the APC/C by inducing the destruction of APC/C inhibitor “Early mitotic inhibitor 1” (Emi1) (Moshe *et al.*, 2004). Similar to other Plk homologues, Plk1 has also been implicated to play a role in cytokinesis. Although the exact role that Plk1 plays in cytokinesis is unknown, Plk1 has been shown to interact with and phosphorylate cytokinetic proteins. Plk1 phosphorylates the kinesin-like motor protein CHO1/MKLP-1 (Lee *et al.*, 1995), NudC (a component of the dynaction complex Zhou *et al.*, 2003), the mitotic kinesin-like protein 2 (MKlp2) (Neef *et al.*, 2003), and the Rho exchange factor ECT2 (Niiya *et al.*, 2005). Though the

functional significance of some of these interactions remains to be elucidated, phosphorylation of NudC and MKlp2 by Plk1 are indispensable for the execution of cytokinesis. To date, Plk2 and Plk3 have not been implicated in mitotic exit or cytokinesis.

Plks and their Role in DNA Damage Pathways

The cellular response to DNA damage by genotoxic stress is crucial, as failure to repair any damage in the genetic material can produce aneuploidy leading to uncontrolled cellular growth and oncogenesis. In response to genotoxic stress, cell cycle checkpoints are employed to repair damage that has occurred to the DNA or to initiate apoptosis if the damage is irreparable. Plks have been implicated to play crucial roles in the DNA damage pathways.

In response to DNA damage, the DNA damage sensor proteins, ataxia-telangiectasia mutated (ATM) or ataxia-telangiectasia and Rad3-related (ATR) become activated (Bakkenist *et al.*, 2003). Activation of ATM or ATR in response to DNA damage inhibits the function of Plk1 (van Vugt *et al.*, 2001). The inhibition of Plk1 by ATM or ATR is mediated by the ATM/ATR downstream effector kinase checkpoint kinase 1 (Chk1). Experimentally it has been observed that the inhibition of Plk1 is rescued in Chk1-depleted cells exposed to UV radiation (Tang *et al.*, 2006). Inhibition of Plk1 in response to DNA damage prevents it from promoting mitotic entry in the presence of genomic instability. Subsequently, Plk1 also binds to and phosphorylates the tumor suppressor p53 inhibiting its function, thus preventing p53 mediated pro-apoptotic pathways. Expression of ATM is able to attenuate Plk1 interaction with p53 (Ando *et al.*,

2004). Whereas Plk1 is able to negatively regulate p53 function, Plk3 positively regulates the transcriptional function of p53. In response to DNA damage, ATM phosphorylates Plk3 activating its kinase ability and Plk3 then phosphorylates p53 on a different residue from Plk1, promoting p53 mediated G₂/M cell cycle arrest and apoptosis (Xie *et al.*, 2001).

In addition, Plk3 has been implicated to play a role in DNA damage repair. Plk3 is able to regulate the activity of DNA polymerase δ (pol δ), a major enzyme in DNA damage repair (Hubscher *et al.*, 2002). Plk3 phosphorylates pol δ on p125, the major pol δ subunit on Ser60. Though the functional significance of this interaction remains to be elucidated, it is speculated that since Plk3 phosphorylates p125 in its nuclear localization signal, this phosphorylation controls the subcellular localization of pol δ (Xie *et al.*, 2005).

Plk2 may also play a role in DNA damage pathways. In response to ionizing radiation, mRNA transcript levels of Plk2 were shown to increase. This response was deemed to be p53 dependent as based on luciferase assay data; a candidate site for a radiation response element was mapped to the Plk2 promoter containing a p53 binding motif (Shimizu-Yoshida *et al.*, 2001). A subsequent study showed that p53 indeed regulates Plk2 in response to genotoxic stress. In response to mitotic spindle damage, Plk2 is activated in a p53 dependent manner and this activation prevents mitotic catastrophe (Burns *et al.*, 2003) (Figure 2).

Figure 2: Role of Plks in the DNA damage Pathways

In response to either ultraviolet radiation (UV) or ionizing radiation (IR), the DNA damage sensor proteins ataxia telangiectesia and Rad3 related (ATR) and ataxia telangiectesia mutated (ATM) become activated, respectively. In response to either UV or IR damage, Plk1 is either inhibited by ATR or ATM. Subsequently, ATR activates checkpoint kinase 1 (Chk1), or ATM activates checkpoint kinase 2 (Chk2). Normally, Plk1 activates cell division cycle 25c (Cdc25c) promoting G₂/M transition. Since Plk1 is inhibited by either ATR or ATM, Cdc25c activity is inhibited by Chk1 or Chk2 in response to UV or IR, respectively. In response to IR, ATM also activates Plk3, which activates DNA polymerase δ , promoting DNA repair. In addition, Plk3 can activate Chk2 and p53, while Chk2 can also activate p53. The activation of p53 inhibits progression of the cell cycle from G₂ to mitosis. Plk2 activity is also initiated by p53 in response to DNA damage. The role that Plk4 may play in the DNA damage pathways remains to be elucidated. Plk4 interacts with ATM, ATR, Chk1, Chk2, p53, and Cdc25c, though the functional significance of these interactions remains to be described. Black arrows denote activation, red bars denote inhibition.

Plks and the Centrosomes

The centrosome plays a major role in organizing the microtubule cytoskeleton of the cell and is the organizational centre of an astral array of microtubules that participate in cellular functions including intracellular trafficking, cell motility, cell adhesion, and cell polarity. In proliferating cells, the centrosomes participate in the assembly and organization of the mitotic spindle, their spatial orientation, and cytokinesis (Azimzadeh and Bornens, 2007).

The centrosome consists of two centrioles with an orthogonal arrangement linked together at their proximal regions by a matrix consisting of proteins of the pericentrin family (Nigg, 2007; Dawe *et al.*, 2007). The centrosomes replicate once during the cell cycle with each centrosome consisting of a mother/daughter centriole. During G₁, centriolar disengagement occurs through the actions of separase (Tsou and Stearns, 2006). Though the orthogonal arrangement is lost, the centrioles are still connected by a tether of microfilaments (Bahe *et al.*, 2005). In S phase, a procentriole grows from the existing centriole at an orthogonal angle through the activity of several centriolar proteins. The procentriole continues to grow till G₂ until it reaches full maturity. Subsequently, the tether of filaments connecting the two mother centrioles together is severed to allow the centrosomes to enable spindle formation and chromosome segregation during mitosis (Mayor *et al.*, 2000).

The centrosome has also been implicated in playing a role in DNA damage checkpoint control (Fletcher and Muschel, 2006). Centrosome inactivation has been observed to be part of the DNA damage control system seen in *Drosophila*. In response to DNA damage, centrosome function was abrogated causing spindle defects and

subsequent failure in chromosomal segregation. These results indicated that centrosome inactivation is a checkpoint independent and mitosis-specific response to genotoxic stresses (Sibon *et al.*, 2000). Additionally, in mammalian cell lines, centrosomal segregation is inhibited in G₂ in response to DNA damage. Centrosomal segregation is controlled by the protein kinase Nek2 whose activity is inhibited by DNA damage (Fletcher *et al.*, 2004). Interestingly, Plk1 can interact with and phosphorylate Nek2 promoting centrosomal segregation. However, in response to DNA damage the activity of Plk1 is inhibited, therefore preventing Nek2 from promoting centrosomal segregation. The inhibition of centrosome segregation occurs in an ATM/ATR dependent manner (Zhang *et al.*, 2005).

Members of the Plk family have been implicated to play additional crucial roles in the centrosome cycle. In fission yeast, loss of function of Plk1 homologue, Plo1 leads to mitotic arrest where the chromosomes are condensed with only a monopolar spindle present (Ohkura *et al.*, 1995). In contrast, in budding yeast, Cdc5 may be required for microtubule nucleation, though Cdc5 activity is not essential for the establishment of bipolar spindles (Lee *et al.*, 2005). In *Drosophila*, Plk homologue polo is required for the recruitment of two crucial centrosomal components: CP190 and γ -tubulin. In polo mutants, CP190 and γ -tubulin are unable to localize specifically to the centrosomes, instead they scatter throughout the mitotic spindles (Dai and Cogswell, 2003). A similar inability to recruit γ -tubulin to the centrosomes has also been observed in mammalian cell lines (Lane and Nigg, 1996). In addition, polo is required to phosphorylate and activate centrosomal protein Asp which is required for microtubule nucleation (Avides *et al.*, 2001). Asp mutants present mitotic spindles with highly unfocused poles and a high

mitotic index. In polo mutants, Asp is still able to localize to the centrosomes, though its activity is negligible. In polo and asp double mutants, there is a substantial increase in mitotic index (Gonzalez *et al.*, 1998). Polo is also required for the nucleation of microtubules by centrosomes. The chaperone protein heat shock protein 90 (Hsp90) is required to ensure the stability of polo. Inhibition of Hsp90 results in inactivation of polo kinase activity, thereby abolishing the nucleation of the microtubules (de Carcer *et al.*, 2001). In *Xenopus* it is also assumed that Plx1 regulates centrosome separation and maturation by recruiting proteins to the centrosomes. This assumption is supported by the finding that inhibition of Plx1 results in monopolar spindles with α -tubulin not localizing to the centrosomes (Qian *et al.*, 1998).

In mammalian cells, centrosome maturation is also dependent on Plk1, which phosphorylates Nlp, a centrosome protein. This allows Nlp to be removed from the centrosomes and for the recruitment of microtubule nucleation scaffolding (Casenghi *et al.*, 2003). In addition, Plk1 plays a role in centrosome separation as depletion of Plk1 leads to monopolar spindles and eventually mitotic arrest (Lane and Nigg, 1996). Plk1 may also regulate spindle formation as it has been shown to phosphorylate α -, β -, γ -tubulins and the tubulin stabilizing protein TCTP (Feng *et al.*, 1999) (Yarm, 2002). Interestingly, it has been shown that Plk1 does not need to be bound to the centrosomes to perform its centrosomal functions. Hanisch *et al.*, 2006 showed that delocalized Plk1 can still contribute to centrosome maturation, separation and spindle formation but not chromosome segregation.

Plk2 kinase activity is required for initiation of centriole duplication at the G₁/S transition. Previous work has shown that overexpression of a catalytically inactive form

of Plk2 blocks centriole duplication (Warnke *et al.*, 2004). Subsequently, inhibition of Plk2 through siRNA also blocked centriole duplication. Alternatively, overexpression of Plk2 causes an increase in centrosome number. Plk1 has also been described to be required for centriole duplication (Liu and Erikson, 2002). Though in contrast to Plk2, kinase activity of Plk1 is not required for initiation of centriole duplication at the G₁/S transition (Warnke *et al.*, 2004). Whereas Plk2 initiates centrosome duplication, Plk1 ensures centrosome maturation (van de Weerd and Medema, 2006). To date, no evidence has been presented implicating Plk3 with a role in centriole duplication or centrosome function.

Plks and Oncogenesis and Tumor Development

Since Plks are crucial cell cycle regulators, aberrant regulation of their function may contribute to oncogenesis, designed as a shift to cellular proliferation stimulating signals to encourage uncontrollable cellular growth. This uncontrolled cell growth will eventually lead to tumor formation and cancer (Eckerdt *et al.*, 2005). Plk1 expression and activity are tightly controlled throughout the cell cycle, though Plk1 mRNA and protein levels have been found to be significantly increased in proliferating cells (Wolf *et al.*, 2000). Plk1 is over expressed in tumor cell lines, indicating that Plk1 could lead to enhanced cellular proliferation and eventually cell transformation (Simizu and Osada, 2000). Elevated Plk1 levels are also found in a number of cancers including non-small-cell lung cancer, head/neck squamous cell carcinomas, esophageal carcinoma, oropharyngeal carcinomas, melanomas, breast cancer, ovarian cancer, pancreatic cancer, prostate carcinomas and papillary carcinomas (Eckerdt *et al.*, 2005). Increased levels of

Plk1 have also been correlated with severity of diagnosis and patient prognosis (Kneisel *et al.*, 2002).

The ability of Plk1 to induce oncogenesis may be due to its capacity to interact with several tumor suppressor genes. Plk1 is able to bind to the DNA binding domain of p53 (Ando *et al.*, 2004) and phosphorylate a residue which blocks p53's transcriptional activity inhibiting its proapoptotic function (Xie *et al.*, 2001). In contrast, p53 activity is significantly stabilized in Plk1-depleted cells (Liu and Erikson, 2003).

Checkpoint kinase 2 (Chk2), another tumor suppressor protein also interacts with Plk1. A Chk2 mutant lacking catalytic activity has been shown to contribute to increased risk of breast cancer (Meijers-Heijboer *et al.*, 2002). Chk2 and Plk1 both colocalize at the centrosomes in early mitosis, and to the mid-body in late mitosis (Tsvetkov *et al.*, 2003). In response to ionizing radiation, Plk1 can phosphorylate Chk2 at Thr-68, a site normally phosphorylated by ATM. The phosphorylation of Chk2 by ATM usually activates Chk2 which then phosphorylates BRCA1 which inhibits the activity of Plk1 (Ree *et al.*, 2003). Though the physiological significance of Plk1's phosphorylation of Chk2 remains to be elucidated, it is believed the Plk1 phosphorylation of Chk2 may contribute to a crosstalk between the DNA damage pathways and mitotic regulation (Matsuoka *et al.*, 2000).

A network of tumor suppressor proteins is in place to suppress the oncogenic functions of Plk1, inhibiting its ability to promote mitosis and cell growth. Therefore, in response to DNA damage, it requires the loss of function of numerous tumor suppressor proteins to promote oncogenesis. It is believed that Plk1 function is inhibited in two ways in response to DNA damage. If damage occurs within interphase, Plk1 activity is inhibited in an ATM/ATR dependent manner through the activity of either Chk1 or BRCA1. In

response to DNA damage occurring within mitosis, Plk1 is inhibited through an ATM/ATR independent manner, through the activation of retinoblastoma protein (RB) by p53 (Eckerdt *et al.*, 2005) (Figure 3).

While Plk2 expression has yet to be correlated with the progression or suppression of tumor formation in any cancer, through its actions in the cell cycle, Plk2 may play a crucial tumor suppressor role. In response to DNA damage, the activity of Plk2 is transcriptionally up-regulated in a p53 dependent manner. This activation is able to prevent mitotic catastrophe following mitotic spindle damage by activating the spindle checkpoint (Burns *et al.*, 2003). The activation of the spindle checkpoint prevents the completion of mitosis which can contribute to genomic instability and the promotion of oncogenesis.

In contrast to Plk1, Plk3 expression is negatively correlated with the development of cancer. Plk3 mRNA levels are either undetectable or down-regulated in lung carcinomas (Li *et al.*, 1996), head/neck squamous cell carcinomas (Dai *et al.*, 2000), and in carcinogen-induced rat colon tumors (Dai *et al.*, 2002). Furthermore, ectopic expression of Plk3 decreases cellular proliferation in fibroblasts (Dai *et al.*, 2000), while over expression of a catalytically active form of Plk3 induces chromatin condensation, rapid cell cycle arrest and eventual apoptosis (Conn *et al.*, 2000; Wang *et al.*, 2002). These observations indicate a tumor suppressor role for Plk3 though, to the contrary, Plk3 along with Plk1 were both found to be over expressed in malignant epithelial ovarian tumors, with over-expression correlating with an enhanced mitotic index and decreased patient survival (Weichert *et al.*, 2004).

In contrast to Plk1 during the cell cycle, which mediates oncogenic cellular transformation, Plk3 inhibits mitosis in the presence of damage to the genome. Plk3 activation in response to DNA damage is mediated in an ATM-dependent fashion. Plk3 can in turn activate tumor suppressor proteins like Chk2, which subsequently inhibit the mitotic-promoting functions of Plk1, or p53 which initiates apoptotic pathways (Xie *et al.*, 2001). Therefore, Plk3 function maybe crucial to inhibiting the progression of cells to an oncogenic state.

Polo-like Kinase 4 (Plk4)/Sak

Plk4 or Sak (Snk/Plk-akin kinase), was first identified in a screen of a murine lymphoid cDNA library for wheat germ agglutinin (WGA) resistant clones and was found to be a putative protein-serine/threonine kinase. Due to its expression pattern and sequence similarity with *Drosophila* polo, it was suggested that Plk4 played a role in cell cycle regulation (Fode *et al.*, 1994). Murine Plk4 is located on chromosome 3 while the human homologue is found on chromosome 4q28 (Swallow *et al.*, 2005). In mice, two isoforms have been identified while only a single isoform of the product protein found in humans. The Plk4-a and Plk4-b variants differ in respect to the C-terminus end. Plk4-a encodes a 925 amino acid (aa) protein while Plk4-b encodes a 464 aa protein. The first 416 aa of Plk4-a and Plk4-b are identical while at the C-terminus end Plk-a region encodes 509 aa and Plk-b encodes 48 aa. Murine Plk4 has 15 coding exons and both the Plk-a and Plk-b variant are encoded for by a single gene. Human Plk4 differs from the murine Plk4-a in that contains a 34 aa insertion adjacent to exon 5 that is found in the murine Plk4-b variant (Hudson *et al.*, 2000).

Figure 3: Interactions between Plks and Tumor Suppressor Proteins

Members of the Plk family interact with tumor suppressor proteins and have been implicated in the progression or inhibition of oncogenesis. Plk1 activity is either inhibited directly or indirectly by ataxia telangiectesia and Rad3 related (ATR), ataxia telangiectesia mutated (ATM), checkpoint kinase 1 (Chk1), checkpoint kinase 2 (Chk2), Breast cancer 1 gene (BRCA1), Retinoblastoma protein (pRb) and p53. The inhibition of Plk1 activity is in response to activation of the DNA damage or mitotic spindle checkpoints. Whereas Plk1 promotes progression through the cell cycle, Plk2 and Plk3 suppress the cell cycle in response to damage. Loss of function of one or more of these tumor suppressor proteins, can lead to aberrant regulation of the cell cycle and the progression of oncogenesis. Though the exact function of Plk4 as a tumor suppressor or oncogene has yet to be determined, the fact that heterozygous Plk4 mice develop tumors at a rate higher than wild type litters, supporting the notion that Plk4 plays a significant role in these oncogenic pathways. Black arrows denote activation; red bars denote inhibition.

Plk4 Expression Profile and Localization

Like Plk1, Plk4 mRNA and protein levels are regulated in a cell cycle dependent manner with Plk4 expression low in G1, increasing during DNA replication and G2 and peaking during cytokinesis. Plk4 is targeted for ubiquitination by the anaphase promoting complex (Fode *et al.*, 1996). Plk4 expression is also highest in rapidly proliferating tissues, such as the testis, spleen, and thymus (Fode *et al.*, 1994). Differing views have emerged concerning the localization of Plk4 during the cell cycle. Previous work has shown that Plk4 localized to the nucleolus and perinuclearly in G2, and to the centrosomes in early mitosis. During anaphase, Plk4 localized throughout the cell and in telophase to the cleavage furrow (Hudson *et al.*, 2001). This pattern of localization was supported by (Martindill *et al.*, 2007) where Plk4 showed a similar localization pattern and was shown to phosphorylate the developmental protein Hand1, controlling its nucleolar release. In contrast, Habedanck *et al.*, 2005 showed Plk4 localized exclusively to the centrosomes throughout the cell cycle. In support of this finding, Bettencourt-Dias *et al.*, 2005 working with *Drosophila melanogaster* cells showed Plk4 localization to the centrosomes throughout the cell cycle. Among the other Plk family members, both of the polo box domains are necessary for subcellular localization (Jang *et al.*, 2002), but in Plk4 there is debate whether the polo box domain itself is sufficient for localization. Previous work has shown that the polo box itself is sufficient for localization of Plk4, though a truncated mutant lacking both the polo box and cryptic polo box region reduced the efficiency of Plk4 for localization (Leung *et al.*, 2002). In contrast, an additional study has shown that the polo box region itself is not sufficient for localization (Habedanck *et al.*, 2005).

Plk4 and the Centrosomes

Plk4 has been identified as a key regulator of centriole duplication. Over-expression of Plk4 leads to centrosome amplification through the generation of numerous progeny centrioles from a parental centriole (Habedanck *et al.*, 2005; Kleylein-Sohn *et al.*, 2007). Conversely, inhibition of Plk4 activity leads to inhibition of centriole formation in *Drosophila* cells and subsequently the formation of basal bodies and flagella (Habedanck *et al.*, 2005; Bettencourt-Dias *et al.*, 2005). In the initial studies, both kinase activity and presence of the cryptic polo box domain of Plk4, which is necessary for localization to the centrosome were required to induce amplification. The necessity of the kinase domain indicates that Plk4 may be required to target key substrates that are involved in the centrosome cycle. It was also observed that over expression of a catalytically inactive form of Plk4 could induce some centrosome amplification, albeit through a different mechanism that likely involves cell division failure through a dominant-negative method of action (Habedanck *et al.*, 2005). Over expression of Plk4 produces a phenotype reminiscent of a flower, with progeny centrioles arranged around the parental centriole like petals. Plk4 appears to localize to the parental centriole at the G₁/S transition, and this localization initiates multiple centriole duplication sites around the parental centriole. In addition, the localization of Plk4 to the parental centriole initiates that rapid recruitment of centriole proteins hSas6, CPAP, Cep135 and γ -tubulin to the parental centriole (Kleylein-Sohn *et al.*, 2007). Whether Plk4 interacts with or phosphorylates any of these proteins to recruit them to the parental centriole remains to be elucidated. These proteins along with CP110 provide the foundation for procentriole formation. Plk4 appears to be the upstream regulator required for initiation of centriole

duplication and the recruitment of other proteins. Inhibition of hSas-6, CPAP, Cep135, CP110 or γ -tubulin *via* siRNA suppresses Plk4's ability to induce centriole formation (Kleylein-Sohn *et al.*, 2007). Therefore, the activity of Plk4 is likely tightly regulated within the cell cycle since aberrant activity would produce centriole over duplication. The kinase responsible for activating Plk4 function or the counteracting phosphatase responsible for suppressing Plk4 activity remains to be identified.

It is noted that cyclin-dependent kinase 2 (Cdk2) has been implicated as having a role in centrosome duplication and that inhibition of Cdk2 activity suppresses centrosome duplication (Matsumoto *et al.*, 1999). Interestingly, over-expression of Plk4 requires the activity of Cdk2 to produce centrosome amplification, while a catalytically inactive Cdk2, or the presence of the Cdk2 inhibitor p27 suppresses Plk4-induced centrosome amplification. Conversely, Cdk2 requires Plk4 activity to perform its role in centrosome duplication, indicating Cdk2 and Plk4 in their respective functions cooperate (Habendanck *et al.*, 2005).

Interestingly, the over-expression phenotype of Plk4 is similar to the phenotype observed in heterozygous Plk4 MEFs. The heterozygous MEFs present a phenotype of increased centrosomal amplification, multipolar spindle formation and subsequent mitotic failure (Ko *et al.*, 2005). It is plausible that reduced Plk4 activity in the heterozygous MEFs can cause cellular division failure from aberrant centrosome segregation or abnormal mitotic spindle formation (Habendanck *et al.*, 2005). The findings within heterozygous MEFs are likely due a reduced gene dose of Plk4.

In contrast, depletion of Plk4 in human cells by siRNA causes a step by step reduction in centriole number resulting in the presence of monopolar spindles during

mitosis (Habedanck *et al.*, 2005). Additionally, inhibition of Plk4 *via* siRNA leads to an increased mitotic index and an increase in apoptotic cells (Bettencourt-Dias *et al.*, 2005). In *Drosophila* cells, inhibition of Plk4 leads to the failure of several centrosomal proteins, γ -tubulin, CP190 and Cnn to localize to the centrosomes. Additionally, cells lacking γ -tubulin at the spindle poles also had no detectable pericentrin-like protein (D-PLP). In contrast, inhibition of polo did not affect D-PLP presence at the spindle poles. Although inhibition of Plk4 leads to a reduction and failure in centrosome number and centriole formation, in contrast inhibition of polo doesn't reduce centrosome number or affect centriole formation. Interestingly, inhibition of Plk4 and a reduction in centrosome number did not effect cell cycle progression. However, Plk4 null *Drosophila* adults were uncoordinated and eventually died as a result of a failure to produce basal bodies, a centriolar derived structure in the sensory neurons (Bettencourt-Dias *et al.*, 2005).

Plk4 Role in Mitosis

Plk4 plays a crucial role in regulating centrosome dynamics, although whether Plk4 plays any additional roles in the cell cycle remains to be elucidated. Experimental evidence suggests a role for Plk4 in promoting mitotic entry since Plk4 interacts with two key genes in the G₂/M transition. Plk4 interacts with and phosphorylates Cdc25C (Bonni *et al.*, 2008) and interacts with cyclin B (Hudson *et al.*, unpublished data), though the functional significance of these interactions remains to be described. Plk4 may also play a role in promoting mitotic exit. In Plk4 null mice where embryonic lethality is observed, high levels of cyclin B are observed in anaphase and telophase cells (Hudson *et al.*,

2001). This is indicative of cells arresting late in mitosis. Therefore, Plk4 may play a crucial role in the APC/C dependent destruction of cyclin B.

Plk4 Role in DNA Damage Pathways

As with the other Plk family members, Plk4 may also play a role in the DNA damage pathways since Plk4 has been shown to interact with p53 (Swallow *et al.*, 2005) and Plk4 expression is repressed in a p53 dependent manner in response to DNA damaging agents (Li *et al.*, 2005). It was determined that p53 repression of Plk4 activity occurred through the recruitment of a histone deacetylase (HDAC) transcription repressor. In addition, Plk4 repression through RNA interference allowed p53-induced apoptosis to occur, while Plk4 overexpression attenuated p53-mediated apoptosis. Though a direct role for Plk4 in DNA damage pathways has yet to be described, Plk4 has been shown to interact with various sensor, transducer and effector proteins including ATM, ATR, Chk1, Chk2, and members of the Cdc25 phosphatase family (Hudson *et al.*, unpublished data). Therefore, it is plausible that Plk4 may play a substantive role in the cellular response to genotoxic stresses.

Plk4 Null Mice

To study the role of Plk4 in embryogenesis and to determine the effect of loss of Plk4 function in mice, a Plk4 null allele was generated by replacing exons 1 and 2 with a Neo gene deleting the start of translation (Hudson *et al.*, 2001). It was discovered that Plk4 null mice arrested at approximately 7.5 days post coitum after gastrulation had occurred. Formation of the neural plate was evident but somite development and neural

tube formation failed to occur (Hudson *et al.*, 2001; Swallow *et al.*, 2005). An examination at 8.5 days found that Plk4 null embryos were smaller than both wild type and heterozygous embryos with the embryonic and extra embryonic structures that were reduced in size. Null embryos showed an increased number of cells present in mitosis indicating a block or delay in mitosis which was confirmed by phosphorylated histone H3 detected six times more frequent in null embryos. Outgrowths from E2.5 blastocysts were compared, and Plk4 null outgrowths were smaller and DNA synthesis was reduced in comparison to the wild type. As seen with embryos at E8.5, 68% of Plk4 null outgrowths were positive for phosphorylated histone H3 compared to only 17% of wild type outgrowths indicating an anaphase block had occurred in the nulls (Hudson *et al.*, 2001). Plk4 null blastocysts also displayed an increased number of cells present with a dumbbell morphology indicating a block in telophase (Hudson *et al.*, 2001; Swallow *et al.*, 2005). Plk4 null embryos also presented a high number of cells with a late mitotic delay leading to a high apoptotic rate.

Plk4 was the first member of the polo like kinase family to be studied by germline mutation; whereas experimental data indicates that Plk4 is required for embryonic development, a study by Ma *et al.*, 2003 showed that in contrast Plk2 null mice were not embryonic lethal. Plk2 null mice were smaller than their littermates and show a slight delay in skeletal development. In addition, Plk2 null mice were all fertile and show comparable survival rates to their heterozygous and wild type littermates (Ma *et al.*, 2003). These results indicated that although Plk2 may play an essential role in cell cycle progression, it is not essential for embryonic development. To date, no germline

mutations of Plk1 or Plk3 have been devised to assess the functional significance of these genes in an animal system.

Plk4 Mouse Embryonic Fibroblasts (MEFs)

Consistent with the embryonic lethality observed with Plk4 null embryos, the establishment of Plk4 null MEFs was unsuccessful indicating the Plk4 is not only necessary for embryonic development but also for cell viability (Hudson et al 2001; Ko *et al.*, 2005). In contrast, Plk2 null MEFs are viable though they are delayed in entering S phase (Ma *et al.*, 2003).

Plk4 heterozygous MEFs are viable though they exhibit a slower growth rate compared to wild type MEFs (Ko *et al.*, 2005). Plk4 heterozygous MEFs presented a number of mitotic defects including abnormal spindle number as well as abnormal chromosomal number and segregation. The percentage of MEFs with greater than three centrosomes was significantly increased in heterozygous Plk4 MEFs, while the presence of more than one microtubule organizing centres (MTOC) was observed in approximately one-third of Plk4 heterozygous MEFs in interphase (Ko *et al.*, 2005; Swallow *et al.*, 2005). A similar phenotype is observed in MEFs deficient in p53 or p21 with an incidence of centrosome amplification similar to that of Plk4 heterozygous MEFs (Carroll *et al.*, 1999). Tatapore *et al.* showed that in p53 null MEFs there was an increase in centrosome and MTOC number. Plk4 heterozygous MEFs contain mRNA and protein levels at about 50% the level found in wild type MEFs (Swallow *et al.*, 2005).

Cancer Development in Plk4 Heterozygous Mice

Plk4 heterozygous mice are healthy and fertile and show no abnormal defects early in development (Hudson *et al.*, 2001; Ko *et al.*, 2005). On the other hand, aged Plk4 heterozygous mice (18-24 months) developed primary hepatocellular (HCC) liver tumors at a frequency of 50% in comparison with only 3% in wild type mice. These liver tumors were typically multifocal indicating a predisposition to tumor development throughout the liver. Further examination showed that the hepatocytes presented a high mitotic index and nuclear atypia. Tumor development in heterozygous mice was also observed in the lung with papillary adenocarcinomas discovered in the periphery of the lung parenchyma. In addition, a few heterozygous mice developed large soft tissue tumors of the axilla and upper chest wall (Ko *et al.*, 2005).

A two-thirds partial hepatectomy was employed to study the molecular basis why Plk4 heterozygous mice were predisposed to mitotic errors. This method was employed to induce dormant hepatocytes back into the cell cycle. It was shown that 44 hours after partial hepatectomy, Plk4 heterozygous hepatocytes had a significantly higher incidence of tri- or tetrapolar spindles leading to abnormal mitosis. Introduction of hepatocytes in S phase was delayed by four hours in heterozygotes as seen by the persistence of Cdk2 activity and the delay of phosphorylation of Rb. Subsequently, entry into mitosis was delayed in heterozygous Plk4 livers as observed by the persistence of cyclin B1, and phosphorylated Cdk1. Seven days post hepatectomy, heterozygous hepatocytes were poorly organized, though normal liver mass was restored and no difference in the survival rate was observed in both wild type and heterozygotes. Six months post partial hepatectomy, 70% of heterozygous mice displayed hepatocellular dysplasia with nuclear

atypia as well as disorganization in the normal liver architecture, while wild type livers were normal. Twelve months post partial hepatectomy, all heterozygous Plk4 mice presented abnormal liver histology with 37% developing HCC tumors that were multifocal in nature with a high degree of aberrant mitotic errors. The majority of the wild type Plk4 mice had normal liver architecture. These studies reasoned that some hepatocytes in heterozygote livers with abnormal spindle morphology escaped programmed cell death and passed this phenotype to subsequent generations of hepatocytes leading to the increased development of liver tumors in the Plk4 mice (Ko *et al.*, 2005).

The results observed in heterozygous mice are consistent with the observation that the Plk4 gene is present on human chromosome 4q28, a syntenic region that frequently undergoes rearrangement in hepatocellular carcinomas. It was determined that the increased incidence of hepatomas in Plk4 heterozygous mice resulted from haploinsufficiency and that the Plk4 gene dosage is crucial for suppression of carcinogenesis (Ko *et al.*, 2005).

Plk4 Role in Oncogenesis

In contrast to heterozygous Plk4 mice where a reduced gene dose of Plk4 was correlated with tumor development, Plk4 was found to be over expressed in colorectal cancers. Similar over expression in colorectal cancers is observed with Plk1. Expression of both Plk1 and Plk4 increased with the age of the patient, and interestingly, the expression profiles of Plk1 and Plk4 correlated with each other (Macmillan *et al.*, 2001).

Few interacting partners of Plk4 have been identified therefore it has been difficult to determine the function that Plk4 may play in the progression or suppression of oncogenesis. Like Plk1, Plk4 expression is transcriptionally repressed by a p53 mediated pathway (Li *et al.*, 2005). Although the characterization of this repression has yet to be characterized in response to DNA damage, it provides evidence that the functions of Plk4 may impact upon oncogenic properties. In contrast, heterozygous Plk4 MEFs display a phenotype typified by multiple centrosomes, multipolar spindles and mitotic failure (Ko *et al.*, 2005). This phenotype was similar to that observed following over expression of a catalytically inactive Plk4 mutant. The results suggest that reduced Plk4 activity can cause occasional cellular division failure as a result of aberrant centrosome duplication and subsequent mitotic spindle malformation. This cell division failure can lead to either aneuploidy or polyploidy, which could in turn contribute to the incidence of tumors in heterozygous mice (Habendanck *et al.*, 2005).

Experimental Approach

The use of microarrays is an established technique in the field of molecular biology which allows for the large-scale examining of the expression profiles of thousands of genes within a genome. Microarrays allow for the characterization of global expression patterns between a reference and one or multiple experimental conditions. The advent of microarray technology has provided researchers with an invaluable tool to elucidate the function of genes in cellular processes. For the purpose of my experimentation, microarray technology was employed to examine cellular variations of transcript levels based of Plk4 gene dosage in mouse embryonic fibroblasts.

Microarray employs the principle that a given cDNA molecule will bind to its complement on a DNA template from which it has originated (Southern *et al.*, 1999). Two types of microarrays technologies are being employed: oligonucleotides and spotted cDNA arrays. Oligonucleotides are short synthetic sequences of DNA often between twenty to sixty base pairs in length which are representative of a single gene or a family of gene splice variants (Lipshutz *et al.*, 1999). Spotted arrays or complementary DNA (cDNA) arrays contain expressed sequence tags (ESTs) which are small pieces of a DNA sequence generally between 200 to 500 nucleotides long in length that are generated by sequencing either one or both ends of an expressed gene (Duggan *et al.*, 1999). Oligo arrays differ from spotted arrays in the way they are manufactured. Oligonucleotide arrays are produced by printing short oligonucleotide sequences directly onto the array surface. Oligo arrays can be synthesized by photolithographic synthesis, where light and light-sensitive masking agents are used to build one nucleotide sequence at a time across an array surface. Spotted arrays probes are synthesized prior to deposition on the array surface and are then "spotted" onto glass. Spotted arrays are usually synthesized by means of a robotic arm, which contains an array of pins or needles which deposits DNA probes on the designated location on the array surface. For the purpose of the present study, cDNA microarrays were employed.

Spotted arrays are scanned *via* a microarray scanner at two wavelengths to produce images for data analysis: 532nm which causes excitation of the Cy3 fluor which emits a wavelength of 570nm in the green part of the visual spectrum and 635nm which causes the excitation of Cy5 which emits a wavelength of 670nm in the red part of the visual spectrum. Differences in gene expression between the reference and experimental

states are measured based on the visual intensities emitted by the Cy3 and Cy5 dyes which represent the amount of mRNA transcript per a specific gene that hybridized to the array. A visual representation of yellow represents equal hybridization of a gene for both the reference and experimental cDNA and therefore equal mRNA expression. While a predominantly red visualization represent that for a gene in the experimental condition, there were more mRNA transcripts present and therefore it was upregulated. A predominantly green visualization represents that the gene in the reference condition presented more mRNA transcripts present and is downregulated (Figure 4).

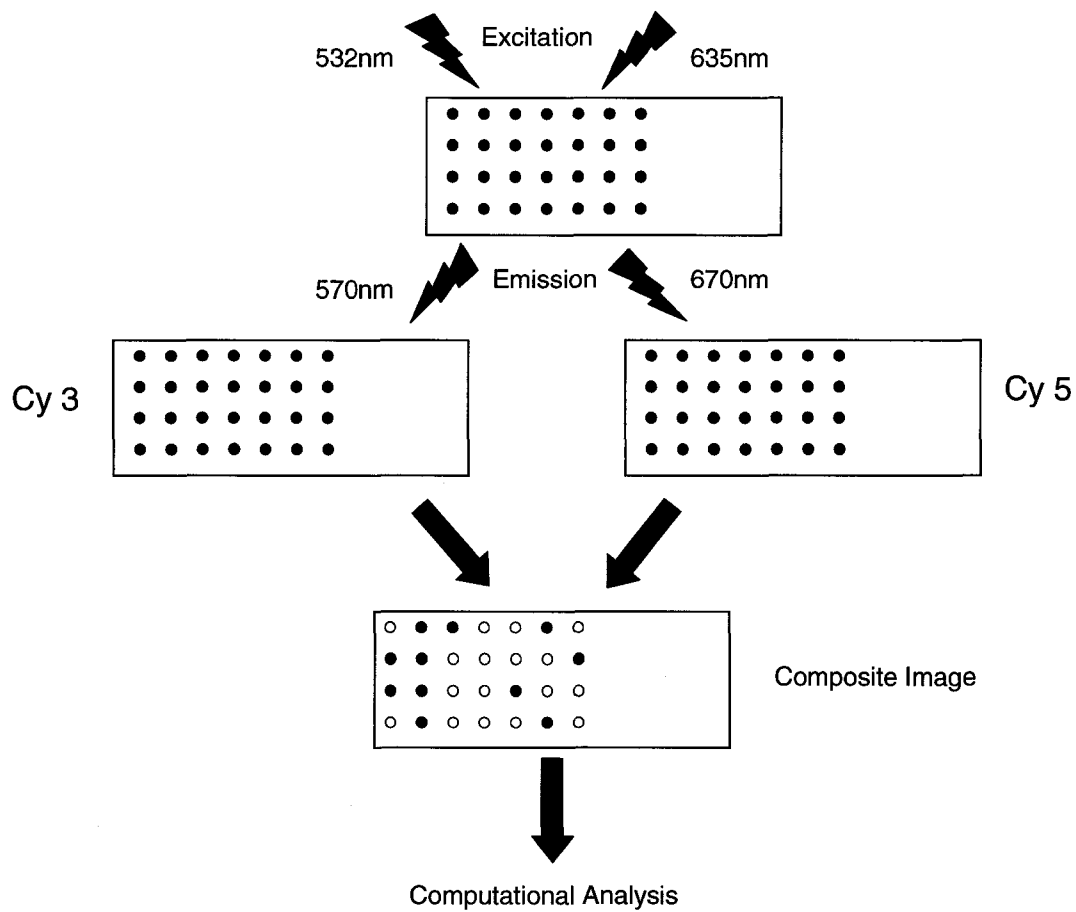

Figure 4: Composite View of Cy3 and Cy5 Labeled Microarray

The wild type Cy3 labeled cDNA is scanned at 532nm causing the Cy3 fluor to emit at 570nm, while the heterozygous Cy5 cDNA is scanned at 635nm causing an emission at 670nm. A composite image is produced by the Scanarray software using the Cy3 and Cy5 scanned images. A predominately green spot indicates increased transcript expression in wild type Plk4 MEFs, while a predominately red spot indicates increased transcript expression in heterozygous Plk4 MEFs. A yellow spot indicates equal transcript expression between wild type and heterozygous Plk4 MEFs.

Chapter 2

Objectives of the Study

Significant phenotypic differences are observed between wild type and heterozygous Plk4 mice and mouse embryonic fibroblasts (MEFs), although the exact mechanisms by which these phenotypic differences occurs has yet to be fully elucidated. The aim of this study was firstly, to provide a general survey of differences in the transcript profile between wild type and heterozygous MEFs using microarray technology. Secondly, Plk1, Plk2, and Plk3 have been implicated to play substantive roles in the cell cycle response to DNA damage. Hence, it is plausible that Plk4 also plays a significant role in the DNA damage pathways. Therefore, transcriptional and protein difference were examined in wild type and heterozygous MEFs in response to both ionizing and ultraviolet radiation.

Chapter 3

Materials and Methods

Establishment of Primary Mouse Embryonic Fibroblasts (MEFs)

Mouse embryonic fibroblast cell lines were established by sacrificing a pregnant female mouse 12.5 days post coitum by carbon dioxide (CO₂) asphyxiation. The uterine horns were removed and washed with 70% ethanol. Each embryo was separated from the placenta and placed in 1ml of Hanks Balanced Salt Solution (HBSS) (Sigma). The embryos were minced with a razor blade until they were pipettable. The resulting cell/tissue solution was suspended in 1ml 10X Trypsin (Sigma) and placed in an incubator at 37°C with 5% CO₂ for 15 minutes. 10ml of MEF media (Dulbecco's Modified Eagles Medium (DMEM; Sigma) containing 20% Fetal Bovine Serum (FBS; Sigma), 1% penicillin-streptomycin (Gibco) and 250 ug/ml gentamicin (Gibco)) were added to the MEF suspension and transferred to a 50 ml falcon tube. Tissue was allowed to settle to the bottom of the tube and the supernatant was transferred to a 15 ml falcon tube and subjected to centrifugation at 100 x g for five minutes. The supernatant was removed and the resulting pellet was suspended in 10 ml of MEF media and plated on a 10 cm tissue culture dish and placed in an incubator at 37°C with 5% CO₂.

When the MEFs reached confluency, they were washed once with HBSS, trypsinized with 1 ml 10X Trypsin (Sigma) for 5 min at room temperature, resuspended in fresh MEF media, pelleted by centrifugation at 100 x g for five minutes and split at a ratio of 1 to 10, with 200 ul kept for genotyping. MEFs were allowed to reach 80% confluency, and then were frozen down. Briefly, MEFs were washed once with HBSS, trypsinized with 1ml 10X Trypsin (Sigma) for 5 min at room temperature, resuspended in

fresh MEF media, pelleted by centrifugation at 100 x g for five minutes and resuspended in 1ml of cold MEF freezing media (MEF media containing 10% dimethyl sulfoxide (DMSO) (Sigma)). MEFs were kept at -80°C for 3 days and then transferred to liquid nitrogen for long term storage.

MEF Genotyping

Isolation of DNA from MEFs was performed by adding 620 ul Proteinase K buffer (50mM Tris, 100mM EDTA, 100mM NaCl, 1% SDS) and 30 ul of 20 mg/ml Proteinase K (Roche). The solution was placed in a 55°C water bath overnight. A 1:1 ratio of water saturated phenol (Sigma) and chloroform (Sigma) was added and the solution was placed on a Nutator Mixer (Becton-Dickinson) for 1hr. The solution was centrifuged in a table top microcentrifuge (Jouan) at 4000 x g for 10 min. The aqueous phase of the resulting mixture was transferred to an eppendorf tube containing 650 ul of isopropanol and centrifuged at 4000 x g to pellet the DNA. The DNA was washed with 70% ethanol and resuspended in 100 ul of deionized water.

PCR genotyping established whether the MEFs were Plk4 wild type or heterozygous. Primers F25 (5'-GCCCCCACTAAGACGAC-3') and VEC523 (5'-AGCTGGGGCTCGACTAG-3') amplified a wild type band at 316bp while primers F25 and PR436 (5'-TGCTAGTAAATAATCCGACAGG-3') amplified a mutant band at 403bp (Hudson *et al.*, 2001).

RNA Isolation

RNA isolation was performed using the RNeasy Mini Kit (Qiagen). Briefly, MEF cells were grown asynchronously to a confluency of 80% and washed twice with HBSS (Sigma) before trypsinization with 10X Trypsin (Sigma). Cells were then pelleted at 100 x g for 5 min in a 15ml falcon tube and washed twice with HBSS in the falcon tube and spun at 100 x g for 3 min. After the second HBSS wash, cells were lysed with the addition of 600 ul lysis buffer and the lysates were homogenized with a Qias shredder (Qiagen) spin column and spun in a microcentrifuge (Juoan) at 4000 x g for 2 mins. 75% ethanol was added to the homogenized lysate to precipitate the total RNA. The solution was placed in an RNeasy Mini Column where the RNA was bound to the column. The RNA was washed three times in the column to get rid of any contaminants and then eluted with Diethyl Pyrocarbonate (DEPC) water. A spectrophotometer reading at A_{260} was performed to estimate the concentration of the RNA. To confirm the integrity and quality of the RNA, a sample was run on the 2100 Bioanalyzer (Agilent) using the RNA 6000 Nano Assay Kit. The RNA was flash frozen in liquid nitrogen and placed in the -80°C freezer until ready for use.

Microarray

Three plates of either wild type or heterozygous MEFs were pooled for RNA isolation as described. RNA was sent to the University Health Network (UHN) Microarray Centre in Toronto where the microarray experiments were performed. The samples were labeled using the UHN's standard indirect labeling protocol. Briefly, 10

micrograms of total RNA sample was used and following reverse transcription to cDNA labeled with Cyanine dyes Cy3 and Cy5 (Amersham Bioscience). Wild type Plk4 cDNA was labeled with Cy3 while heterozygous Plk4 cDNA labeled with Cy5. The labeled samples were hybridized to a Mouse 22.4K microarray chip containing 22 400 features. Hybridization was performed on an Advantix Slidebooster (Advantix) using DIG easy hybridization solution. The arrays were scanned using an Agilent G2565BA scanner and quantified using ArrayVision v.8.0 (Imaging Research Inc.).

Synthesis of Complementary DNA (cDNA)

RNA isolation was performed by the method stated previously. The quality of the RNA was examined using the bioanalyzer with the RNA used for reverse transcription if the RNA integrity number was greater than 8.0. Reverse transcription (RT) was performed to convert the total RNA isolated from the MEFs into cDNA. Complementary DNA was synthesized using 5 ug of total RNA, 1ul 0.5ug/ul oligo (dT)₁₂₋₁₈ primer (Invitrogen), 1ul 10mM dNTPs (Invitrogen) to a volume of 12ul with DEPC water. The mixture was incubated at 65°C for five minutes in a heating block and then placed on ice for 2 minute. 4ul of 5X First-Strand Reaction Mix (Invitrogen) and 2ul 0.1M dithiothreitol (DTT) of were added to the mixture and incubated in a heating block at 42°C for 2 minutes. 1 ul of Superscript II Reverse Transcriptase was added and the reaction was incubated at 42°C for 50 minutes for first strand synthesis. The reaction was terminated by incubating the mixture in a heating block at 70° for 15 minutes. The cDNA was stored at -20°C until use.

Polymerase Chain Reaction (PCR)

i) Plk4

All forward and reverse primers for PCR were designed to span intron/exon boundaries to prevent amplification of contaminating genomic DNA in the cDNA mixture. The primers for Plk4 (5'-AGGGAAGCTAGGCACTTCATG-3'; 5'-GGAAGACCACCTTTTGAC-3') yielded a PCR product of 310 bp. PCR was performed in a 20 ul reaction mixture containing 2 ul of cDNA template, 2.5 ul of 10X PCR buffer, 4.625mM MgCl₂, .5mM of dNTPs, 1 ul each of forward and reverse primers and 2.5 U of Hot Star Taq DNA Polymerase (Qiagen). PCR was performed using a Tpersonal (Biometra) programmable thermal cycler as follows: denaturation at 95°C for 15 minutes, then 38 to 42 cycles of denaturation at 94°C for 30 seconds, annealing at 48°C for 30 seconds and extension at 72°C for 60 seconds. Completed PCR reactions were cooled to 4°C and aliquots resolved by electrophoresis on a 2% tris-acetate-EDTA (TAE) agarose gel at 85 V for 85 minutes and visualized by ethidium bromide staining. Gels were imaged using a Chemi Genius Bio Imaging System (Perkin Elmer) using the Gene Snap software. All PCR products were run and imaged using the same methodology and equipment.

ii) Glyceraldehyde 3-phosphate dehydrogenase (GAPDH)

Oligonucleotide primers for GAPDH (5'-GCTGAGTATGTCGTGGAGTCT-3'; 5'-CAGAGCTGAACGGGAAGCTC-3') yielded a product of 410 bp. PCR was performed in a 20 ul reaction mixture containing 1 ul of cDNA template, 2.5 ul of 10X PCR buffer, 4.625mM MgCl₂, .5mM of dNTPs, .5 ul each of forward and reverse primers

and 1 U of Hot Star Taq DNA Polymerase (Qiagen). PCR was performed using a programmable thermal cycler as follows: denaturation at 95°C for 15 minutes, then 28 to 32 cycles of denaturation at 94°C for 30 seconds, annealing at 57°C for 40 seconds and extension at 72°C for 40 seconds. PCR reactions were cooled to 4°C and aliquots resolved on a 2% agarose gel.

iii) Prohibitin

The primers for prohibitin (5'-CGTATCTACACCAGCATTGGC-3'; 5'-TGTGGTGGAAAAGGCTGAGC-3') yielded a product of 301 bp. PCR was performed in a 20 ul reaction mixture containing 2 ul of cDNA template, 2.5 ul of 10X PCR buffer, 2.0mM MgCl₂, .5mM of dNTPs, .75 ul each of forward and reverse primers and 2.5U of Hot Star Taq DNA Polymerase (Qiagen). PCR was performed using a programmable thermal cycler as follows: denaturation at 95°C for 15 minutes, then 32 to 36 cycles of denaturation at 94°C for 30 seconds, annealing at 55°C for 30 seconds and extension at 72° for 30 seconds. PCR reactions were cooled to 4°C and aliquots resolved on a 2% agarose gel.

iv) SAP30 Binding Protein (SAP30BP)

The primers for SAP30BP (5'-CCAGAAGCTCTACGAGCGGAA-3'; 5'-TGGTCTGAAGACTCCTACTATGAG-3') yielded a product of 190 bp. PCR was performed in a 20 ul reaction mixture containing 2 ul of cDNA template, 2.5 ul of 10X PCR buffer, 2.75mM MgCl₂, .5mM of dNTPs, 1 ul each of forward and reverse primers and 2.5 U of Hot Star Taq DNA Polymerase (Qiagen). PCR was performed using a

programmable thermal cycler as follows: denaturation at 95°C for 15 minutes, then 38 to 42 cycles of denaturation at 94°C for 30 seconds, annealing at 57°C for 30 seconds and extension at 72°C for 30 seconds. PCR reactions were cooled to 4°C and aliquots resolved on a 2% agarose gel. .

v) WNT-Inducible Signaling Pathway Protein 1 (Wisp1)

The primers for Wisp1 (5'-GCCTAATCACAGATGGCTGTG-3'; 5'-CAATAGGAGTGTGTGCACAGGTG-3') yielded a product of 150 bp. PCR was performed in a 20 ul reaction mixture containing 2 ul of cDNA template, 2.5 ul of 10X PCR buffer, 1.5mM MgCl₂, .5mM of dNTPs, 1ul each of forward and reverse primers and 2.5U of Hot Star Taq DNA Polymerase (Qiagen). PCR was performed using a programmable thermal cycler as follows: denaturation at 95°C for 15 minutes, then 36 to 40 cycles of denaturation at 94°C for 60 seconds, annealing at 54°C for 60 seconds and extension at 72°C for 60 seconds. PCR reactions were cooled to 4°C and aliquots resolved on a 2% agarose gel.

Densitometry

Densitometry was performed using the Gene Tools software from Perkin Elmer. Briefly, the program identified the correct gel lanes associated with the samples run using an algorithm. Subsequently, any unwanted lanes were deleted. Next, using a predetermined algorithm, the computer identified bands on the gel and was allowed to assign intensity values for the bands to eliminate any bias. Unwanted bands not necessary for analysis were removed.

TdT-Mediated dUTP Nick-End Labeling (TUNEL) Assay

Wild type and heterozygous MEFs were plated on glass coverslips at 70% confluency in six well plates. MEFs were exposed to 40 mJ/cm² ultraviolet radiation. MEF media was removed and the cells were washed twice with 1X phosphate buffer saline (PBS). Cells were fixed in 4% paraformaldehyde in PBS at 4°C, 0hr, 1hr, 2hr, 4hr, 6hr, and 8hr post radiation. Cells were permeabilized in 0.2% Triton X-100 (Sigma) in PBS and washed twice in 1X PBS. Cells were equilibrated in Equilibration buffer for 10 minutes at room temperature. Equilibration buffer was removed and the cells were incubated with rTdT incubation buffer (88% equilibration buffer, 10% nucleotide mix, 2% rTdT enzyme) for 60 minutes at 37°C in the dark to label apoptotic cells with fluorescein-12-dUTP. Cells were washed with 2X Sodium Salt Citrate (SCC) (20X SCC in deionized water) 15 minutes at room temperature to terminate the labeling reaction. Cells were washed three times with 1X PBS at room temperature for 5 minutes. Cells were stained with 5µg/ml of propidium iodide (PI) in 1X PBS to stain the nuclei of the cells. Subsequently, cells were washed three times with deionized water. Excess water was removed from the cover slips, one drop of Anti-Fade solution (Molecular Probes) was added and the cover slips were mounted on glass slides. Cells were viewed at high magnification at red fluorescence at 620 nm for propidium iodide and green fluorescence at 520 nm for fluorescein-12-dUTP. 200 cells per slide were counted to analyze the number of apoptotic cells and three trials were performed. DNase I was used as a positive control to induce DNA fragmentation indicative of apoptosis.

Exposure of MEFs to DNA Damaging Agents

Wild type and heterozygous MEFs were exposed to ultraviolet light (UV) at 40 mJ/cm² using a GS Gene Linker UV Chamber (Biorad) or ionizing radiation (IR) of 25 Gy using a RX-650 Cabinet X-ray System (Faxitron) and RNA was isolated from the MEFs at desired time points.

SDS-PAGE

MEFs were exposed to either ultraviolet or ionizing radiation and then lysed 6 hours post radiation. Cells were lysed with 1ml lysis buffer (50 mM Tris-Cl, 100 mM NaCl, 500 mM EDTA, 1% Triton-X) on ice for 20 min. Lysates were spun in a microcentrifuge at 4000 x g for 20 min at 4°C to remove cellular debris. A Bradford assay was performed to find out protein concentration. 2X loading dye containing 5% β-mercaptoethanol was added to 30 ug of lysates, and the samples were boiled for 5 min. The lysates were loaded onto either an 8% or 15% protein gel and subjected to SDS-PAGE for 48 minutes at 200V.

Western Blot Analysis

After SDS-PAGE, the proteins were transferred onto a PVDF membrane (Millipore) using a semi-dry transfer apparatus (Biorad) at 12V for 45 minutes. The membrane was then blocked with Tris-buffer saline and Tween (TBST) buffer with 1% blotto to block non-specific protein binding for 1hour at room temperature with gentle agitation. The membrane was washed three times with TBST for 5 minutes at room temperature. The membrane was then incubated with the desired primary antibody

(Appendix A) in TBST with 1% blotto for 1 hour at room temperature; then washed three times with TBST for 5 minutes. The membrane was incubated with the appropriate horseradish peroxidase secondary antibody (Appendix A) in TBST with 1% blotto for 45 minutes at room temperature; then again washed three times with TBST for 5 minutes. 1 ml of Supersignal West Femto Maximum Sensitivity Substrate (Pierce) was added to the membrane and the reaction between the horseradish peroxidase and its substrate was allowed to occur for 5 minutes. The proteins were then visualized by chemiluminescence.

Stripping of Western Blots for Re-probing

Stripping of Western blots was used to remove any bound primary and secondary from the blot so that other primary antibodies could be tested. Stripping buffer (100 mM β -mercaptoethanol, 2% SDS, 62.5 mM Tris-Cl at pH 6.7) was prewarmed to 50°C and added to the blot for 25 minutes at 50°C with gentle agitation. The stripping buffer was removed and the blot was incubated with prewarmed TBST for 25 minutes at 50°C. The blot was washed with water and then incubated with the desired primary antibody.

Chapter 4

Results

Comparison between Transcript Profiles in Wild Type and Heterozygous Plk4 MEFs using Microarray.

A number of phenotypic differences have been observed between wild type and heterozygous Plk4 MEFs including that heterozygous MEFs exhibit a growth rate approaching $\frac{1}{2}$ that of their wild type counterparts (Ko *et al.*, 2005). In addition, heterozygous MEFs present an increase in the number of cells with multiple centrosomes which have the potential to lead to abnormal chromosome alignment and segregation (Ko *et al.*, 2005). These abnormalities have been proposed as a mechanism that leads to genomic instability and the observed increase incidence of tumor development in aged heterozygous Plk4 mice in comparison to the wild types. Therefore, it was of interest to study the effect of lower Plk4 levels on the expression pattern of other genes. We measured the global transcriptional differences between wild type and heterozygous MEFs using microarray technology using RNA samples isolated from both Plk4 wild type and heterozygous MEFs using three microarray replicates were performed. The experiments were performed at the University Health Network (UHN) Microarray facility using Mouse 22.4k cDNA arrays using an indirect labeling methodology. Scanned TIFF images of both the Cy3-labeled and Cy5-labeled were received from UHN and analysis was performed.

Quantification of results was performed using ScanArray Express v.3.0 (Perkin Elmer). Cy3-labeled and Cy-5 labeled images were loaded on the ScanArray Express Software producing a composite image of the array (Figure 5). A QuantArray microarray

gene annotation file was obtained from the University Health Network (UHN) Microarray Centre website indicating the identification of each spot on the array (<http://www.microarrays.ca/products/glists.html>). Using the template obtained from the gene list, a grid overlay was designed of the microarray spots and was aligned with the scanned image. Quantification was performed by the ScanArray Express software to measure the intensity of the hybridization of both the Cy3 and Cy5 labeled samples to its complement on the chip. Locally Weighted Scatter Plot Smoother (LOWESS) normalization was performed to account for any intensity dependent effects that may occur when differences in log ratio values are observed (Quackenbush, 2001). The resulting quantification and normalization of the data produced a data file that allowed transfer to “The Institute for Genomic Research” (TIGR) TM4 microarray data analysis suite for further analysis. Further normalization and filtering of the data was performed using the TIGR Microarray Data Analysis System (MIDAS) application. Analysis of all microarray data sets for the different microarray experiments (ex. Wild type Plk4 MEFs vs Heterozygous Plk4 MEFs) were performed independently. Initial filtering of the data was performed. Spots were removed from downstream analysis if an intensity value for either the Cy3-labeled or Cy5-labeled spot were invalid (an intensity less than 1). Next, flag filtering was performed to remove invalid spots from further analysis. For example, if the Cy-3 or Cy5 samples had an intensity of 0 non-saturated pixels within a spot, the spot was removed. Subsequently, background filtering was employed. If the background-corrected intensity of a spot was greater than or equal to the background intensity for both the Cy3 and Cy5 labeled samples than the spot was kept in the data set for further downstream analysis.

Figure 5: Composite View of Cy3 and Cy5 Labeled Microarray

The wild type Cy3 labeled cDNA was scanned at 532nm causing the Cy3 fluor to emit at 570nm, while the heterozygous Cy5 cDNA was scanned at 635nm causing an emission at 670nm. A composite image was produced by the Scanarray software using the Cy3 and Cy5 scanned images. 1) A predominately green spot indicated increased transcript abundance in wild type Plk4 MEFs, 2) while a predominately red spot indicated increased transcript abundance in heterozygous Plk4 MEFs. 3) A yellow spot indicated equal transcript levels between wild type and heterozygous Plk4 MEFs

Locfit (LOWESS) normalization was performed with specific parameters set. Block LOWESS normalization was applied to the data set meaning that only spots within a certain block or grid on the microarray chip contribute to the bias of the spots intensity. A smoothing parameter was established at 33 percent to compute the normalization of each spot using the LOWESS algorithm. These computations were performed by MIDAS with the input that the Cy3 labeled sample (wild type MEFs) was the reference or the control and the Cy5 labeled sample (heterozygous MEFs) was the experimental value. Next, standard deviation regularization parameters were established ensuring that all spots within each block or grid of the microarray chip have the same standard deviation with the Cy3 labeled sample being the reference. Spots were then filtered from the further analysis based on the raw intensity of the hybridization. The cutoff raw intensity was set at 10000 with any spots with intensity lower than this threshold removed from any further analysis.

The normalized and filtered data set was loaded into TIGR Multiexperiment Viewer (MEV) for clustering analysis. For clustering, the filtered data from all three chips was loaded into MEV simultaneously for clustering to occur. The data set was clustered using K-Means clustering. K-means clustering divides the filtered data into clusters based on the principle that genes within a cluster are closely related. Genes were divided into ten different clusters. Within each cluster, genes having a log ratio value greater than 1 or less than -1 on each microarray chip were identified. Genes having a log ratio greater than 1 represented genes in the heterozygous MEFs that have at least a two fold increase in gene expression. As the wild type MEFs was used as the control, genes with a log ratio greater than 1 were classified as up-regulated in the heterozygous MEFs.

While, a log ratio less than -1 represented genes in the wild type MEFs that have at least a two fold increase in gene expression or are down-regulated in the heterozygous MEFs.

From the microarray data, 9 genes were identified as having at least a two fold decrease in transcript profile in the heterozygous MEFs or were down-regulated in the heterozygous MEFs when compared to the wild-type control (Table 1) (Appendix J), while 146 genes were identified as having at least a two fold increase in transcript profile in the heterozygous MEFs (Table 2) (Appendix K). Cellular function for each gene was identified using annotation data from the Pubmed database or the Online Mendelian Inheritance in Man (OMIM) database.

Confirmation of Microarray Results Using RT-PCR

To confirm the validity of the microarray results, qualitative RT-PCR was employed. Three genes classified as having increased transcript profiles in the heterozygous MEFs were examined: Wnt1 inducible signaling pathway protein 1 (Wisp1), Sap30 Binding Protein (SAP30BP), Prohibitin (PHB).

a) Wisp1 Expression in Heterozygous Plk4 MEFs

Wisp1 over expression has been implicated in cellular morphological transformation (Xu *et al.*, 2000) as well as and tumor formation in hepatocellular carcinomas (Cervello *et al.*, 2004). In addition, over expression of other Wnt pathway proteins have also been implicated in tumor formation. I speculate that over expression of Wisp1 and other Wnt pathway proteins could contribute to tumor formation in heterozygous Plk4 mice. To confirm the validity of the microarray results, RT-PCR was

performed to compare *Wisp1* expression rates in wild type and heterozygous *Plk4* MEFs, and subsequently densitometry was performed to measure the quantitative differences. RNA was isolated from both wild type and heterozygous MEFs and a reverse transcription reaction was performed to produce first strand cDNA. PCR primers for *Wisp1* were designed to amplify a product of 150 base pair, while PCR primers for glyceraldehyde 3-phosphate dehydrogenase (GAPDH), amplified a product 410 base pairs in length and was used as an internal loading control. PCR products amplified from cDNA taken at three time points for both *Wisp1* and GAPDH, were performed and terminated the PCR in the linear part of the PCR amplification curve. The PCR products were resolved on a 2% agarose gel to view their difference in relative abundance in the wild type and heterozygous MEFs (Figure 6a).

Densitometry was performed using the Gene Tools software. Intensity values were assigned to the bands for *Wisp1* and GAPDH by the software to eliminate any bias. To determine the relative expression of *Wisp1* in the heterozygous MEFs compared to wild type, first the ratio of the value for *Wisp1* to GAPDH was taken for each individual time point. Next, the ratio of GAPDH to *Wisp1* was determined for the wild type time points. The ratio of *Wisp1* to GAPDH for the heterozygous time points was multiplied by the ratio of GAPDH to *Wisp1* to determine the relative expression of *Wisp1* in the heterozygous MEFs to the *Wisp1* in the wild type MEFs (Appendix B). Densitometry was performed for three individual trials of RT-PCR for *Wisp1*. The relative expression for *Wisp1* over the three trials was calculated along with the standard error of the mean. For the three trials of *Wisp1*, the average change in expression of *Wisp1* over the three PCR time points was between 1.36 and 1.48 times greater level of transcriptional

Table 1: Down-regulated Genes in Heterozygous Plk4 MEFs

Developmental

Procollagen, type III, alpha 1

Procollagen, type V, alpha 2

Oral-facial-digital syndrome 1 gene homolog

Procollagen, type I, alpha 2

Metabolism

Stearoyl-Coenzyme A desaturase 2

Unknown Function

Mus musculus mVL30-1 retroelement mRNA sequence

Transmembrane protein 34

Mus musculus 0 day neonate cerebellum cDNA

Hypothetical protein LOC639390

Table 2: Up-regulated Genes in the Heterozygous Plk4 MEFs

Cell Cycle	Developmental
Casein kinase II	Sal-like 3
Protein phosphatase 1F (PP2C domain containing)	Transducin-like enhancer of split 1
Squamous cell carcinoma antigen recognized by T-cells 1	T-cell factor 4
Origin recognition complex, subunit 4-like	Inositol 1,4,5-triphosphate receptor 5
Inhibitor of DNA binding 2	Procollagen, type VI, alpha 3
Protein phosphatase 5	Fetal Alzheimer antigen
Prohibitin	WNT1 inducible signaling pathway protein 1
Cyclin dependent kinase 8	T-box transcription factor Tbx15
Phosphatidylinositol 3-kinase	Nuclear factor I/X
Pituitary tumor-transforming 1	Thrombospondin 2
Heterogeneous nuclear ribonucleoprotein C	Osteopontin
heme binding protein 2	Fukuyama type congenital muscular dystrophy homolog
TVMSFG fibroblast growth factor receptor 1 precursor	Nuclear receptor co-repressor 1
Neuropilin	
	DNA Repair
DNA Methylation	Thymine DNA glycosylase
SET domain ERG-associated histone methyltransferase	Uracil-DNA glycosylase
SAP30 binding protein	MutS homolog 6

Table 2: Up-regulated Genes in the Heterozygous MEFs

Metabolism	Cellular/Ion Transport
N-acylsphingosine amidohydrolase (acid ceramidase) like	Protein kinase, cAMP dependent regulatory, type I beta
Leucyl/cystinyl aminopeptidase	Pleckstrin
Galactose-4-epimerase	Calcium binding and coiled coil domain 1
L-2-hydroxyglutarate dehydrogenase	Aquaporin-1
Fatty acid desaturase 3	Solute carrier family 6
Carbohydrate sulfotransferase 2	Exocyst complex component 3
Stearoyl-Coenzyme A desaturase 1	Protein-coupled receptor 19
CCR4 carbon catabolite repression like 4	Solute carrier family 39

expression in the heterozygous Plk4 MEFs than in the wild type (Figure 6b). The average log ratio from the three microarray chips for *Wisp1* was 1.64 corresponding to an average 3.28 change increase in expression for *Wisp1* in the heterozygous MEFs. Though the change in expression appears to differ substantially from the microarray data to the RT-PCR data, differences are most likely attributed to the fact that the MEFs used for the microarray experiments were different MEFs than the MEFs used for the RT-PCR experiments.

b) SAP30-Binding Protein Expression in Heterozygous Plk4 MEFs

Preliminary data shows that methylation of the *Plk4* gene in heterozygous mice occurs at a substantially higher rate than in wild type mice. Therefore, it is hypothesized that the transcriptional repression of *Plk4* in heterozygous mice contributes to the increased incidence of tumorigenesis within these mice. Since SAP30BP binds SAP30 (Li *et al.*, 2004), a component of the SIN3 histone deacetylase complex, it is plausible that the increased methylation status of *Plk4* heterozygous mice could be contributed to a complex that includes SAP30BP.

RNA was isolated from both wild type and heterozygous *Plk4* MEFs and a reverse transcription reaction was performed to produce cDNA. PCR primers for SAP30BP amplified a product of 190 base pairs, while GAPDH, used as an internal loading control amplified a product of 410 base pairs. PCR products were run at three time points for both SAP30BP and GAPDH, while amplification was in the linear part of the PCR amplification curve except for cycle 42 for SAP30BP which became saturated. PCR products were run on a 2% agarose gel to view the differences in the transcript

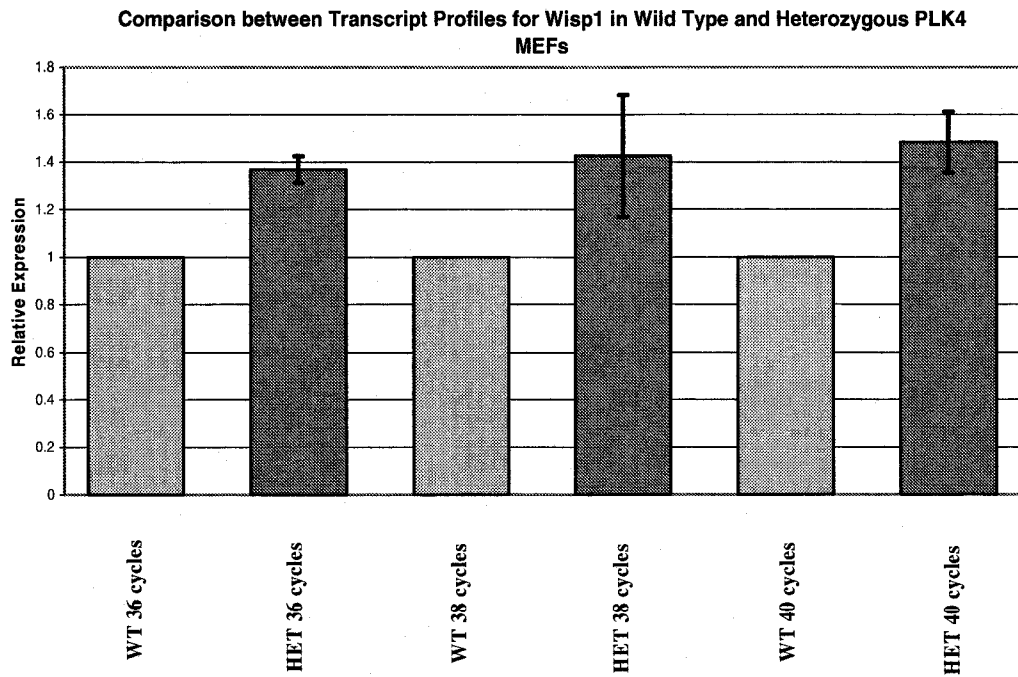

Figure 6: Wisp1 Transcript Expression in Heterozygous Plk4 MEFs

a) RT-PCR was performed over three PCR time points to measure the relative quantitative difference in the transcript expression of Wisp1 in wild type and heterozygous Plk4 MEFs. GAPDH was used as an internal loading control. b) Densitometry was performed to measure the raw intensity of each band. Values for Wisp1 were normalized to GAPDH and the relative mean expression over three PCR trials was graphed. The average increase in transcript expression for Wisp1 in heterozygous Plk4 MEFs was between 1.36 to 1.48 greater than in wild type Plk4 MEFs. (NB WT: Wild Type; HET: Heterozygous)

A

B

Wisp1 Transcript Profile in Wild Type & Heterozygous MEFs over Three PCR cycles

profiles of SAP30BP in wild type and heterozygous Plk4 MEFs (Figure 7a).

Densitometry was used to quantify the differences in transcript expression of SAP30BP. The same rationale was used to determine the relative expression of SAP30BP in the heterozygous MEFs compared to the wild type MEFs as with *Wisp1*. The ratio of SAP30BP to GAPDH was determined for both wild type and heterozygous SAP30 at the three different PCR time points. Next, in the wild types, the ratio of GAPDH to SAP30BP was determined. This value was multiplied with the SAP30BP to GAPDH value for heterozygous SAP30 to get the relative expression in relation to wild type SAP30BP (Appendix C). Densitometry was performed on three individual RT-PCR trials for SAP30BP. The average relative expression and standard average of the mean was calculated for the three RT-PCR trials. For the three trials of SAP30BP, the average change in expression of SAP30BP over the three PCR time points was between 1.36 and 1.81 times greater level of transcriptional expression in the heterozygous Plk4 MEFs than in the wild type (Figure 7b). The average log ratio for the three microarray chips was 1.49 corresponding to an average increase in expression of 2.98 in the heterozygous Plk4 MEFs. Similar to *Wisp1*, MEFs from different embryos were used for both the microarray and the RT-PCR experiments. These differences possibly could contribute to the variation in change of expression between the microarray and the RT-PCR. Also, the relative expression of SAP30BP decreases in the heterozygous MEFs over the three PCR time points due to a result that the PCR product was becoming saturated, and therefore not in the linear part of the PCR product amplification curve.

c) Prohibitin Expression in Heterozygous Plk4 MEFs

Prohibitin (PHB) has been implicated to play a role in cellular senescence (Rastogi *et al.*, 2006). Since mouse embryonic fibroblasts are primary cell lines, they eventually stop dividing and take a senescent phenotype of flattened morphology and increased granularity. In heterozygous Plk4 MEFs, the senescent phenotype is observed at an earlier passage than in the wild types. Therefore, it is plausible that increased prohibitin expression in heterozygous Plk4 MEFs contributes to this observed earlier senescent phenotype.

RNA was isolated from both wild type and heterozygous Plk4 MEFs and a reverse transcription reaction was performed to produce cDNA. PCR primers for PHB multiplied by the ratio of PHB to GAPDH for the heterozygous time points to determine the relative expression of PHB in the heterozygous Plk4 MEFs to the wild type MEFs (Appendix D). Densitometry was performed for three individual PCR experiments and the average of the relative expression and standard error of the mean were calculated. Over three PCR trials, the average mean transcript expression of prohibitin in heterozygous MEFs was between 1.83 and 2.37 times greater than in the wild type Plk4 MEFs (Figure 8b). The average log ratio for the three microarray experiments for prohibitin was 1.52 corresponding to an increase in transcript expression of 3.04 times greater in the heterozygous MEFs. Similar to *Wisp1* and *Sap30BP*, MEFs from different mice were used for the RT-PCR experiments than for the microarray, possibly explaining a reason for the variance in the results.

The Effect of Ionizing and Ultraviolet Radiation on the Plk4 Transcript Profile in MEFs

Though it is not yet known whether Plk4 plays a crucial role in response to DNA damaging agents, Plk4 has shown to interact with crucial DNA damage proteins including p53 (Swallow *et al.*, 2005), Cdc25c (Bonni *et al.*, 2008), ATM, ATR, Chk1 and Chk2 (Hudson *et al.*, unpublished data). Subsequently, it was of interest to analyze the effect of DNA damaging agents on the transcript profile of Plk4, and whether there exist a difference in transcript expression between wild type and heterozygous MEFs.

Wild type and heterozygous MEFs were exposed to 25 Gy IR or 40 mJ/cm² UV. RNA was isolated at various time points and RT-PCR was performed to visualize if there were differences in transcript expression. PCR primers for Plk4 amplified a PCR product of 310 base pairs, while GAPDH, used as an internal loading control amplified a product 410 base pairs. PCR products were amplified at three time points in the linear range of the PCR amplification curve. PCR products were run on a 2% agarose gel to visualize differences between the wild type and heterozygous Plk4 MEFs in response, first to IR then to UV.

Densitometry was performed to quantitate the transcriptional difference between wild type and heterozygous Plk4 MEFs. The control with no exposure was used as a base line with the subsequent time points normalized back to it. Densitometry for both wild type and heterozygous samples was done separately and differences were visualized using a graph. Briefly, for each time point post exposure to DNA damage, and each PCR cycle time point, a ratio of Plk4 to GAPDH was determined. Then for the control with no exposure, a ratio of GAPDH to Plk4 was determined. The relative expression was

determined by multiplying the Plk4 to GAPDH ratio for time points post exposure to the ratio of GAPDH to Plk4. Densitometry was performed for three individual PCR reactions. The average relative expression was determined along with the standard error of the mean. Subsequently, the values for the heterozygous MEFs were normalized back to the wild type MEFs as RNA levels in the wild type MEFs are expressed twice as much as in heterozygous MEFs (Swallow *et al.*, 2005).

In response to IR, the Plk4 transcript profile of the wild type MEFs stays constant until one hour post exposure when levels declined to between 60-70% relative to the control. These levels continue to remain at this decreased level 24 hours post irradiation (Figure 9a) (Appendix E). Similarly, for the heterozygous MEFs in response to IR, the Plk4 transcript profile remains constant till one hour post exposure, until a similar decline in transcript expression is observed. Between 2 and 24 hours post irradiation, the Plk4 transcript levels were between 60-70% relative to the control (Figure 9b) (Appendix F). When a comparison between wild type and heterozygous MEFs at the first PCR time point is observed, there is no comparable difference between Plk4 transcript profiles (Figure 9c). When a comparison of the Plk4 transcript profile at the second PCR time point is examined, the differences in transcript profile 2 hours post exposure for both the wild type and heterozygous MEFs is 70-90% relative to the control (Figure 9d). At the third PCR time point, observable differences between wild type and heterozygous transcript profile appear (Figure 9e). The difference for the heterozygous MEFs for all time points is within the standard error relative to the control. This is most likely due to the PCR amplification being in the non-linear part of the amplification curve. Subsequent differences are noticed between wild type and heterozygous transcript profile. At one

Figure 9: Effect of Ionizing Radiation on the Transcript Profile of Plk4 in Wild Type and Heterozygous MEFs

Wild type and heterozygous MEFs were exposed to 25 Gy ionizing radiation (IR), and RNA was isolated at various time points post exposure. RT-PCR was performed to measure the relative quantitative difference in Plk4 expression after exposure in both wild type and heterozygous MEFs. GAPDH was used as an internal loading control. PCR cycles for GAPDH were 28, 30, 32 cycles while for Plk4 38, 40, 42 cycles. Within each time post IR exposure, PCR products over three PCR cycles is shown corresponding to the number of cycles for GAPDH and Plk4 a) For wild type MEFs, in response to IR, Plk4 transcript levels remain constant until 1hr post radiation when a reduction in levels is observed to between 60-70% relative to the control. b) Similarly, for heterozygous MEFs, Plk4 transcript levels remained constant until 1hr post radiation when a decrease to 60-70% relative to the control was observed. c) Densitometry was performed to measure the raw intensity for each band. Values for Plk4 were normalized to GAPDH, and subsequently values for the heterozygous MEFs were normalized to the wild type to determine the mean relative expression over the three PCR time points. For the first PCR time point, there is no comparable difference between the wild type and heterozygous Plk4 transcript levels. d) At the second PCR time point, the difference in transcript levels between wild type and heterozygous is minimal. e) At the third PCR time point, differences are apparent between the transcript profiles of Plk4 in wild type and heterozygous MEFs. hour to 24 hours post exposure to IR, the transcript profile is 70-90% relative to the control. Most likely, in correlation with the first PCR time point, levels of Plk4 for both the wild type and heterozygous MEFs drop to around 70% relative to the control.

Upon exposure to UV, there is a striking difference in transcript profile levels of Plk4 between wild type and heterozygous MEFs. In the wild types, upon exposure to UV, levels of Plk4 are undetectable. At 2 hours post UV exposure levels reappear to the level of the control, then increase to 40% greater expression than is observed in the control (Figure 10a) (Appendix G). Unfortunately, at a dosage of 40 mJ/cm², the majority of cells undergo apoptosis, so levels of Plk4 at 24 hours were unable to be determined. In contrast, upon exposure to UV, no levels of Plk4 were detected in the heterozygous MEFs at any time (Figure 10b) (Appendix H). Similarly, to the wild type MEFs, the heterozygous MEFs undergo apoptosis prior to 24 hours post exposure. The results for the wild type and heterozygous Plk4 transcript profiles are consistent across all three PCR time points (Figure 10c,d,e). In the heterozygous MEFs in response to UV, the levels of Plk4 are undetectable. Therefore, it is plausible that since there is only one dose of the Plk4 gene in heterozygous MEFs, that Plk4 is transcribed at such low levels that it is undetectable by the conditions of PCR that were run. Since levels of wild type Plk4 increased relative to the control 4 to 8 hours post UV exposure, it could be hypothesized that Plk4 plays a dispensable role in apoptosis.

The Effect of Ionizing and Ultraviolet Radiation on Plk4 Protein Levels in MEFs

As RNA transcript levels do not necessarily correlate with protein levels, Plk4 protein levels in wild type and heterozygous MEFs were examined to determine if there

Figure 10: Effect of Ultraviolet Radiation on the Transcript Profile of Plk4 in Wild Type and Heterozygous MEFs

Wild type and heterozygous MEFs were exposed to $40\text{mJ}/\text{cm}^2$ ultraviolet radiation (UV), and RNA was isolated at various time points post exposure. RT-PCR was performed to measure the relative quantitative difference in Plk4 expression after exposure in both wild type and heterozygous MEFs. GAPDH was used as an internal loading control. PCR time points for GAPDH were 28, 30, 32 cycles while time points for Plk4 were 38, 40, 42 cycles. Within each time post UV exposure, PCR products over three PCR cycles is shown corresponding to the number of cycles for GAPDH and Plk4a) In response to UV, Plk4 transcript levels in wild type MEFs decrease to undetectable levels immediately after exposure. At 2hrs post exposure, Plk4 levels start to continually increase to levels greater than observed in the control. b) In contrast, levels of Plk4 are completely undetectable in heterozygous MEFs upon exposure to UV through to 8hrs post exposure. c) Densitometry was performed to measure the raw intensity for each band. Values for Plk4 were normalized to GAPDH, and subsequently values for the heterozygous MEFs were normalized to the wild type to determine the mean relative expression over three PCR time points and the results were graphed. For all three PCR time points (c, d, e), both wild type and heterozygous Plk4 levels decrease after exposure to UV. But at two hours, levels of Plk4 in wild type MEFs increase and continue to increase to levels greater than control, while heterozygous Plk4 levels remain undetectable. (NB WT: Wild Type; HET: Heterozygous)

is a difference in response to both ionizing and ultraviolet radiation. Wild type and heterozygous Plk4 MEFs were exposed to 25 Gy IR and 40mJ/cm² UV, lysed 6hr post exposure, and the cell extracts were subjected to Western Blot analysis. For both wild type and heterozygous MEFs, levels of protein expression do not change when the MEFs were exposed to either IR or UV; 6 hours post exposure (Figure 11). GAPDH was used as a loading control to ensure equal protein loading. Though, it is apparent that protein levels in heterozygous MEFs are half the level present in wild type MEFs. This finding supports previous evidence presented by Swallow *et al*, 2005.

The Effect of Plk4 Gene Dosage on Protein Levels of DNA Damage Proteins

Plk4 is able to interact with a number of DNA damage and DNA repair proteins including Cdc25c, Chk1, Chk2, Cyclin B1, p53 and Gadd45 α , and in the case of Cdc25c (Bonni *et al.*, 2008), Chk2 (Hudson, unpublished data) and p53 (Swallow *et al.*, 2005) is able to phosphorylate these proteins. It was interesting to determine whether there is a difference in protein levels in wild type and heterozygous Plk4 MEFs in response to DNA damage. Wild type and heterozygous Plk4 MEFs were exposed to 25 Gy IR or 40mJ/cm² UV, lysed 6hr post exposure, and the cell extracts were subjected to Western Blot analysis. Results displayed are the representative data from three experiments. Cdc25c is the phosphatase responsible for removing the inhibitory phosphates from the cyclin B1/Cdk1 complex, promoting its activation and initiating the G₂/M transition. When protein levels of Cdc25c were observed in wild type and heterozygous Plk4 MEFs, in general there is no difference in levels of Cdc25c (Figure 12a). Interestingly, the levels of Cdc25c do not change in response to IR or UV relative to the control. Also, there is no

Figure 11: Plk4 Protein Levels do not Change in Response to IR or UV

Wild type and heterozygous Plk4 MEFs were exposed to either 25 Gy ionizing radiation (IR) or 40mJ/cm² ultraviolet radiation (UV) and lysed 6 hr post exposure to obtain whole cell lysates. The lysates were run on SDS Page gel and then subjected to Western blot. The blots were probed with an anti-Plk4 antibody and with an anti-GAPDH antibody, as a control to ensure equal protein loading. No difference in Plk4 protein levels were observed for either wild type or heterozygous MEFs in response to IR or UV. Plk4 protein levels in heterozygous MEFs were approximately half the observable level than in wild type MEFs. (NB WT: Wild Type; HET: Heterozygous)

observable change in Cdc25c levels in response to DNA damage between wild type and heterozygous MEFs. GAPDH was used as a loading control to ensure equal protein loading and it is used in all subsequently experiments with additional proteins.

Chk1 is a signal transducer protein activated in response to DNA damage (Abraham, 2001). When Chk1 levels were examined, there is no detectable difference between wild type and heterozygous Chk1 protein levels (Figure 12b). Strikingly, there was no increase in protein level in either the wild type or heterozygous MEFs in response to IR. Similarly, there was no change in protein level in cells exposed to UV.

Chk2 is another signal transducer protein activated in response to DNA damage (Matsuoka *et al.*, 2000). In general, Chk2 levels in heterozygous MEFs appear to be greater than in the wild type (Figure 12c). While in response to UV, levels of Chk2 are elevated in both the wild type and heterozygous MEFs. Interestingly, levels of Chk2 are also elevated in response to IR, indicating that there is some degree of cross talk between the IR and UV DNA damage pathways.

Activation of the cyclin B1/Cdk1 complex is necessary for the G₂/M transition to occur (Bassermann *et al.*, 2005). In general, cyclin B1 levels in heterozygous MEFs are significantly lower than those observed in the wild types (Figure 12d). While in response to UV, both wild type and heterozygous levels of cyclin B1 are decreased proportionately to the levels observed in the controls. In contrast, levels observed with IR exposure are similar to levels of cyclin B1 seen with their respective controls.

The tumor suppressor protein, p53 is considered the “guardian of the genome for the numerous cellular functions it performs (Efeyan and Serrano, 2007). p53 plays a crucial role in the cells response to genotoxic stress by initiating DNA damage pathways. In

Figure 12: Differences in Protein Levels of DNA Damage Proteins in Plk4 MEFs

Wild type and heterozygous Plk4 MEFs were exposed to either 25 Gy ionizing radiation (IR) or 40mJ/cm² ultraviolet radiation (UV) and lysed 6 hr post exposure to obtain whole cell lysates. The lysates were run on SDS Page gel and then subjected to Western blot analysis. GAPDH was used to ensure equal protein loading. a) No change in Cdc25c levels were observed in response to IR or UV. b) In response to IR or UV, no observable differences in Chk1 protein levels were observed. c) Chk2 levels are elevated in heterozygous MEFs in comparison to the wild types, while in response to both IR and UV in both type of MEFs Chk2 levels increase. d) In general, cyclin B1 levels are lower in heterozygous MEFs than wild types. In addition, for both wild type and heterozygous MEFs, cyclin B1 levels decrease in response to UV. e) Levels of p53 are increased in heterozygous MEFs in general and in response to UV, while levels are constant in both wild type and heterozygous MEFs in response to IR. f) Gadd45 α levels are increased in heterozygous MEFs and in response to IR, while no induction of Gadd45 α is observed in wild type MEFs. (NB: WT: Wild Type; HET: Heterozygous)

A**B****C****D**

E

F

response to DNA damage, p53 expression is crucial to blocking cell cycle progression until the DNA is repaired or apoptotic pathways are initiated (Bunz *et al.*, 1999). In Plk4 MEFs, there is a sharp contrast between wild type and heterozygous MEFs, with levels of p53 protein expression substantially higher in the heterozygotes. A similar finding is observed in response to UV. In contrast, levels of p53 are similar for both wild type and heterozygous samples when exposed to IR (Figure 12e).

The growth arrest and DNA damage-inducible gene (Gadd45 α) expression is induced by DNA damage and growth arrest signals (Zhan, 2005). In Plk4 MEFs, Gadd45 α expression is significantly higher in heterozygous than wild type MEFs. No Gadd45 α induction is observed in wild type MEFs in response to either IR or UV. Levels of Gadd45 α are similar to the wild type control. Interestingly, Gadd45 α expression is elevated in heterozygous control and IR exposed MEFs. In comparison to the heterozygous control MEFs, no increase in Gadd45 α expression levels occurred in the UV exposed MEFs (Figure 12f).

Apoptotic Rate for Plk4 MEFs in Response to UV

In response to 40 mJ/cm² of ultraviolet radiation, a significantly high percentage of both wild type and heterozygous MEFs undergo apoptosis before 24 hours. Therefore, to determine whether there was a difference between susceptibility, a TdT-mediated dUTP Nick-End Labeling (TUNEL) assay was performed. Wild type and heterozygous MEFs were grown on glass cover slips, exposed to 40 mJ/cm² of UV and a TUNEL assay performed 0, 1, 2, 4, 6, 8 hours post exposure. DNase I treatment was used as a positive control as the enzyme induces fragmentation of DNA similar to what is observed in

apoptotic cells. The cells were stained red with propidium iodide (PI) to locate the nuclei, while staining green with fluorescein-12-dUTP was indicative of apoptotic cells (Figure 13a) 200 cells were counted per slide and the percentage of apoptotic cells per slide was determined. Three trials at each time point were performed and the average percentage of apoptotic cells and the standard error of the mean was determined (Figure 13b) (Appendix I).

In response to UV, there was a no significant difference in susceptibility to apoptosis between wild type and heterozygous MEFs. At 0 and 1 hour post exposure, no apoptotic cells were observed; similar to what was seen in MEFs exposed to no UV. At 2 hours post exposure, between 5 to 10% of the cells were apoptotic, though there was no statistical difference between wild type and heterozygous MEFs. The percentage of apoptotic cells at 4 hours increased to 20%, again with no statistical difference. At 6 hours post exposure, there appears to be a difference in susceptibility with 28% of wild type MEFs with 37% of heterozygotes apoptotic. At 8 hours, 65% of both wild type and heterozygous cells were apoptotic. The only statistical difference in apoptotic rate between the wild type and heterozygous MEFs was observed at 6 hours.

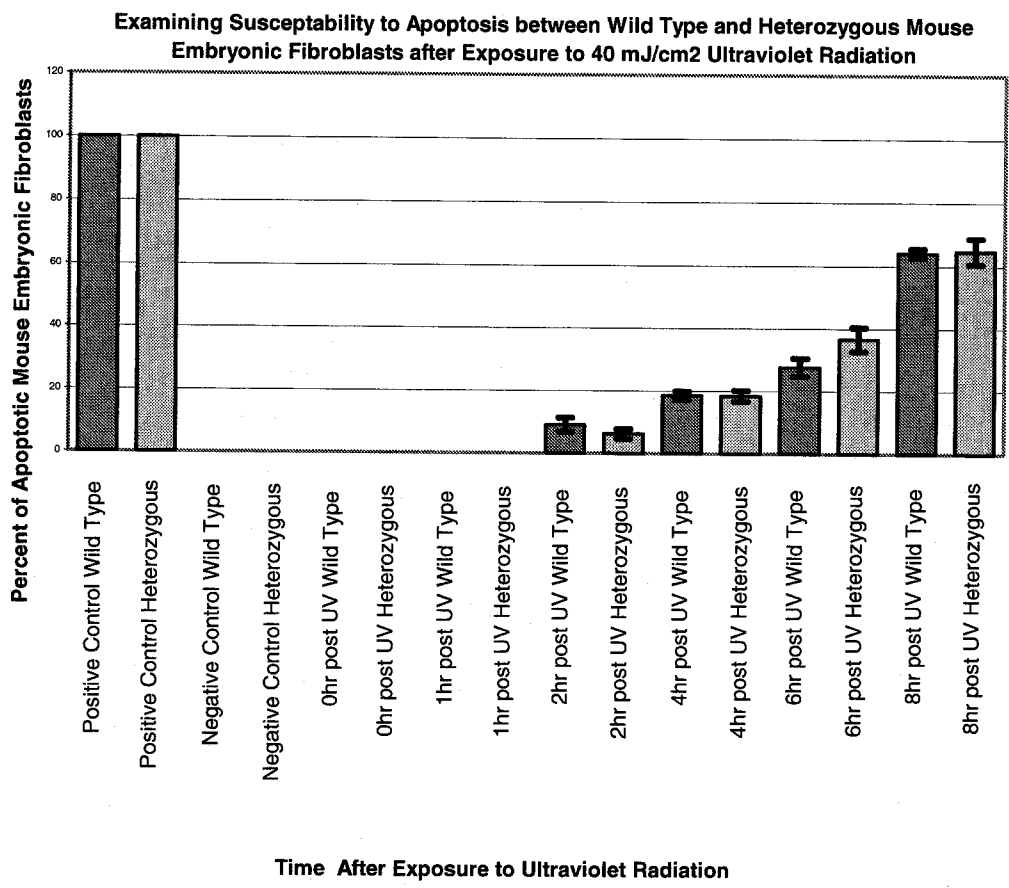

Figure 13: No Difference in Apoptotic Susceptibility between Wild Type and Heterozygous MEFs

Wild type and heterozygous MEFs were exposed to $40\text{mJ}/\text{cm}^2$ of ultraviolet radiation (UV) and a TUNEL assay was performed at various time points post exposure a) Cells were stained red with propidium iodide (PI) to identify the nucleus, while green staining with TUNEL was indicative of apoptotic cells. DNase I treatment was used as a positive indicator of apoptotic cells. b) As time post exposure increased, there was a greater percentage of both wild type and heterozygous MEFs susceptible to apoptosis. Though, no statistical differences between susceptibility rates of apoptosis were observed.

A

B

Comparison between Transcript Profiles in Wild Type and Heterozygous Plk4 MEFs in Response to UV using Microarray.

In response to ultraviolet radiation (UV), the transcript profiles for Plk4 differ significantly between wild type and heterozygous. After exposure to UV, transcript profiles in heterozygous MEFs decline significantly in comparison to control levels. In contrast, in wild type MEFs after an initial decline in Plk4 transcript levels, levels increase after 2 hours exposure and continue to increase. Therefore, it was of interest to investigate transcript profiles of other genes in response to UV.

Both wild type and heterozygous MEFs were exposed to $40\text{mJ}/\text{cm}^2$ and RNA was isolated 4 hours post exposure to UV. The RNA was sent to the UHN Microarray Centre where three microarray replicates were performed using an indirect labeling methodology. A face to face hybridization using a Mouse 7.4k and Mouse 15k microarray chips was performed. A QuantArray microarray gene list was obtained from the University Health Network (UHN) Microarray Centre website indicating the identification of each spot on the Mouse 7.4K and Mouse 15k array (<http://www.microarrays.ca/products/glists.html>). Quantification and analysis of the microarray chips was done in a similar method as previously stated. To obtain differences in transcript profiles between the wild type and heterozygous MEFs, the analysis of the Mouse 7.4k and Mouse 15k array were performed separately. Similarly to the previous microarray, genes were identified with a log ratio equal or greater than 1, corresponding to genes within the heterozygous MEFs that have at least a 2 fold or greater rate of transcript expression than in the wild type MEFs. These genes were up-regulated in the heterozygous MEFs. Genes identified with a log ratio equal or less than -1, corresponded

to genes having at least a 2 fold or greater rate of transcript expression or were down-regulated in the heterozygous MEFs.

From the microarray data, 27 genes were identified as having at least a two fold increase in transcript profile or were down-regulated in the heterozygous MEFs 4 hours post exposure to UV (Table 3) (Appendix L), while 84 genes were identified as having at least a two fold increase in transcript profile in the heterozygous MEFs 4 hours post exposure to UV, or were up-regulated in the heterozygous MEFs (Table 4) (Appendix J). Cellular function for each gene was identified using either Pubmed database or the Online Mendelian Inheritance in Man (OMIM) database.

Transcription factor ELYS; AT hook containing transcription factor 1 (Ahctf1)	
Apoptosis	
WW domain-containing oxidoreductase (Wwox) (Wox1)	
CASP2 and RPK1 domain containing adaptor with death domain (Cradd) (RAIDD)	
Transducin-like enhancer of split 1; Groucho-Related Gene 1	
Tumor necrosis factor, alpha-induced protein 3 (A20)	
Notch gene homolog 2 (Notch2)	
bromodomain PHD finger transcription factor (Bptf); FETAL ALZHEIMER ANTIGEN	
Forehead box O3a (Foxo3a)	
DNA Damage	
Mitogen activated protein kinase kinase 5 (MAP2K5)	
Fanconi anemia, complementation group M (Fancm)	
Tumorigenesis	
Deleted in bladder cancer chromosome region candidate 1 (DBC1)	
Cadherin 6	
Rho-related BTB domain containing 1 (Rhohtb1)	
Metabolism	
Gamma-aminobutyric acid (GABA-A) receptor, subunit gamma 2 isoform 1	
Glutathione reductase 1 (Gsr)	
Leucyl/cystinyl aminopeptidase (Lnpep) (IRAP)	
Fatty acid desaturase 3 (Fads)	
Mannosidase alpha class 2B member 2 (Man2b2)	
Phosphatidylinositol glycan, class A (Piga)	
ADP-ribosylation factor related protein 2 (Arl15)	
SH3-domain GRB2-like (endophilin) interacting protein 1 (SGIP1)	
Dipeptidylpeptidase 8 (Dpp8)	
Dual specificity phosphatase 27 (Dusp27)	
Xylosyltransferase I (Xylt1)	
Cellular Transport	
Protein phosphatase 1F (PP2C domain containing) (Ppm1f)	
Frequenin homolog (Freq)	
Myotubularin related protein 10 (Mtmr10)	
Oxysterol binding protein (Osbp)	
Ring finger protein 17 (Rnf17)	
Epigenetics	
Sal-like protein 3	
TOX high mobility group box family member 3 (Tox3)	
Cat eye syndrome critical region protein 2 isoform 9 (Cecr2)	
Synovial sarcoma translocation, Chromosome 18 (Ss18)	

Table 4: Up-regulated Genes in the Heterozygous MEFs 4 hours Post UV Exposure Cont.

Transcriptional/Translational Regulation	Developmental
WW domain-containing protein 2	Thrombospondin 2
Avian musculoaponeurotic fibrosarcoma (v-maf) AS42 oncogene homolog	Frizzled 5 precursor (FZD5)
Phenylalanine-tRNA synthetase 2 (mitochondrial) (Fars2)	T-cell factor 4 (Tcf4)
WW domain-containing protein 4 (Wbp4)	Stathmin-like 2
GLIS family zinc finger 3 (Glis3)	Odd Oz/ten-m homolog 3 (Odz3)
cAMP responsive element binding protein 3 like-2 (Creb3l2)	Chemokine-like factor super family 3 (CKLFSF3); Transducin-like enhancer protein 3 isoform 1 (Tle3)
	ADAMTS-like 3 (Adamtsl3)
Cellular Signaling	Angiopoietin-like 2
Estrogen related receptor, beta (Esrrb)	SWI/SNF-related, matrix associated actin dependent regulator of chromatin, subfamily a, containing DEAD/H box 1 (Smarcad1)
Eukaryotic translation initiation factor 4 gamma, 3 (Eif4g3)	
Rap guanine nucleotide exchange factor (GEF) 6 (Rapgef6)	Miscellaneous Function
Unc93 homolog B (Unc93b1)	CDC42 effector protein (Rho GTPase binding) 4 (CDC42EP4) (binder of Rho GTPases)
Transmembrane protein 32 (Tmem32)	Pleckstrin homology domain containing, family F (with FYVE domain) member 1 (Plekhf1)
Bassoon protein (BSN); zinc finger protein 231 (ZNF231)	Similar to high-mobility group box 3
RUN and FYVE domain-containing 2 (Rufy2)	CD96 antigen (CD96)
Nuclear receptor co-repressor 1 (Ncor1)	FERM, RhoGEF and pleckstrin domain protein 2 (FGD2)
Neurexophilin 2 (Nxph2)	Ubiquitin specific protease 31 (Usp31)
RNA-binding region containing protein 2 (Rnpc2) (Caper)	Kalirin, RhoGEF kinase (Kalm)
Pleckstrin (Plek)	DCN1, defective in cullin neddylation 1, domain containing 2 isoform a (Dcun1d2)
Nuclear receptor subfamily 2, group F, member 2 isoform 2	Villin 1 (Vil)
Activin receptor IIA (Acvr2a)	

Comparison between Transcript Profile in Wild Type vs. Wild Type UV Exposure and Heterozygous vs. Heterozygous UV Exposure Using Microarray

The data from the two microarray experiments was analyzed to determine differences in transcript profile, firstly in the wild type vs. wild type MEFs 4 hours post UV exposure; and secondly for the heterozygous vs. heterozygous MEFs 4 hours post UV exposure. Since a substantial percentage of the MEFs exposed to UV were destined for apoptosis, the analysis would provide a general survey of differences in cellular mechanics between normal and apoptotic MEFs.

Since the two different microarray experiments were performed using chips with different formats, similar analysis to the previous two microarray experiments couldn't be performed. Instead, data for each cyanine labeled sample was quantified individually, unlike the previous two experiments where a composite of the Cy3 and Cy5 image were quantified together. Quantification was performed using LOWESS normalization within the ScanArray Express Software. From this normalization, data was removed from analysis if the raw intensity was not at least two standard deviations above the background. Secondly, data was removed if the minimum signal to noise ratio was not greater than 200. The parameter of signal to noise ratio uses the ratio of the spot intensity to the standard deviation of the local background of all spots on the microarray. The data was transferred to MEV where a low intensity cutoff of 100 000 was used to further streamline the data. In order to determine differences in transcript profile, the raw intensity values for the three non UV exposure chips were compared to the raw intensity values of the UV exposure chips. To eliminate possible error in selecting candidate genes

due to variance between raw intensity values between the three chips of one treatment, genes with at least a three fold increase in raw intensity were selected.

For the comparison of normal wild type MEFs versus wild type MEFs exposed to UV, 171 genes were identified with at least a three fold greater raw intensity, or being up-regulated in the normal wild type MEFs (Table 5). Conversely, 83 genes were identified as having at least a three fold greater expression in the wild type MEFs 4 hours post UV exposure, or being down-regulated in the normal wild type MEFs (Table 6). Comparing the normal heterozygous MEFs to heterozygous MEFs 4 hours post UV exposure, 151 genes were observed with at least a three fold increase in raw intensity, or being up-regulated in the normal heterozygous MEFs (Table 7). While 24 genes were identified as having at least a three fold increase in expression in the heterozygous MEFs 4 hours post UV exposure, or being down-regulated in the normal heterozygous MEFs (Table 8). Cellular function for each gene was identified using either Pubmed database or the Online Mendelian Inheritance in Man (OMIM) database.

The analysis from this microarray experiment was compared to the other two microarray experiments (wild type vs. heterozygous MEFs; UV wild type vs. UV heterozygous MEFs) and there was no overlap between the genes that were up- or down-regulated in the experiments. Though, from the comparisons in this experiment (wild type MEFs vs. UV wild type MEFs; heterozygous MEFs vs. UV heterozygous MEFs), there were 56 genes that were up-regulated in both the wild type and heterozygous MEFs, while 115 genes in just the wild type MEFs and 95 genes in just the heterozygous MEFs were up-regulated. Similarly, 19 genes were up-regulated in both the wild and

heterozygous MEFs exposed to UV, while 64 genes were up-regulated in just the UV wild type MEFs and 5 genes were up-regulated in just the UV heterozygous MEFs.

Table 5: Up-regulated Genes in Normal Wild Type MEFs Cont.

Cell Signaling	
Growth factor receptor bound protein 7	Solute carrier family 22 member 5
Sequestosome 1	Solute carrier family 6 (neurotransmitter transporter, taurine), member 6
Protease (prosome, macropain) 26S subunit, ATPase 5	Endoplasmic reticulum chaperone SIL1 homolog
Calmodulin 2	Receptor-activity modifying protein 1
Ral-interacting protein 1	Solute carrier family 25 (mitochondrial carrier oxoglutarate carrier), member 11
Protein O-fucosyltransferase 1 isoform 1	Transmembrane protein 38a
Tnf receptor-associated factor 7	ADP-ribosylation factor-like 4
NTF2-related export protein 1	
Ly6/neurotoxin 1	
Rho GDP dissociation inhibitor (GDI) alpha	
transglutaminase 2, C polypeptide	
GRIP1 associated protein 1

Chapter 5

Discussion

Transcript Analysis in Wild Type and Heterozygous Plk4 MEFs

Wild type and heterozygous Plk4 MEFs exhibit a number of phenotypic differences including a slower proliferation rate and increased centrosomal number leading to chromosomal misalignment and improper segregation in heterozygotes (Ko *et al.*, 2005). It can be hypothesized that these cell cycle abnormalities lead to the increased incidence of tumor formation observed in the heterozygous mice. In this study, murine embryonic fibroblasts (MEFs) derived from approximately 12.5 day old embryos were used as a model to examine the effect of lower Plk4 levels on the expression pattern of other genes. Both wild-type and heterozygous Plk4 MEFs were used as they are both viable. Since Plk4 nulls spontaneously abort at E7.5, the use of MEFs from this genotype was not an option. In order to examine the nature of these global differences a microarray based approach was utilized. MEFs were used to do the microarray and subsequent confirmation *via* RT-PCR because they are easier to manipulate and provide a strong reference point to compare differences between the wild type and heterozygous Plk4 phenotype. Analysis done within the MEFs would provide clues to possible differences that may exist within adult cells.

It was determined that 9 genes contained at least a two fold decrease in transcriptional expression in the heterozygous MEFs (Table 1), while 146 genes were identified that had at least a two fold increase in transcriptional expression in the heterozygous MEFs (Table 2). Three candidate genes were picked for further analysis that may potentially contribute to the malignant phenotype seen in adults. This is

discussed in more detail below. Specifically, a RT-PCR densitometry based approach was used to re-examine that the relative expressions of Wisp1 (Figure 6), SAP30 Binding Protein (Figure 7), and Prohibitin (Figure 8) were greater in heterozygous than wild type MEFs. The results obtained through RT-PCR analysis parallel the microarray data observed.

i) Wisp1 Expression in Heterozygous MEFs

Wnt1-inducible signaling pathway protein 1 (Wisp1) is a member of the connective tissue growth factor family (CCN). It was first identified as being upregulated in Wnt1-transformed mouse mammary epithelial cells and elevated levels were present in colon cancer (Pennica *et al.*, 1998). Additionally, aberrant Wnt signaling has been implicated in the development of hepatocellular carcinomas (HCC) (Lee *et al.*, 2006), and Wisp1 (Cervello *et al.*, 2004) over expression has been characterized in HCC. It is plausible to believe that aberrant Wnt regulation and Wisp1 over expression could contribute to the increased incidence of HCC observed in heterozygous mice.

Wisp1 activity is transcriptionally regulated by both Wnt1 and β -catenin. In addition, Wnt1 and β -catenin regulated over expression of Wisp1 contributes to increased morphological transformation and accelerated cell growth. Also, over expression of Wisp1 in nude mice contributed to tumor formation, therefore promoting Wisp1 as an oncogene (Xu *et al.*, 2000). Wisp1 over expression has been implicated in additional malignancies including scirrhous gastric carcinoma (Tanaka *et al.*, 2001), breast cancer (Xie *et al.*, 2001), and cholangiocarcinoma (Tanaka *et al.*, 2003). Interestingly, Wisp1

also attenuates p53-mediated apoptosis through the Akt/PKB signaling pathway (Su *et al.*, 2002).

Members of the CCN family contain four conserved modules present in other unrelated extracellular proteins. One of the modules is a thrombospondin domain (Lau and Lam, 1999). Interestingly, thrombospondin was one of the genes that also contained increased transcript expression in heterozygous MEFs. Thrombospondin is a potent inhibitor of angiogenesis, which is crucial for the growth and metastasis of tumors. Thrombospondin expression is positively regulated by p53 (Dameron *et al.*, 1994). Loss of wild type p53 leads to a loss of thrombospondin expression and the development of an angiogenic phenotype (Volpert *et al.*, 1997). Though no direct interaction has been shown between Wisp1 and thrombospondin, it could be interesting to speculate that Wisp1 could bind to thrombospondin, inhibiting its function, promoting angiogenesis and tumor formation.

In addition, in response to DNA damage, data shows that Wisp1 can attenuate p53 mediated apoptosis through the activation of the Akt pathway (Su *et al.*, 2002). Wisp1 activation of Akt allows Akt to block the release of cytochrome c from the mitochondria (Kennedy *et al.*, 1999), preventing cytochrome c activation of the caspases which would lead to apoptosis (Gottlob *et al.*, 2001). Also, expression of Wisp1 upregulates Bcl-X_L activity. Bcl-X_L has been shown to interact with caspase-9 (Pan *et al.*, 1998) and Apaf-1 (Hu *et al.*, 1998) resulting in inhibition of caspase activity. In addition, Bcl-X_L also can block cytochrome c release from the mitochondria, preventing apoptosis (Kharbanda *et al.*, 1997).

Interestingly, in the microarray data, phosphatidylinositol 3-kinase (PI3K) was also over expressed in the heterozygous MEFs. PI3K has shown to be an upstream regulator of Akt (Nicholson and Anderson, 2002). Wisp1 activation of Akt and Bcl-X_L pathways along with PI3K activation of Akt provides a mechanism within the heterozygous MEFs to overcome apoptotic pathways in response to DNA damage. Therefore, it is likely that genetic instability becomes prevalent leading to possible tumorigenesis and the increased incidence of tumors observed in heterozygous mice.

Wisp1 was first identified as a Wnt1 and β -catenin induced oncogene (Xu *et al.*, 2000). Though the exact method of Wisp1 activation has yet to be elucidated, it is known that activation of Wnt target genes occurs through β -catenin. β -catenin forms a complex with the T-cell factor/lymphocyte enhancing factor (TCF/LEF) family of transcription factors to activate the expression of target genes (Polakis, 1999). Interestingly, TCF4 also came up as being over expressed in heterozygous MEFs. Though the transcription factor responsible for the activation of Wisp1 is yet to be known, it is interesting to speculate that TCF4 may be responsible as both were observed as being over expressed in heterozygous MEFs.

Along with Wisp1 (Cervello *et al.*, 2004), TCF4 (Zhao *et al.*, 2004) over expression has also been implicated in the development of HCC. It is plausible to believe that aberrant Wnt regulation could contribute to the increased incidence of HCC observed in heterozygous mice. It has been established that Wisp1 expression blocks p53 mediated apoptosis (Su *et al.*, 2002). Heterozygous Plk4 MEFs present a number of abnormal phenotypes including abnormal centrosome number leading to improper chromosome segregation (Ko *et al.*, 2005). Therefore, it seems plausible that heterozygous MEFs may

be unable to undergo p53 mediated apoptosis due to over-expression of Wisp1. It is possible that a similar phenotype as seen in the heterozygous MEFs may occur in adult cells. Without apoptosis occurring, these cells continue to go through the cell cycle leading to a greater number of cells with abnormalities and greater genomic instability which eventually will contribute to tumor formation.

ii) SAP30 Binding Protein Expression in Heterozygous MEFs

Epigenetic modification to genes has been well documented as a method to promote oncogenesis within the cell. Since heterozygous mice develop cancer at a rate significantly higher than their wild type littermates, it has been hypothesized that epigenetic silencing of Plk4 could be a possible mechanism for the increased incidence of tumorigenesis observed. Plk2 has been implicated in mediating apoptosis as a target gene of p53, though epigenetic silencing of Plk2 transcriptional expression *via* methylation is a common occurrence in B cell lymphomas (Smith *et al.*, 2006). While epigenetic silencing of Plk1 or Plk3 has not been characterized, preliminary evidence suggests that Plk4 in heterozygous mice livers undergoes methylation in the CpG island region of its promoter at a significantly higher rate than wild types. Methylation of Plk4 has also been observed in the liver tumors of heterozygous mice. Methylation of the Plk4 promoter increases with age and is more frequent in male mice. Additionally, chronic alcohol exposure has been implicated to promote methylation (Kim and Shukla, 2006). Heterozygous MEFs become methylated upon exposure to a lower concentration of ethanol than wild types (Ward, Hudson unpublished data).

Though little is known about the function of SAP30 binding protein (SAP30BP), it has been determined that SAP30BP binds to SAP30, a component of the Sin3 histone deacetylase complex (Sin3-HDAC) (Li *et al.*, 2004). The Sin3-HDAC complex is primarily responsible for deacetylating nucleosomes in Sin3 regulated promoters, resulting in repressed chromatin structure and transcriptional silencing (Kuzmichev *et al.*, 2002). In addition, through the enzymatic function of Sin3, the Sin3-HDAC complex can also participate in DNA methylation, N-acetylglucosamine transferase activity, and histone methylation. The Sin3-HDAC lacks DNA-binding capacity, so therefore it must be targeted to gene promoters by DNA-binding proteins (Silverstein and Ekwall, 2005). In yeast, SAP30 has the ability to recruit the complex to the gene promoters, but as yet this function hasn't been established in mammals (Zhang *et al.*, 1998). Therefore, though the structure of SAP30BP has yet to be elucidated, it is interesting to speculate that SAP30BP could contain a DNA-binding domain to target the Sin3-HDAC complex to the promoter region.

In addition, p53 is able interact with TATA box binding-protein (TBP) to facilitate the recruitment of Sin3-HDAC complex to the gene promoter for transcriptional repression (Farmer *et al.*, 1996). Li *et al.*, 2005 found that in response to DNA damaging agents, p53-mediated transcriptional repression of Plk4 occurs through the activity of HDAC. p53 regulates not only DNA damage pathways but also the mitotic spindle checkpoint. Previous work showed that in heterozygous Plk4 hepatocytes there was a significant increase in multipolar spindle complexes with aberrant mitosis (Ko *et al.*, 2005). The mitotic spindle checkpoint is necessary to ensure proper mitotic spindle formation, so that inaccurate chromosomal segregation does not occur (Xie *et al.*, 2005).

Therefore, it could be hypothesized that methylation of Plk4 occurs in a p53-mediated manner and consequently could inhibit oncogenesis.

Methylation and other epigenetic modifications are responsible for altering chromatin structure. Preliminary evidence shows that Plk4 is methylated, though the functional cascade responsible for this methylation is unknown. Li *et al.*, 2005 showed that Plk4 undergoes repression in a p53-mediated manner through HDAC. Plk4 is able to interact and phosphorylate p53 on Ser-293 (Swallow *et al.*, 2005), though the functional significance of this interaction is unknown. Observed results within the heterozygous MEFs show that p53 levels are significantly greater than in the wild types (Figure 13e). Therefore, it can be hypothesized that with lower levels of Plk4 in heterozygous MEFs, Plk4 is unable to phosphorylate p53 to the extent that wild type Plk4 can; thus p53 function is not inhibited in the heterozygous MEFs. This could explain the increase in methylation observed in heterozygous mice livers, as p53 which is not inhibited by Plk4 is able to inhibit Plk4 function through methylation.

iii) Prohibitin Expression in Heterozygous MEFs

Cellular senescence occurs when normal cells lose their ability to divide and is indicative of cells with a flattened morphology and an increased granularity phenotype (Campisi, 2001). These phenotypes are observed at a greater frequency and at an earlier passage in heterozygous Plk4 MEFs than in wild types.

The cellular senescent phenotype is observed when shortening of the telomeres is recognized by the cell as a DNA double strand break, and DNA damage pathways are initiated. ATM/ATR mediate the activation of cell-cycle checkpoints associated with

cellular senescence, mainly via p53, CHK1 and CHK2, with the participation of p21, p16 and retinoblastoma protein (RB) (Schmitt *et al.*, 2007). RB function has been deemed necessary for inducing senescence (Lowe and Sheer, 2003). RB has been shown to interact with various transcriptional co repressors including heterochromatin protein 1 (HP1) (Narita *et al.*, 2003), histone deacetylase 1 (HDAC1) (Brehm *et al.*, 1998), DNA methyltransferase (Vandel *et al.*, 2001), Polycomb proteins (Ross *et al.*, 1999), and chromatin-remodeling complexes Brg and Brm (Strober *et al.*, 1996) to repress E2F transcription factor (E2F) transcriptional activity. E2F activity is essential for cell proliferation and its reduction immediately provokes cellular senescence (Maehara *et al.*, 2005).

Prohibitin has been implicated to play a crucial role in cellular senescence though the mechanism has yet to be elucidated (Dell'Orco *et al.*, 1996). It is believed that prohibitin's role in senescence acts through its ability to repress E2F transcription factor 1 (E2F1) mediated transcriptional activity (Wang *et al.*, 1999). In response to senescence-inducing DNA damage agents, prohibitin localizes to specific heterochromatic foci, where it binds with members of the heterochromatin protein 1 (HP1) family of proteins. Prohibitin and HP1 bind to the E2F1-responsive proliferative promoter, leading to repression of E2F1 transcriptional activity (Rastogi *et al.*, 2006). Prohibitin is able to bind p53 to enhance its transcriptional abilities (Fusaro *et al.*, 2003), though it is not clear whether p53 functions in a positive feedback loop to activate prohibitin or an upstream protein is responsible. Also, p53 levels are elevated within heterozygous MEFs (Figure 12e), indicative of senescence occurring at an earlier passage in the heterozygous MEFs.

Additionally, with both prohibitin and RB binding HP1 to inactivate E2F1, this suggests redundancy within the signaling cascade.

Testing for the senescent phenotype in Plk4 MEFs was attempted through a β -galactosidase staining assay. Though efforts to get the assay to work failed, as no blue colour indicate of senescence was observed, even though characteristics such as flattened morphology and increased granularity were observed in the heterozygous MEFs at an earlier passage than wild types.

It is plausible that heterozygous Plk4 MEFs are senescent at an earlier passage than wild types, as a mechanism to prevent oncogenesis. Though no DNA replicative differences have been characterized between wild type and heterozygous MEFs, aberrant DNA replication may cause the telomeres in heterozygous MEFs to shorten at an accelerated rate. Therefore, the shortening of the telomeres could give cause to genetic instability which would lead to oncogenesis.

Plk4 Expression in MEFs: Response to DNA Damaging Agents

Other members of the Plk family are implicated to play crucial roles in response to DNA damage. In response to both ionizing radiation (IR) and ultraviolet radiation (UV), Plk1 activity is repressed by the DNA damage sensor protein ATM and ATR, respectively, to inhibit Plk1 from pushing cells through the cell cycle (van Vugt *et al.*, 2001). In contrast, Plk3 is activated by ATM in response to IR to prevent cell cycle progression (Xie *et al.*, 2001), while Plk2 is activated by p53 (Shimizu-Yoshida *et al.*, 2001). Subsequently, Plk4 has been hypothesized to play a role in the DNA damage pathways, therefore Plk4 MEFs were examined in response to IR or UV.

i) Plk4 Transcript Abundance in Response in Ionizing Radiation

In response to IR, for both wild type and heterozygous MEFs, the levels of Plk4 decreased to 60 to 80% relative to the control, with no difference between the two (Figure 9). Both wild type and heterozygous MEFs were resistant to this dose of IR, as 24 hours post exposure, the cells were viable. As Plk4's prominent identified role within the cell is centrosome duplication and dynamics (Habedanck *et al.*, 2005), it is likely that cell cycle checkpoints were enabled to ensure that any damage to the genome was repaired before cell growth and division ensued, coinciding with a decrease in Plk4 levels. At 8 and 24 hours post exposure, Plk4 levels in both wild type and heterozygous MEFs started to increase to levels relative to the control, indicating that any DNA damage was repaired and the normal cellular dynamics were resuming.

ii) Plk4 Transcript Abundance in Response to Ultraviolet Radiation

In response to UV exposure, there was a sharp contrast observed between Plk4 levels in the wild type and heterozygous MEFs. After UV exposure, both wild type and heterozygous levels decrease immediately, until 2 hours when wild type levels increased and continued to increase to levels greater relative to the control, 8 hours post exposure. In contrast, no detectable levels of Plk4 were observed in the heterozygous MEFs (Figure 10). p53 transcriptionally represses Plk4 function (Li *et al.*, 2005), so it is possible that with lower levels of Plk4 as observed in the heterozygous MEFs, the repression of Plk4 by p53 is stronger. Furthermore, p53 protein levels are also increased in heterozygous MEFs in comparison to wild types in response to UV (Figure 12e).

Twenty-four hours post exposure to UV, both wild type and heterozygous MEFs were not viable, as greater than 95% of the cells were floating. It can be assumed that the heterozygous MEFs undergo apoptosis through a p53-mediated pathway, but for wild type MEFs it is difficult to make this assumption. Over-expression of Plk4 attenuates p53-mediated apoptosis (Li *et al.*, 2005) and p53 protein levels were not elevated in wild type MEFs in response to UV (Figure 12e), so it can be hypothesized that wild type MEFs undergo apoptosis through another pathway.

iii) Plk4 Protein Levels in Response to DNA Damage

As differences were observed in mRNA levels, it was of interest to see whether changes in protein levels actually corresponding to the mRNA levels. In response to both IR and UV, no changes were observed in Plk4 protein levels for both wild type and heterozygous MEFs, 6 hours post exposure. Consistent with previous studies Plk4 protein levels in the heterozygous MEFs were half the level observed in the wild type MEFs (Figure 11) (Swallow *et al.*, 2005).

iv) DNA Damage Protein Levels

Proteins with known roles in the DNA damage pathways were examined in the MEFs to see if a difference in Plk4 gene dose would have an effect on their response to either IR or UV. Cdc25c is the phosphatase responsible for removing the inhibitory phosphates from the cyclin B1/Cdk1 complex, promoting its activation and initiating the G₂/M transition. In response to ionizing radiation and ultraviolet radiation, Cdc25c activity is inhibited by Chk2 (Matsuoka *et al.*, 1998) and Chk1 (Lam and Rosen, 2004),

respectively. Levels of Cdc25c did not change in either wild type or heterozygous MEFs in response to either IR or UV (Figure 12a).

Activation of the cyclin B1/Cdk1 complex is necessary for the G₂/M transition to occur (Bassermann *et al.*, 2005). In response to DNA damage, a cell cycle block occurs at the G₂/M transition and either the damage to the genome is repaired or the cell enters programmed cell death. In response to UV, levels are minimal in comparison to the control, indicative of a cell cycle block that would occur as the cells prepare to undergo apoptosis. In contrast, levels of cyclin B1 in IR exposed cells were identical to control levels, indicating that any DNA damage done was repaired and the cells are normally going through the cell cycle. Though, control and IR levels of cyclin B1 in heterozygous MEFs were about half of what was observed in the wild types (Figure 12d). Since no flow cytometry was performed to assure a normal cell cycle profile amongst the MEFs, it is impossible to state that there was an equal percentage of wild type and heterozygous MEFs at the G₂/M transition. Though, the observed data is supported by previous findings, which showed that heterozygous MEFs have a slower growth rate which would be consistent with a delay entry into mitosis (Ko *et al.*, 2005). Additionally, when examining hepatocytes, the appearance of cyclin B1 protein levels was delayed and persisted longer in heterozygous Plk4 hepatocytes than in wild types (Ko *et al.*, 2005).

The checkpoint kinase members Chk1 and Chk2 protein levels were examined to observe the response elicited by DNA damage. Chk1 is a signal transducer protein activated in response to DNA damage. In response to ultraviolet radiation, Chk1 is activated by ATR (Abraham, 2001), allowing it to phosphorylate members of the Cdc25 phosphatase family inhibiting their ability to promote cellular progression (Lam and

Rosen, 2004). Interestingly, no differences in Chk1 protein levels were observed in response to either IR or UV (Figure 12b). Assuming a normal cell cycle profile, the majority of MEFs would have been present within either G₁ or S phases of the cell cycle. Cann and Hicks, 2006 found that in response to IR, primary MEFs lack an immediate G₁/S checkpoint and that any response to DNA damage occurs at the level of individual replication origins, instead of inducing a complete shutdown of S-phase entry. This rationale explains why no Chk1 response was elicited in the MEFs.

Chk2 is another signal transducer protein activated in response to DNA damage. In response to ionizing radiation, Chk2 is activated by ATM (Matsuoka *et al.*, 2000). Chk2 phosphorylates members of the Cdc25 phosphatase family inhibiting their function and delaying the cell cycle (Lam and Rosen, 2004). In addition, Chk2 is able to activate p53, allowing p53 to initiate a halt to cell cycle progression (Hirao *et al.*, 1998). Chk2 protein levels increased for both wild type and heterozygous MEFs in response to both IR and UV (Figure 12c). Elevated levels in response to UV suggest that there may be some cross talk in the DNA damage pathways. Previous work confirms the notion of cross talk between the DNA damage pathways. Cisplatin, an anticancer drug functions by inducing DNA cross linking in base pairs which is a similar phenotype observed in response to UV. Interestingly, in response to cisplatin treatment ATR and not ATM was activated (Pabla *et al.*, 2007). Downstream, both Chk1 and Chk2 are phosphorylated in an ATR-dependent manner, though Chk1 degradation occurs by the proteasome shortly after phosphorylation. Chk2 activation of p53 leads to a p53-dependent cell cycle checkpoint activation. In terms of the MEFs, the induction of Chk2 in response to IR probably

activated cell cycle checkpoints while DNA damage was repaired, while in response to UV, Chk2 activated p53-dependent apoptotic pathways.

p53 is widely considered the guardian of the genome, and its expression is activated in response to genotoxic stresses (Efeyan and Serrano, 2007) .). p53 plays a crucial role in the cells response to genotoxic stress by initiating DNA damage pathways. In response to DNA damage, p53 expression is crucial to blocking cell cycle progression until the DNA is repaired or apoptotic pathways are initiated (Bunz *et al.*, 1999). In heterozygous Plk4 MEFs, protein levels of p53 are substantially higher than in wild types, with a similar scenario observed in response to UV. In response to IR, an induction of p53 expression is observed in wild type MEFs, while levels of p53 are constant with control levels for the heterozygotes (Figure 12e). There are a multitude of possible reasons to explain these variances. Firstly, Plk4 has been shown to phosphorylate p53 on serine 293 (Swallow *et al.*, 2005). Though the significance of this interaction has yet to be characterized, it could be possible that the phosphorylation of p53 on this residue is inhibitory or that it may affect p53 stability. Based on the fact that there is only one dose of Plk4 present in the heterozygous MEFs, there may not be enough Plk4 present to inhibit p53 transcriptional activity, explaining the higher degree of p53 expression observed in the heterozygotes. It is also possible that the interaction between Plk4 and p53 maybe part of a negative feedback mechanism as p53 inhibits Plk4 through HDAC (Li *et al.*, 2005) and Plk4 inhibits p53 through direct phosphorylation. The second reason for increased p53 levels in heterozygous MEFs may be due to the fact that aberrant mitotic spindle formation and chromosome mis-segregation is exhibited in heterozygous MEFs (Ko *et al.*, 2005). In response to these defects, p53 is activated by the mitotic

spindle checkpoint causing a delay in mitotic progression (Xie *et al.*, 2005). In addition, the lack of p53 induction in wild type MEFs in response to UV, suggests that apoptosis occurs in these cells in a p53-independent manner, while in response to IR, cell cycle checkpoints are established in a p53-dependent manner.

The growth arrest and DNA damage-inducible gene (*Gadd45 α*) expression is induced by DNA damage and growth arrest signals (Zhan, 2005). In response to ionizing radiation, *Gadd45 α* is transcriptionally activated by p53 (Zhan *et al.*, 1994), while disruption of p53 transcriptional ability inhibits *Gadd45 α* induction (Zhan *et al.*, 1996). In contrast, the induction of *Gadd45 α* via UV is p53 independent. The induction is dependent on transcription factors Oct-1 and NF-YA (Jin *et al.*, 2001). In response to genotoxic stress, *Gadd45 α* is able to initiate a G₂/M block on the cell cycle but is not necessary for the block to occur (Wang *et al.*, 1999). Induction of *Gadd45 α* was only observed in the control heterozygous MEFs and the heterozygous MEFs exposed to IR. In the heterozygous MEFs where p53 expression was induced, this corresponded to an increase in *Gadd45 α* , except in the MEFs exposed to UV (Figure 12f). As these cells would eventually undergo apoptosis, as would the wild type MEFs, it is unclear whether *Gadd45 α* expression is necessary. *Gadd45 α* has been implicated to play a role in apoptosis (Takekawa and Saito, 1998), though it is unclear whether *Gadd45 α* activates apoptosis or whether *Gadd45 α* up-regulation occurs as a consequence of apoptotic response to genotoxic stress (Zhan, 2005). No induction of *Gadd45 α* expression was observed in the control wild type or IR exposed wild type MEFs. As p53 expression was observed in the wild type MEFs exposed to IR and no *Gadd45 α* induction was observed,

it is possible that p53 mechanism of inducing cell cycle checkpoints and DNA repair was independent of Gadd45 α expression.

Apoptotic Susceptibility in MEFs

Wild type and heterozygous Plk4 MEFs were exposed to 40 mJ/cm² UV and subjected to a TUNEL assay to determine if there was a difference in susceptibility to undergo apoptosis. At each of the time points examined, there was no statistical difference between the percentages of MEFs that stained positive for DNA fragmentation characteristic of apoptotic cells (Figure 13). As this experiment was performed using 40 mJ/cm² UV, it is unknown whether there would be a difference in percentages at a lower exposure rate. Subsequently, it is not known the dose of UV where the majority of MEFs start undergoing apoptosis. At a lower dose it could be hypothesized that there would be statistical differences observed with a higher percentage of heterozygous cells escaping apoptosis and promoting oncogenesis. This assumption is made as a microarray experiment comparing wild type and heterozygous MEFs exposed to 40 mJ/cm² UV, 4 hours post exposure showed Cdc25b as being over expressed in the heterozygous MEFs. Cdc25b is essential for mitotic entry when cells recover from a DNA damage checkpoint-induced arrest (van Vugt *et al.*, 2004). Cdc25b's requirement for mitotic entry after DNA damage and its involvement in tumorigenesis will be explained in further detail in the next section.

Transcript Differences in Plk4 MEFs: Response to Ultraviolet Radiation

Transcriptional differences were observed in Plk4 mRNA transcript profiles between wild type and heterozygous MEFs upon exposure to UV. Therefore, it was of interest to gain a further understanding of differences in the transcript profiles of additional genes within the Plk4 MEFs. Microarray analysis was performed comparing wild type and heterozygous MEFs 4 hours post UV exposure. It was discovered that 27 genes presented at least a two fold decrease in transcript profile in the heterozygous MEFs (Table 3), while 84 genes had a least a two fold increase in transcript profile in the heterozygous MEFs (Table 4). As stated above, by far the most unique finding from the microarray data was *Cdc25b* being over expressed in the heterozygous MEFs.

Cell division cycle 25b (*Cdc25b*) is a member of the *Cdc25* phosphatase family that plays a major role in the cell cycle control by dephosphorylating and activating cyclin-dependent kinases at stages during the cell cycle (Burgler *et al.*, 2006). *Cdc25b* plays a role in mitotic entry though its function is dispensible (van Vugt *et al.*, 2004). Ferguson *et al.*, 2005 showed that mice lacking *Cdc25b* were normal for development, cell cycle and DNA damage response and that *Cdc25a* or additional phosphatases could compensate for its loss. In contrast, *Cdc25b* function is essential for resuming the cell cycle after DNA-damage cell cycle arrest (van Vugt *et al.*, 2004). Re-entry of the cell cycle is also reliant on Plk1-dependent degradation of Wee1 (Watanabe *et al.*, 2004), which phosphorylates and inhibits the CDKs. Removal of Wee1 allows *Cdc25b* to more efficiently dephosphorylate and activate cyclin B1/CDK1 (van Vugt *et al.*, 2004). Additionally, over expression of *Cdc25b* can lead to the accelerated exit of cells from the G₂/M transition after the checkpoint has been activated. Though, this acceleration can be

reversed by inhibiting the catalytic activity of Cdc25b using pharmacological inhibitors against Cdc25 (Bugler *et al.*, 2006).

Cdc25b has been identified as being over expressed in a number of human cancers including head and neck cancer (Gasparotto *et al.*, 1997), non-small cell lung cancer (Wu *et al.*, 1998) gastric cancer (Kudo *et al.*, 1997), non-Hodgkins lymphoma (Hernandez *et al.*, 1998), colon cancer (Takemasa *et al.*, 2000), esophagus cancer (Nishioka *et al.*, 2000), breast cancer (Cangi *et al.*, 2000), and ovarian cancer (Broggini *et al.*, 2000). In these types of cancers, over expression of Cdc25b correlated with a higher degree of malignancy and a poorer prognosis for the patient (Kristjansdottir and Rudolph, 2004).

In addition, in an examination of hepatocellular carcinomas (HCC), Cdc25b was one of the most significantly over expressed genes in comparison to non-tumor liver tissue (Chen *et al.*, 2002); while silencing of Cdc25b expression in HCC cell lines has been shown to prevent cell proliferation, migration and invasion and delay xenograft growth (Yan *et al.*, 2008).

It can be hypothesized that over expression of Cdc25b in heterozygous Plk4 mice could contribute to the increased tumorigenesis observed. In response to DNA damage, cell cycle checkpoints are employed to repair any damage to the genome. Loss of an upstream tumor suppressor which targets Cdc25b and Plk1 for repression would contribute to Cdc25b and Plk1 initiating re-entry to the cell cycle without errors in the genome being repaired. Combined with the heterozygous Plk4 MEFs and hepatocytes displaying aberrant spindle formation and abnormal chromosome segregation during mitosis (Ko *et al.*, 2005), it is plausible that these factors could contribute to cellular

transformation leading to an oncogenic state. It will be interesting to examine Cdc25b mRNA and protein levels within heterozygous liver tumors in comparison to normal tissue within both wild type and heterozygous liver samples to see if there is an observable difference in Cdc25b levels. If Cdc25b levels are elevated within heterozygous liver tumors, it provides a possible explanation for increased liver tumor incidence within heterozygous Plk4 mice.

In comparison of the microarray data between normal wild type and heterozygous MEFs and Plk4 MEFs exposed to UV, six genes were over expressed in heterozygous MEFs within both data sets. This indicates that these genes are over expressed in heterozygous MEFs in normal pathways and in response to DNA damage. These genes include T-cell factor 4, villin 1, fetal alzheimer antigen, thrombospondin, transducin-like enhancer of split 1 and sal-like 3.

The T-cell factor/ lymphocyte enhancing factor (TCF/LEF) are a family of transcription factors involved in the Wnt signaling pathway (Polakis, 1999). B-catenin binds TCF4 to activate its transcriptional activity in Wnt signaling and TCF4 has been implicated in neural and limb development (Cho and Dressler, 1998). TCF4 has been shown to transcriptionally activate cell cycle regulating genes such as cyclin D1 and c-myc. As stated above, TCF4 over expression has been implicated in the development of hepatocellular carcinoma (Zhao *et al.*, 2004). As numerous Wnt genes and their targets over expression has been characterized in hepatocellular carcinoma, it is possible that aberrant Wnt regulation could be a contributing factor in the development of liver tumors in heterozygous mice.

Villin 1 has been characterized as an actin-binding protein associated with the striated border of simple columnar epithelium in the body. Villin is believed to function in the bundling, nucleation, capping, and severing of actin filaments, though its exact function is unknown (Friederich *et al.*, 1999). Since the exact cellular function of villin has yet to be fully characterized, it is difficult to speculate as to the exact implications over expression of villin may have in heterozygous MEFs.

Fetal alzheimer antigen (FAC1) was first characterized as being developmentally regulated in the cortex of the brain (Bowser *et al.*, 1995). Subsequent results show FAC1 as a DNA binding protein capable of functioning as a transcription factor (Jordan-Sciutto *et al.*, 1999), and capable of inducing apoptosis by activating caspase 3 (Strachan *et al.*, 2005). Over expression of FAC1 in heterozygous MEFs exposed to UV is rational as these MEFs undergo apoptosis due to UV exposure. Given FAC1's role to activate caspase 3 and initiate apoptotic pathway in normal heterozygous MEFs, it possible to speculate that there is genomic instability within these cells that would mediate the initiation of these pathways. Since the heterozygous MEFs continue to divide, it is also possible that some downstream effector inhibits these apoptotic pathways, continuing the presence of genomic instability leading to cellular transformation.

Thrombospondin is a crucial inhibitor of angiogenesis (Volpert *et al.*, 1997) whose expression is positively regulated by p53 (Dameron *et al.*, 1994). p53 mutations have been extensively characterized in hepatocellular carcinomas (Aguilar *et al.*, 1994). Therefore it is possible that loss of or a mutation in p53 would inhibit thrombospondin from prevent angiogenesis and allowing tumor formation to occur. It would be interesting

to examine levels of both p53 and thrombospondin in hepatocellular carcinomas in heterozygous mice to see if this hypothesis is true.

Transducin-like enhancer of split 1 (TLE1) or Groucho-related gene 1 (GRE1) is a member of the Notch signaling pathway that is a transcriptional repressors of Wnt signaling and other cell fate determination signals (Liu *et al.*, 1996). In a study examining dedifferentiation from a well-differentiated tumor to a moderately-differentiated tumor in hepatocellular carcinomas (HCC), TLE1 was discovered as being over expressed (Midorikawa *et al.*, 2002). TLE1 over expression in HCC may provide for an additional mechanism for tumor formation within heterozygous Plk4 mice. In addition, Allen *et al.*, 2006 used a mouse model to examine TLE1 over expression. TLE1 over expression induced lung adenocarcinoma formation with reduced levels of p53 and increased levels of the receptor tyrosines kinases ErbB1 and ErbB2. Interestingly, in Plk4 heterozygous mice, the second most common site of tumor formation was the lung, with the tumors characterized as adenocarcinomas (Ko *et al.*, 2005). TLE1 over expression and p53 down regulation may provide a mechanism for lung tumor formation in heterozygous Plk4 mice.

Sal-like 3 (SALL3) is a homologue of the *Drosophila* *splat* gene which is required for development of the head and tail segments in an organism (Kohlhase *et al.*, 1999). Loss of SALL3 expression leads to embryonic lethality from failure of cranial nerve formation from the hindbrain (Parrish *et al.*, 2004). Beyond this information, little is known about SALL3 and its functional role within the cell. Therefore it is difficult to make an assumption to the exact role that SALL3 over expression plays within heterozygous MEFs.

Transcriptional Difference between Normal & UV Wild Type and Normal & UV Heterozygous MEFs

To gain an understanding of the transcriptional differences between normal and UV exposed MEFs, the two previous microarray data sets were compared. It was discovered that 171 genes were up-regulated in normal wild type MEFs (Table 5), while 83 genes were down-regulated in the normal wild type MEFs (Table 6). 151 genes were observed to be up-regulated in normal heterozygous MEFs (Table 7), while 24 genes were down-regulated in the normal heterozygous MEFs (Table 8). In addition, there were a number of common genes that were up-regulated in both the normal wild type and normal heterozygous MEFs. Similarly, there were common genes within the UV wild type MEFs and the UV heterozygous MEFs. The differences in the genes that were up-regulated in both the wild type and heterozygous MEFs provide additional clues to possible mechanistic differences, explaining the phenotypic differences observed between wild type and heterozygous MEFs. Likewise, differences observed between the UV wild type MEFs and UV heterozygous MEFs could provide mechanistic pathways to explain possible differences in the MEFs response to ultraviolet radiation.

While this analysis may provide a general survey of the differences between normal and UV exposed MEFs, without secondary validation using northern analysis, RT-PCR or real-time PCR, the validity of the results remains debatable. Proper statistical microarray analysis was unable to be performed due to software limitations with the TIGR software suite. The microarray analysis was performed manually using comparing raw intensity, so it is possible that errors could have been made.

Future Directions

It is necessary to determine the function significance of the interaction between Plk4 and p53. Plk4 is able to phosphorylate p53 on Ser-293 (Swallow *et al.*, 2005). Ser-293 is within the DNA-binding domain of p53 (Bell *et al.*, 2002). It is hypothesized that Plk4 and p53 interact through a feedback mechanism and p53 is able to repress Plk4 function through HDAC. It is assumed that over-expressing Plk4 causing phosphorylation of Ser-293 will inhibit p53's ability to bind the TATA box binding protein to facilitate the recruitment of HDAC to repress Plk4. Additionally, it is of interest to determine how the phosphorylation of Ser-293 affects the conformational structure of p53 and how this affects its function. Furthermore, it is of interest to investigate how the phosphorylation of Ser-293 affect protein levels of known downstream p53 targets and that this phosphorylation could affect p53 function in multiple signaling cascades. Elucidating the functional interaction between p53 and Plk4 will provide a more thorough incite to the observed phenotypic differences between wild type and heterozygous MEFs. This interaction may provide a clue as to why heterozygous Plk4 mice develop cancer at a rate twenty times greater than wild types.

Appendix A

Antibodies used for Western Blotting

Primary Antibody	Species of Origin	Company
Anti-Plk4	Rabbit	Cell Signaling
Anti-Chk1	Mouse	Sigma
Anti-Chk2	Mouse	Sigma
Anti-Cdc25c	Rabbit	Santa Cruz
Anti-Cyclin B1	Rabbit	Sigma
Anti-Gadd45 α	Mouse	Santa Cruz
Anti-p53	Mouse	Sigma
Anti-GAPDH	Rabbit	Santa Cruz

Appendix J: Expression Levels of Down-Regulated Genes in Heterozygous MEFs

Change in Expression

	Change in Expression
Developmental	
Procollagen, type III, alpha 1	-4.6364
Procollagen, type V, alpha 2	-4.1420
Oral-facial-digital syndrome 1 gene homolog	-3.0782
Procollagen, type I, alpha 2	-2.9648
Metabolism	
Stearoyl-Coenzyme A desaturase 2	-2.4729
Unknown Function	
Mus musculus mVL30-1 retroelement mRNA sequence	-2.5566
Transmembrane protein 34	-2.5241
Mus musculus 0 day neonate cerebellum cDNA	-2.3000
Hypothetical protein LOC639390	-2.2121

Appendix K: Expression Levels of Up-Regulated Genes in Heterozygous MEFs

	Change in Expression	Metabolism	Change in Expression
Cell Cycle			
Casein kinase II	5.8040	N-acylsphingosine amidohydrolase (acid ceramidase) like	6.0539
Protein phosphatase 1F (PP2C domain containing)	4.8644	Leucyl/cystinyl aminopeptidase	4.8539
Squamous cell carcinoma antigen recognized by T-cells	4.6888	Galactose-4-epimerase	4.7700
Origin recognition complex, subunit 4-like	4.5661	L-2-hydroxyglutarate dehydrogenase	4.6257
Inhibitor of DNA binding 2	4.4323	Fatty acid desaturase 3	4.2976
Protein phosphatase 5	4.0765	Carbohydrate sulfotransferase 2	4.2926
Prohibitin	3.0459	Stearyl-Coenzyme A desaturase 1	3.9806
Cyclin dependent kinase 8	3.0094	CCR4 carbon catabolite repression like 4	3.7939
Phosphatidylinositol 3-kinase	2.1636	protein kinase, cAMP dependent regulatory, type I beta	3.3199
Pituitary tumor-transforming 1	1.9518		
Heterogeneous nuclear ribonucleoprotein C	2.5962	DNA Repair	
heme binding protein 2	3.8955	Thymine DNA glycosylase	2.0156
TVMSFG fibroblast growth factor receptor 1 precursor	2.2643	Uracil-DNA glycosylase	4.1846
Neuropilin	3.0956	MutS homolog 6	2.1811
Developmental			
Sal-like 3	7.9335	Transcriptional/Translational Regulation	
Transducin-like enhancer of split 1	6.7010	Transcription factor A	2.0680
T-cell factor 4	4.7804	Zinc finger protein 689	3.0464
Inositol 1,4,5-triphosphate receptor 5	3.6909	Transmembrane and tetratricopeptide repeat containing ;	2.2096
Procollagen, type VI, alpha 3	3.5828	GLIS family zinc finger 3	2.6233
Fetal Alzheimer antigen	3.3594	Phenylalanine-tRNA synthetase 2	3.0678
WNT1 inducible signaling pathway protein 1	3.2886	Glutamyl-prolyl-tRNA synthetase	3.3065
T-box transcription factor Tbx15	2.9248	Highly similar to CBP_MOUSE CREB-binding protein	3.7483
Nuclear factor I/X	2.8883	Tetratricopeptide repeat domain 1	4.0003
Thrombospondin 2	2.5437	CysteinyI -tRNA synthetase	4.8072
Osteopontin	2.4717	Negative elongation factor B	4.2456
Fukuyama type congenital muscular dystrophy homolog	2.2362		
Nuclear receptor co-repressor 1	4.4658		

Appendix K: Expression Levels of Up-Regulated Genes in Heterozygous MEFs Cont.

	Change in Expression	Cellular/Ion Transport	Change in Expression
DNA Methylation			
SET domain ERG-associated histone methyltransferase	2.0889	Pleckstrin	6.0575
SAP30 binding protein	2.9834	Calcium binding and coiled coil domain 1	5.6489
		Aquaporin-1	4.4128
Miscellaneous Cellular Functions		Solute carrier family 6	4.4110
Thyroid hormone receptor interactor 11	5.8691	Exocyst complex component 3	3.9296
Smg-6 homolog	5.3375	Protein-coupled receptor 19	3.8281
Talin 2	5.2780	Solute carrier family 39	3.5028
Tomoregulin 1	5.1116	Frequenin homolog	3.1881
Syntaxin 18	5.0970	Serine Hydrolase like	3.1718
Channel-interacting PDZ domain protein	4.9504	Solute carrier family 14	3.0842
Inositol hexaphosphate kinase 1	4.8086	Translocator of inner mitochondrial membrane	2.7129
Multiple PDZ domain protein	4.0596	ATPase, Ca++ transporting, plasma membrane 2	2.4328
Myosin heavy chain 10	3.8880	Transient receptor potential cation channel, subfamily M,	1.9917
CDC42 effector protein (Rho GTPase binding) 2	3.5581		
Zinc finger protein 507	3.4688		
Zinc finger protein 689	3.4636		
Ring finger protein 11	3.1199		
GC-rich sequence DNA-binding factor homolog candidate	3.0984		
Villin	2.9808		
3-phosphoglycerate dehydrogenase	2.9427		
Olfactory receptor 202	2.9278		
Discs, large homolog 5	2.9094		
2'-phosphodiesterase	2.8426		
Heat shock protein 1	2.7243		
Similar to crooked neck protein	2.5873		
Oxysterol binding protein like protein 9	2.5501		
Mitochondrial ribosomal protein L50	2.2540		
Proteasome (prosome, macropain) 26S subunit, non-ATP	2.2031		
Coiled Coil domain containing 131	6.4372		
WD repeat domain 50	4.9252		
Spetex-2E protein	4.6574		
Zinc Finger Protein 451	4.1537		
aarF domain containing kinase 1 (Adck1)	3.4641		
AHNAK nucleoprotein	3.2688		
Arginine/serine-rich coiled-coil 1	2.9404		
HD domain containing 3 (Hdccc3)	2.7345		
Myotubularin related protein 7	2.4370		
NICE-5 protein	2.1272		

Appendix L: Expression Levels of Down-Regulated Genes in Heterozygous MEFs upon UV Exposure

	Change in Expression	Change in Expression
Cell Cycle		
CLIP-associating protein CLASP2 isoform a (Clasp2)	-2.1851174	-2.253557
centromere protein P (CENPP)	-2.271258133	
tousled-like kinase 1	-3.1221408	-2.227575
DNA Damage/DNA Repair		
Rad51-like 3 (RAD51)	-3.2187268	
Essential meiotic endonuclease (Eme2)	-2.44656925	-2.188290593
excision repair cross-complementing rodent repair deficiency, complementation group 6 (Ercc6)	-2.108886433	
Transcription/Translation		
General transcription factor II A, 1 isoform 1 (Gtf2a1)	-2.0738409	-2.252575267
Polypyrimidine tract binding protein 2 (Ptbp2)	-2.2659343	-2.3487106
MIF4G domain containing (Mif4gd)	-2.4006736	-2.63721535
		-2.346700133
Cell Signaling		
Phosphatidylinositol-4-phosphate 5-kinase, type II, alpha (Pip5k2a)	-2.2464884	-2.235478867
Lymphocyte protein tyrosine kinase (Lck)	-2.520506933	
Cellular Transport		
Complement component 3a receptor 1 (C3ar1)	-2.4551529	-2.2936206
Membrane-spanning 4-domains, subfamily A, member 4B (Ms4a4b)	-3.3053385	-2.23249735
Glutamate receptor, ionotropic, AMPA4 (alpha 4) (Gria4)	-2.197512433	-2.1057106
		-3.1265202
Developmental		
Developing brain homeobox 1 (Dbx1)	-2.1851174	-2.253557
DNA Binding		
Thymocyte selection-associated HMG box (TOX)	-3.1221408	-2.227575
Epigenetics		
Ring finger protein 20	-2.44656925	-2.188290593
Metabolism		
Neuraminidase 1 (NEU1)	-2.0738409	-2.252575267
Alpase, class VI, type 11C isoform a (Atp11c)	-2.2659343	-2.3487106
Phosphodiesterase 3B, cGMP-inhibited (Pde3b)	-2.2659343	-2.63721535
DnaJ (Hsp40) homolog, subfamily C, member 1 (Dnajc1)	-2.4006736	-2.346700133
Unknown Function		
Testis-specific LRR protein	-2.2464884	-2.235478867
Leucine rich repeat containing 18 (Lrrc18)	-2.520506933	
Hypothetical protein LOC236312		-2.2936206
C21orf19-like protein		-2.23249735
Hypothetical protein LOC66132	-2.4551529	-2.1057106
Zinc finger protein 655 isoform a (Zip655)	-3.3053385	-3.1265202

Appendix M: Expression Levels of Up-Regulated Genes in Heterozygous MEFs upon UV Exposure

	Change in Expression	Change in Expression
Cell Cycle		
Cell division cell 25B; Cdc25B		2.5406
SCY1-like 1		2.2866
Protein phosphatase 2, regulatory subunit B", alpha; (PPP2R2A)		3.0918
Transcription factor ELYS; AT hook containing transcription factor 1 (Ahctf1)		2.2541
Apoptosis		
WW domain-containing oxidoreductase (Wwox) (Wox1)		2.9443
CASP2 and RIPK1 domain containing adaptor with death domain (Cradd) (RAIDD)		3.4588
Transducin-like enhancer of split 1; Groucho-Related Gene 1		3.0116
Tumor necrosis factor, alpha-induced protein 3 (A20)		2.0551
Notch gene homolog 2 (Notch2)		2.2404
bromodomain PHD finger transcription factor (Bptf); FETAL ALZHEIMER ANTIGEN forehead box O3a (Foxo3a)		2.1736
DNA Damage		
mitogen activated protein kinase kinase 5 (MAP2K5)		3.0437
Fanconi anemia, complementation group M (Fancm)		3.7131
Tumorigenesis		
deleted in bladder cancer chromosome region candidate 1 (DBC1)		5.3918
cadherin 6		4.8852
Rho-related BTB domain containing 1 (Rhotb1)		3.1603
Epigenetics		
2.8501 sa1-like protein 3		3.8107
2.7101 TOX high mobility group box family member 3 (Tox3)		2.1824
3.3581 Cat eye syndrome critical region protein 2 isoform 9 (Cecc2)		2.2149
3.8073 synovial sarcoma translocation, Chromosome 18 (Sst18)		2.2425
Transcriptional/Translational Regulation		
2.6092 WW domain-containing protein 2		2.2436
2.4479 avian musculoaponeurotic fibrosarcoma (v-maf) AS42 oncogene homolog		2.2737
3.6890 phenylalanine-tRNA synthetase 2 (mitochondrial) (Fars2)		2.2984
2.0954 WW domain-containing protein 4 (Wbp4)		2.3460
3.2719 GLIS family zinc finger 3 (Glis3)		
5.0646 cAMP responsive element binding protein 3 like-2 (Creb3l2)		
2.7962		
Cellular Signaling		
Estrogen related receptor, beta (Esrrb)		
2.4029 Eukaryotic translation initiation factor 4 gamma, 3 (Eif4g3)		
2.6582 Rap guanine nucleotide exchange factor (GEF) 6 (Rapgef6)		
Unc93 homolog B (Unc93b1)		
Transmembrane protein 32 (Tmem32)		
3.0688 Bassoon protein (BSN); zinc finger protein 231 (ZNF231)		
2.5016 RUN and FYVE domain-containing 2 (Ruly2)		
2.3125 Nuclear receptor co-repressor 1 (Nco1)		
Neurexophilin 2 (Nxph2)		
RNA-binding region containing protein 2 (Rnpc2) (Caper)		
Plectstrin (Plek)		
Nuclear receptor subfamily 2, group F, member 2 isoform 2		
Activin receptor IIA (Acvr2a)		

Appendix M: Expression Levels of Up-Regulated Genes in Heterozygous MEFs upon UV Exposure Cont.

	Change in Expression	Change in Expression
Metabolism		
Gamma-aminobutyric acid (GABA-A) receptor, subunit gamma.2 isoform 1		3.1657
Glutathione reductase 1 (Gsr)		5.0787
Leucyl/cystinyl aminopeptidase (Lnpep) (IRAP)		2.2192
Fatty acid desaturase 3 (Fads)		2.5815
Mannosidase alpha class 2B member 2 (Man2b2)		2.8505
Phosphatidylinositol glycan, class A (Piga)		2.0607
ADP-ribosylation factor related protein 2 (Arf15)		2.3679
SH3-domain GRB2-like (endophilin) interacting protein 1 (SGIP1)		2.5040
Dipeptidylpeptidase 8 (Dpp8)		3.7469
Dual specificity phosphatase 27 (Dusp27)		3.7494
Xylosyltransferase 1 (Xytl1)		
Developmental		
2.5693 Thrombospondin 2		
2.6765 Frizzled 5 precursor (FZD5)		
2.4543 T-cell factor 4 (Tcf4)		
2.4122 Statmin-like 2		
2.2077 Odd Ozten-m homolog 3 (Odz3)		
2.0879 Chemokine-like factor super family 3 (CKLFSF3);		
2.0393 Transducin-like enhancer protein 3 isoform 1 (Tle3)		
3.1163 ADAMTS-like 3 (Adamts3)		
3.4002 Angiopoietin-like 2		
3.0121 SWI/SNF-related matrix associated actin dependent regulator of chromatin,		
4.7743 subfamily a, containing DEAD/H box 1 (Smarca1)		
Miscellaneous Function		
CDC42 effector protein (Rho GTPase binding) 4 (CDC42EP4) (binder of Rho GTPases)		2.8581
2.3188 Pleckstrin homology domain containing, family F (with FYVE domain) member 1 (Plekhf1)		2.7558
2.0461 Similar to high-mobility group box 3		2.8033
2.1037 CD96 antigen (CD96)		2.8583
3.0331 FERM, RhoGEF and pleckstrin domain protein 2 (FGD2)		2.6772
5.3912 Ubiquitin specific protease 31 (Usp31)		2.2304
Kalirin, RhoGEF kinase (Kalrn)		3.0801
DCN1, defective in cullin neddylation 1, domain containing 2 isoform a (Dcun1d2)		3.4097
Villin 1 (Vil1)		3.3178
Cellular Transport		
Protein phosphatase 1F (PP2C domain containing) (Ppm1f)		
Frequenin homolog (Freq)		
Myotubularin related protein 10 (Mtmr10)		
Oxysterol binding protein (Osbp)		
Ring finger protein 17 (Rrf17)

VITA AUCTORIS

NAME: Alan James Morettin

PLACE OF BIRTH: Sault Ste. Marie, ON

YEAR OF BIRTH: 1980

EDUCATION: St. Mary's College, Sault Ste. Marie, Ontario

1994-1999

Lake Superior State University, Sault Ste. Marie, MI

1999-2003 B.Sc.

University of Windsor, Windsor, Ontario

2005-2008 M.Sc.
