Experimental petrology constraints on the recycling of mafic cumulate: a focus on Cr-spinel from the Rum Eastern Layered Intrusion, Scotland

Julien Leuthold, Jonathan D. Blundy, Richard A. Brooker

Abstract:

Reactive liquid flow is a common process in layered intrusions and more generally in episodically refilled magma chambers. Interaction between newly injected melt and cumulates, or crystal mushes, perturbs the liquid line of descent of the melt and modifies mineral chemistry and texture. We present insights into the effects of assimilation of mafic cumulate rocks (gabbro, troctolite) by co-genetic Mg-rich basalt liquid using one-atmosphere, controlled- fO_2 phase equilibrium experiments on picritic parental liquid to the Rum layered intrusion, Scotland. For picrite-only experiments at $fO_2=QFM$, Cr-spinel ($Cr\# = Cr/[Cr + Al + Fe^{3+}] = 0.43$; $Fe\# = Fe^{2+}/[Mg + Fe^{2+}] = 0.32$) saturates at 1320°C, olivine (Fo_{88}) at ~1290°C, plagioclase (An_{77}) at 1200°C and clinopyroxene ($Mg\#$: 0.81) at 1180°C. In melting experiments on picrite + gabbro mixtures, plagioclase (1230°C, An_{80}) and clinopyroxene (1200°C, $Mg\#$: 0.85) saturation temperature and mode are increased significantly. Cr-spinel in these experiments has a distinctive, low $Fe\#$. In melting experiments on picrite + troctolite mixtures, plagioclase (An_{86}) saturates at 1240°C and clinopyroxene ($Mg\#$: 0.81) at 1170°C. Al-rich spinel crystallizes at high temperature (>1220°C) and becomes more Cr-rich upon cooling, reaching the highest $Cr\# = 0.47$ at 1180°C (0.54 at QFM-1.2). The experimental results confirm that plagioclase and clinopyroxene stability plays a major role in determining the composition of coexisting spinel. Comparing our experimental results to the Rum Eastern Layered Intrusion, we propose a model for the precipitation of spinel from picrite-troctolite hybrid melt that is compatible with the observed olivine, plagioclase and clinopyroxene chemistry.

Introduction:

Magma chambers are built up incrementally by repeated injections of melt into a growing crustal reservoir (e.g. Saint-Blanquat et al., 2011; Leuthold et al., 2012). In open magmatic systems, successive recharge of hot melt rejuvenates and assimilates resident crystal mush and cumulates (Tronnes, 1990; Hildreth and Moorbath, 1988; Bédard and Hébert, 1998; Dungan and Davidson, 2004; Leuthold et al., 2014a, 2014b). This process plays a critical role in the construction of large magma chambers via accumulation of successive sills or dykes (Annen et al., 2006; Solano et al., 2012) and is responsible for modification of percolating melt composition and cumulate/crystal mush mineral chemistry, texture and abundance. Interaction between resident cumulate mush and newly injected liquid (*reactive liquid flow*, or *infiltration metasomatism*, as defined by Irvine, 1980) modify both the cumulate and the reactive liquid, changing their modal composition, chemistry and texture (Figure 1) (Leuthold et al., 2014a). O'Hara and Herzberg (2002) stated that despite its importance, the assimilation of mafic crystals/cumulates by mafic melts is frequently underestimated. The lack of mineralogical, chemical and isotopic contrast between reactants can make it difficult to detect and distinguish crystal-melt interaction from simple crystallisation. Nevertheless, modifications of mineral chemistry and texture and melt composition have been revealed by detailed studies of intrusive rocks in a variety of geodynamic settings (e.g. Hildreth and Moorbath 1988; Bédard and Hébert, 1998; Leuthold et al., 2014a, 2014b).

In this study, we will examine the consequences of *reactive liquid flow* on the newly injected hot liquid whose composition is modified by assimilation of co-genetic mafic crystal mush and cumulate (troctolite,

gabbro). We show that this has important consequences for the phase equilibria and chemistry, particularly spinel compositions. Spinel crystallize down temperature from the liquidus for a wide range of mafic magmas, in different tectonic environments (Roeder, 1994). Understanding Cr-spinel (chromite) petrogenesis is of particular importance in layered intrusions, where chromitites are associated with platinum group element (PGE) ore deposits (e.g. Power et al., 2000; Grieko et al., 2004; O'Driscoll et al., 2009a, Latypov et al., 2013). Chromitite formation has long been debated and several petrogenetic models exist (see Campbell and Murck, 1993; Naldrett et al., 2012), including: liquid immiscibility (McDonald, 1965), oxidation (Ulmer, 1969; Cameron and Desborough, 1969), pressure fluctuations (Lipin, 1993), and assimilation of silicic crustal rock by mafic magma (Irvine, 1975; Spandler et al., 2005). Studying ophiolites, Bédard and Hébert (1998) have demonstrated the formation of chromitite via assimilation of crustal pyroxenite and gabbro by picrite melt intrusion. However, the most widely accepted model involves Cr-spinel saturation by mixing and hybridization of a newly injected olivine-saturated magma with a cogenetic, differentiated, more siliceous melt (Irvine, 1977).

We will use the Rum Eastern Layered Intrusion (Scotland) as a case study. This shallow, open-system, layered intrusion shows some of the world's best examples of *reactive liquid flow* (Leuthold et al., 2014a). The hybridization model of Irvine (1977) was applied to the Rum Eastern Layered Intrusion chromitites layers by Young (1984). O'Driscoll et al. (2009b) proposed an alternative model for the same chromitite occurrences on Rum whereby new picritic liquid assimilated troctolite cumulate. We will run a series of experiments to test the effect of gabbro and troctolite assimilation on the picrite liquid line of descent. We have chosen to run our experiments at atmospheric pressure (0.1 MPa) because of the ease of controlling oxygen fugacity, a key magmatic variable, in a gas mixing furnaces and the very low emplacement pressure of the Rum Eastern Layered Intrusion. The present experiments allow us to evaluate different hypotheses regarding the origin of chromitites on Rum, but with application to other layered intrusions and spreading ridges.

The Rum Eastern Layered Intrusion:

The Paleogene Rum Igneous Complex is part of the British Tertiary Volcanic Province and the North Atlantic Igneous Province (Emeleus and Gyopari 1992; Bell and Williamson 2002), dated at 60.53 ± 0.08 Ma by Hamilton et al. (1998), and related to the proto-Iceland plume (Kent 1995; Saunders et al. 1997; Bell and Williamson 2002). The Complex was intruded along the unconformity between the Archaean Lewisian gneiss and the overlying Precambrian arkoses of the Torridonian Group, at a pressure of 15 ± 5 MPa (Holness, 1999). It is a bimodal intrusive complex with an initial episode of felsic activity and subsequent emplacement of a layered ultramafic to mafic braided sill complex (Leuthold et al., 2014b) into a caldera (Emeleus, 1997). Successive replenishments by mafic magma have built alternating olivine-rich and plagioclase-rich cumulate layers (Appendix figure 1). The Eastern Layered Intrusion is composed of a 750m-thick cumulate pile, divided into 15 intrusive units (Appendix figure 2). Each unit is formed of *peridotite* (olivine-rich cumulate) overlain by plagioclase-bearing cumulate (troctolite, gabbro and poikilitic gabbro, in variable proportions; known collectively as *allivalite*). The sill complex was fed by new magma injections along the Central Zone fault originating from a magma source at a depth of several kilometres (Emeleus et al., 1996). The intrusive units were thought originally to have formed by fractionation of individual batches of olivine-phyric picrite melts (Brown, 1956; Upton et al., 2002). Later studies showed that many units are composite and formed from successive, relatively small batches of either picritic or basaltic magma (Renner and Palacz, 1987; Bédard et al., 1988;

1 Holness and Winpenny, 2009). The cumulates themselves were later intruded by picritic magma (Bédard et al.,
2 1988). Thus the Rum Eastern Layered Intrusion is an excellent example of *reactive liquid flow processes* (Figure
3 1) in an open magmatic system. Some of the best evidence of partial melting of resident troctolite and gabbro
4 rocks by intrusive picrite liquids and subsequent melt hybridization include: Cr-spinel-bearing anorthosite
5 produced after picrite percolation through troctolite (O'Driscoll et al., 2009b, 2010); formation of poikilitic
6 gabbro with clinopyroxene oikocrysts (ca. 1 cm across) formed in gabbro percolated by hybrid melt (Leuthold et
7 al., 2014a); and bulk rock reversals in isotopic composition (Palacz and Tait, 1985). Some troctolite and
8 peridotite might also be the products of such modifications, representing highly reacted cumulates (Leuthold et
9 al., 2014a).

14 **Methods:**

15 Starting materials:

16 Starting materials consisted of finely ground rock powders from four samples of the Rum Eastern Layered
17 Intrusion (Table 1): a near-primary olivine-phyric picritic dyke (B62/2; McClurg, 1982, unpublished PhD. thesis;
18 Upton et al., 2002), a basaltic dyke (11JL33; Leuthold et al., 2014a), a gabbro (11JL27; Leuthold et al., 2014a)
19 and a troctolite (11JL16, Leuthold et al., 2014a). B62/2 contains euhedral to subhedral olivine phenocrysts (~10
20 vol%, Fo_{85.9-80.5}) in a fine-grained matrix composed of granular olivine (Fo₇₈₋₇₅) + plagioclase (An₆₉₋₆₆) +
21 clinopyroxene (Mg#¹ = 0.82-0.71) + magnetite, with minor amounts of amphibole, mica and Cr-spinel (Cr#² =
22 0.32-0.43). B62/2 has a mildly alkalic, high MgO (Mg#: 0.67) composition that is a close match to the inferred
23 Rum parental liquid (Upton et al., 2002). B62/2 is thought to have originated from low-degree partial melting of
24 a lherzolite source close to the garnet-spinel transition within the proto-Icelandic mantle plume, with minor
25 subsequent crustal contamination. Recent Icelandic picrites have a similar composition to B62/2 (Hémond et al.,
26 1993). Basaltic dyke starting material 11JL33 has a composition (Mg#: 0.51) very similar to those studied by
27 Toplis and Carroll (1995) and Thy et al. (2006) in the context of the liquid line of descent of the Skaergaard
28 layered intrusion (Greenland). 11JL33 is composed of normally zoned plagioclase (An₆₁₋₁₅), clinopyroxene (Mg#
29 = 0.73 to 0.65), K-feldspar, magnetite with ilmenite exsolution (3 vol%), titanite, zircon, epidote, and chlorite.
30 According to McClurg (1982, unpublished PhD. Thesis) and Upton et al. (2002) B62/2 picrite and 11JL33 basalt
31 represent co-existing mafic end-member liquid compositions (Figure 2). A few picritic dykes at Rum (e.g. M9)
32 have accumulated olivine and spinel macrocrysts crystallized in a near-Moho reservoir (Upton et al., 2002);
33 these deeper intrusions were not considered experimentally but are discussed in terms of petrogenesis.

34 Partial melts of troctolite and gabbro co-existed with intrusive picrite (Leuthold et al., 2014a). To study
35 experimentally the effect of mafic crystal assimilation into picrite, we used as starting material mechanical
36 mixtures (hybrids) of picrite (B62/2) with gabbro (11JL27) and troctolite (11JL16). Gabbro 11JL27 is composed
37 of 13 vol% olivine, 53 vol% plagioclase and 34 vol% clinopyroxene. Troctolite 11JL16 is composed of 26 vol%
38 olivine, 0.2 vol% Cr-spinel, 70 vol% plagioclase and 4 vol% clinopyroxene (see Leuthold et al. [2014a] for
39 details). The hybrid series of experiments is intended to evaluate the effect of variable proportions of mafic rock
40 assimilation (0, 50 and 100%) on the reactive picrite liquid line of descent.

Experiments:

Experiments #27 to #109 were performed at the University of Bristol in GERO™ vertical furnaces at atmospheric pressure. We controlled the oxygen fugacity (fO_2) by employing mixed CO and CO₂ gases controlled by Alicat Scientific flow controllers. The fO_2 was measured before and after each experiment with SIRO2™ solid zirconia oxygen sensors. The temperature was monitored adjacent to the sample with a Type B thermocouple. Additional experiments (#110 to #173) were run at ETH Zurich using a similar GERO™ vertical furnaces with controlled fO_2 conditions by mixing CO₂ and H₂. Results from the two laboratories are mutually consistent.

The starting material powder was mixed with a small amount of ultrapure water, as a binder, and mounted on a thin Pt-Rh wire loop. Most individual mounts were initially melted at supraliquidus conditions and then quenched to a glass. In isothermal experiments, the crystal-free glass was taken directly to the desired temperature at fO_2 of QFM-2.2 to QFM+1.8³ (see Appendix figure 2). In cooling-rate experiments, different cooling modes were used. In these experiments, we progressively ramped the temperature (<100°C/h), whilst adjusting fO_2 . This method is very similar to that used by Fisk and Bence (1980). In both cases, we also used the temperature oscillation ($\pm 10^\circ\text{C}$) technique (Mills et al., 2011; Mills and Gardner, 2013) to grow coarse crystals. Following ramped cooling the sample was left to equilibrate typically for 5 to 15h and then drop-quenched into water. Crystals show no evidence of quench overgrowths and the quenched liquid is pure glass. High spatial resolution core-rim chemical profiles show no rim zoning between crystal pairs or with liquid. These observations are considered to indicate both equilibrium and effective quenching without re-equilibration or recrystallization (e.g. Sisson and Grove, 1993b). For comparison with fully molten starting material, we have also run a few melting experiments, where the starting material was equilibrated at a temperature below the liquidus. Additionally, we have also reacted picrite with troctolite. Samples were melted above the liquidus, quenched and equilibrated at 1250 and 1220°C at QFM-1.2 prior to juxtaposition and reaction for 2 to 18 hours. Experimental run conditions and products are given in the Tables 2 to 5, schematic cooling paths are presented in the Appendix figure 2, selected BSE images are shown in Figure 3 and mineral stability fields are presented in Figure 4.

Analyses:

Run products were mounted in EPOFIX™ resin blocks and polished to 1 μm . We used the University of Bristol Hitachi S-3500N and the ETH Zürich Jeol JSM-6390 LA scanning electron microscopes (SEM), both equipped with Thermo Fisher Noran energy dispersive spectrometer (EDS x-ray detector), to acquire backscatter electron (BSE) images and characteristic X-ray maps at 20kV that were used to determine phase assemblages and proportions using *imageJ* software. Repeated analyses on the same samples provided an estimate of the uncertainties on mineral proportions, which were typically less than ± 5 vol%. The Bristol JEOL 8530F FEG-EMPA operating at low voltage was required to measure accurately the major element composition of small phases, without contamination by fluorescence from the surrounding glass (Saunders et al., 2014). The operating conditions were 10kV, 10nA and a beam size of 0.1 μm for crystals (spinel has a typical diameter of ~ 2 μm) and 5-10 μm for glass. Natural and synthetic silicates and oxides were used as primary and secondary standards. The EMP analyses of the Pt-13Rh wire showed very limited Fe gain during short experiments (<1h) at high

³ [QFM: quartz-fayalite-magnetite equilibrium, corresponding to Ni-NiO-0.8 \(NNO-0.8\)](#)

1 temperature (1260°C). After an extreme run duration of 60 hours at 1170°C and QFM conditions, the glass once
2 remolten above the liquidus had only lost 1 wt% FeO_{tot} (10% relative). The glass Fe³⁺/Fe_{tot} ratio was calculated
3 using Kress and Carmichael (1991) algorithm at the experimental temperature and *f*O₂. Glass compositions in
4 fully molten and subsequently re-equilibrated experiments and in partially molten powder are identical, but
5 crystals are strongly zoned in the later and difficult to interpret. Thus, we have decided to focus on the results
6 from fully molten starting materials. Analytical results are presented in Appendix table 1.
7
8
9

10 **Liquid line of descent:**

11 Phase proportions and compositions:

12 The mineral modes are given in Tables 2 to 5 and Figure 5; mineral compositions are given in Appendix
13 table 1 and Figure 6. From 1160°C, the crystals form a connected framework in picrite experiments (46 vol%
14 liquid).
15
16

17 Picritic dyke B62/2, considered as the most probable parental liquid for Rum (Leuthold et al., 2014a), has
18 liquidus and solidus temperatures of 1320°C and 1110°C respectively (Figure 4). Olivine and Cr-spinel are the
19 liquidus phases, plagioclase saturates at 1200°C and clinopyroxene at 1180°C (Figure 4 and Appendix figure 3).
20 The liquid fraction strongly decreases once plagioclase and clinopyroxene saturate (Figure 5). Upon cooling, the
21 B62/2 experimental glasses become basaltic and finally basanitic (Figure 2). Their compositions are identical to
22 Iceland plume lavas (Hémond et al., 1993) (Figure 2). As expected, the olivine forsterite content is higher under
23 more oxidized conditions.
24
25

26 Basalt 11JL33, which is similar in composition to other basaltic dykes on Rum (McClurg, 1982,
27 unpublished PhD thesis) has a liquidus temperature of 1165°C, when olivine, spinel and plagioclase co-saturate
28 (Figures 4, 5 and Appendix figure 3). The 11JL33 experiments corroborate the Toplis and Carroll (1995) and
29 Thy et al. (2006) experiments with comparable saturation temperatures and modes for olivine, plagioclase and
30 clinopyroxene.
31
32

33 Gabbro assimilation by picrite tends to reduce the liquidus and increase the solidus temperatures (Figures 4,
34 5). Olivine saturation is delayed in comparison to the picrite starting material and is modally less important,
35 resulting in a higher Mg# at high melt fractions (Figures 2, 6), amplified by the low liquid FeO content. The
36 glass is CaO- and Al₂O₃-enriched which increases plagioclase and clinopyroxene saturation temperatures
37 (Figures 2, 4 and Appendix figure 3).
38
39

40 Troctolite assimilation increases the liquidus and solidus temperatures of picrite (Figures 4, 5), as well as the
41 glass Al₂O₃ and MgO contents. The plagioclase, olivine and spinel saturation temperatures are all increased
42 while clinopyroxene stability is decreased (Figures 4, 5).
43
44

45 **Spinel**

46 Crystals are typically euhedral and ~2µm across. Only spinel in contact with glass was considered, to
47 guarantee equilibration with melt during cooling-rate experiments. Cr-spinel Fe-Mg re-equilibration with melt is
48 relatively rapid (Scowen et al., 1991); nevertheless core and rim analyses obtained by the FEG-EMPA reveal
49 absence of any zoning that may be related to quenching. B62/2 picrite high temperature QFM crystals (1280°C),
50 co-crystallizing with olivine, are Cr-rich (Cr# = 0.43, Al/(Al+Cr) = 0.53). From 1230-1200 to 1150°C the spinel
51 Al/(Al+Cr) progressively decreases from 0.65 to 0.54 (Figure 7a). Upon further cooling along the QFM
52

60
61
62
63
64
65

1 equilibrium, the Fe^{3+} content strongly increases. At and below 1140°C, Fe-enrichment rapidly increases and
2 magnetite becomes the stable spinel phase. Crystals in cooling-rate experiments have slightly higher Cr# and
3 lower $\text{Fe}^{\#4}$ than in isothermal experiments at the same temperature. The Fe# increases upon cooling (from 0.32
4 at 1280°C, to 0.78 at 1110°C), together with TiO_2 (Figure 7). Spinel is distinctly more abundant in oxidized
5 experiments (~1 vol%) (Figure 3e). Conversely, it is rare and corroded in reduced (QFM-2.2) experiments
6 (Figure 3f) and is absent in clinopyroxene-bearing runs. The $\text{Fe}^{2+}/\text{Fe}^{3+}$ ratio of spinel is strongly affected by the
7 $f\text{O}_2$, with higher Fe^{3+} content and Fe# under oxidized conditions (Figures 7a, 8c).
8
9

10 In the basaltic experiments, minor spinel (maximal Cr# = 0.46 at 1150°C, QFM) saturates at 1160°C. At
11 1090°C, abundant titanomagnetite crystallizes (7 vol%) and the liquid has a ferrogabbro composition (Figures 2
12 and 7b). Under reduced conditions, Cr-spinel and titanomagnetite co-exist.
13
14

15 Spinel in picrite-gabbro and gabbro experiments follow very similar trends. They have a slightly lower
16 $\text{Al}/(\text{Cr}+\text{Al})$ and higher Fe# than the B62/2 picrite (Figure 7a) consistent with variation in starting compositions.
17 The gabbro spinel Mg# and Cr# vary within a limited range. Noticeably, the Fe^{3+} does not increase from liquidus
18 to solidus conditions (Figure 8).
19
20

21 Along the picrite-troctolite QFM liquid line of descent, Cr# increases from 0.11 (Al-spinel) to 0.48 (Cr-
22 spinel) in the interval from 1230 (58 vol% melt) to 1190°C (28 vol% melt). Concomitantly, the Fe# strongly
23 increases to 0.47 (Figure 7a, 8). At QFM-1.2, Cr# reaches a maximum value of 0.54 at 1180°C. At similar
24 temperatures, the TiO_2 concentration is slightly higher in picrite-troctolite experiments compared to picrite
25 experiments, despite the lower Ti-content of the starting material, most probably related to a lower melt fraction
26 (Figure 7b). Spinel in the troctolite-only experiment at 1210°C (5 vol% liquid) is strongly Al-enriched
27 ($\text{Al}/[\text{Al}+\text{Cr}] = 0.98$).
28
29
30

31 In picrite-troctolite experiment reacted for 5 hours at 1250°C, we observe a 200 μm reaction rim with olivine
32 and spinel at the interface between the two magmas (Figure 9). Upon longer reaction times, this rim disappears.
33 The spinel modal abundance varies from 1.2 vol% in troctolite to 3.5 vol% in the inner part of the reaction rim to
34 0.1vol% in the picrite. The spinel chemistry spatially evolves from Al-spinel in troctolite to Cr-spinel in the
35 picrite. The two extremes in composition are identical to the picrite and troctolite experiments equilibrated under
36 similar conditions (Figure 8). At the same time, the liquid Al_2O_3 content decreases from 18.4 to 14.2 wt% and
37 the Cr_2O_3 concentration increases from 0 to 0.13wt%.
38
39
40
41
42
43

44 Olivine

45 The olivine proportion in picrite experiments increases from 3 vol% at 1280°C to ~15 vol% at 1110°C
46 (Figure 5). The forsterite (Fo) content varies very little until clinopyroxene saturation at 1180°C (Figure 6). At
47 identical melt volume fraction, Fo is slightly higher in oxidized experiments due to reduction in $\text{Fe}^{2+}/\text{Fe}^{3+}$ ratio in
48 the coexisting melt. Olivine is zoned in cooling-rate experiments, especially when equilibrated at a low final
49 temperature. However, rim composition are identical to olivine crystals in isothermal experiments. In the basaltic
50 experiments, olivine saturates at 1160°C. The crystals have the lowest forsterite content (down to 0.54).
51
52
53

54 At identical temperatures, the olivine fraction is lower in picrite-gabbro (50-50 mix) and gabbro experiments
55 (Figure 3d). Glass in picrite-gabbro and gabbro experiments is relatively Fe-depleted and the olivine forsterite
56 content is, therefore, elevated compared to picrite experiments. At identical temperatures, the olivine fraction is
57
58
59

60 ⁴ $\text{Fe}^{\#} = \text{molar } \text{Fe}^{2+}/(\text{Mg}+\text{Fe}^{2+})$
61
62
63
64
65

1 higher for the picrite-troctolite 50-50 mix (Figure 3d), but the forsterite and NiO contents are indistinguishable
2 from B62/2 liquids prior to clinopyroxene saturation.
3

4 Plagioclase

5 In the picritic experiments, plagioclase saturates at 1200°C (85 vol% melt) and modally increases to 45
6 vol% at 1110°C (4 vol% melt) (Figures 4, 5). The anorthite content regularly decreases while the Fe₂O₃ content
7 linearly increases upon cooling at QFM. The *f*O₂ has no effect on the anorthite content, but plagioclase is more
8 Fe-rich at more oxidized conditions, supporting prevalent incorporation of Fe³⁺ (Wilke and Behrens, 1999).
9 Under reducing conditions, the Fe₂O₃ content decreases down-temperature. Crystals in cooling-rate experiments
10 are unzoned and their chemistry is identical to plagioclase in isothermal runs.
11

12 In the basaltic liquid experiments, plagioclase is a liquidus phase, together with olivine and spinel, at
13 1160°C. The anorthite content extends the picrite plagioclase trend, down to An₅₁. The Fe₂O₃ progressively
14 decreases during cooling, once titanomagnetite saturates.
15

16 In picrite-gabbro and gabbro experiments, the plagioclase saturation temperature increases to 1230°C and
17 ~1240°C respectively. At similar temperature, the plagioclase anorthite content is higher than in pure picrite
18 experiments (Figure 6). The Fe₂O₃ concentration is lower in hybrid liquid experiments.
19

20 In picrite-troctolite experiments, plagioclase saturates at ~1240°C and its modal abundance increases
21 rapidly. At 1190°C (38 vol% melt), it amounts to ~36 vol%. The plagioclase anorthite content is higher than
22 along the B62/2 picrite liquid line of descent (up to An₈₆ in picrite-troctolite experiment at 1230°C) (Figure 6).
23 The plagioclase Fe₂O₃ content in picrite-troctolite experiments is highly variable.
24

25 Clinopyroxene

26 For the picrite QFM line of descent, clinopyroxene saturates at 1180°C (68 vol% melt) and its proportion
27 progressively increases to 30 vol% at 1110°C (Figures 4, 5). The clinopyroxene Al₂O₃ and Fe₂O₃ concentrations
28 are distinctly higher and Cr, Fe²⁺ and Si contents are lower under oxidized conditions (Figure 6). TiO₂ increases
29 constantly during cooling (not shown), from 0.8 to 2.2 wt%, regardless of *f*O₂.
30

31 In the basaltic liquid experiments, clinopyroxene saturates from 1120°C at QFM, but at 1150°C at QFM-0.7
32 and QFM-1.2. The Mg# and Cr₂O₃ (<0.3wt%) contents are the lowest of all experiments. The Al₂O₃ content
33 shows a large scatter (Figure 6). TiO₂ increases from 1.1 to 2 wt% at 1085°C, before it drops to 0.9 at lower
34 temperature, once titanomagnetite saturates.
35

36 In picrite-gabbro and gabbro experiments, the clinopyroxene saturation temperature is increased to ~1200°C
37 and ~1220°C respectively. The clinopyroxene mode is highest along these liquid lines of descent and the Cr₂O₃
38 concentration is distinctly higher (up to 1.40 wt%) (Figure 6). As for olivine, the clinopyroxene Mg# is higher
39 than in picrite experiments and the TiO₂ concentration is distinctly lower (increase from 0.1 to 1.3 wt%).
40

41 In picrite-troctolite experiments, clinopyroxene saturation is delayed until 1170°C. The Al₂O₃ and Cr₂O₃
42 concentrations are similar to those in the picrite experiments at QFM.
43

44 MELTS calculations:

45 It is instructive to compare our experimental results to those calculated using MELTS (Ghiorso and Sack,
46 1995; Asimow and Ghiorso, 1998). MELTS calculations were run using identical starting picritic and basaltic
47
48
49
50
51
52
53
54
55

1 liquid compositions and similar conditions to our experiments. Mineral modes and saturation temperatures
2 appear to accurately reproduce our Rum liquid line of descent (Figure 5). The spinel, olivine, clinopyroxene and
3 liquid compositions are also very similar (Figures 6, 8), but the predicted plagioclase anorthite content is
4 systematically too low; clinopyroxene Cr₂O₃ content is not considered by MELTS (Cr is only incorporated into
5 Cr-spinel). This comparison confirms that MELTS calculations can be used to estimate anhydrous basalt liquid
6 and crystal compositions at low pressure. Hybrid melts experiments mineral saturation temperatures and modal
7 abundances are also well reproduced by MELTS calculations.
8
9

10 As a first approximation, based on the observation that MELTS calculations are valid at our conditions, we
11 have run additional MELTS calculations varying the pressure (up to 0.3 GPa), starting liquid composition (Rum
12 picritic and basaltic dykes, picrite doped with 0.2 wt% Cr₂O₃, 50% plagioclase or 50% clinopyroxene crystals,
13 troctolite or gabbro melt), oxygen fugacity (QFM+0.8 to QFM-2) and varying water content (anhydrous to 0.2
14 wt%), whilst considering both equilibrium and fractional crystallization. The various liquid lines of descent are
15 presented in Figure 8b. Most calculations were run along a fixed oxygen buffer, which is consistent with the
16 experiments, but not necessarily appropriate to natural systems. It is interesting to note that calculations where
17 the fO_2 is left free to vary during crystallization from initially reduced conditions (QFM-1), produce a second Fe-
18 rich, Si-poor low temperature liquid at the saturation point of whitlockite/apatite. Such an immiscible Fe-rich
19 liquid has not been documented on Rum, but has been described from the Skaergaard and Sept Iles layered
20 intrusions (Jakobsen et al., 2005; Charlier et al., 2011) and the British Tertiary Volcanic Province island of Mull
21 (Kerr et al., 1999).

30 **Case study: Cumulates of the Rum Eastern Layered Intrusion**

31 Our experimental results can be used to evaluate magmatic evolution in the Rum Eastern Layered Intrusion.
32 The Rum cumulate assemblage comprises olivine-rich gabbro (60-75 vol% olivine, 15-35 vol% plagioclase and
33 <15 vol% clinopyroxene), troctolite (15-55 vol% olivine, 45-85 vol% plagioclase and <10 vol% clinopyroxene)
34 and gabbro (5-20 vol% olivine, 50-60 vol% plagioclase and 20-50 vol% clinopyroxene) (Holness et al., 2007;
35 Leuthold et al., 2014a). Poikilitic gabbro with clinopyroxene oikocrysts and Cr-spinel bearing anorthosite are
36 also found. Along the profile F (see location on Appendix figure 1) sampled by Holness et al. (2007) across
37 Units 8 and 9, the Unit 9 peridotite sill is absent and cumulates are mainly composed of texturally mature gabbro
38 with olivine, plagioclase and clinopyroxene as liquidus phases. These are interpreted to be unmodified by
39 subsequent reactive liquid flow processes (Holness et al., 2007). Leuthold et al. (2014) studied the Unit 9 in the
40 profile M area, sampled by Sides (2008, unpublished PhD thesis), 400 m south of profile F.
41
42
43
44
45
46
47

48 Spinel:

49 At the Unit 7-8 and 11-12 boundaries, millimetre-thick chromitite seams occur at the interface between
50 overlying olivine-rich feldspathic peridotite and underlying feldspar-rich allivalite (anorthosite, troctolite)
51 (Dunham and Wadsworth, 1978 and references therein; O'Driscoll et al., 2009b, 2010). Spinel is frequently
52 associated with plagioclase, either in anorthosite or mantled by plagioclase in olivine rim embayments (similar to
53 Bell and Claydon [1992] for the Skye layered intrusion) (e.g. see Figures 4e and h in O'Driscoll et al., 2010).
54 Similar textural associations are observed in other layered intrusions (see Lenaz et al., 2011). At the Unit 7-8
55 boundary (O'Driscoll et al. 2009b), spinel shows two trends, with large Al/(Al+Cr) and Fe³⁺ variations (Figure
56
57
58
59
60
61
62
63
64
65

8a). At the Unit 11-12 boundary (O'Driscoll et al., 2010), spinels show limited Fe³⁺-enrichment, but the strongest Al/(Al+Cr) variation.

In Unit 9, the spinel grains are disseminated throughout the cumulates (i.e. mostly peridotite, troctolite and rare anorthosite). Spinel grains from the Unit 9 matrix (i.e. not fully included in olivine, plagioclase or clinopyroxene) analysed by Holness et al. (2007) and Leuthold et al. (2014a) generally have a higher Cr# (0.53 to 0.03) than grains crystallized along the B62/2 picrite QFM liquid line of descent (0.38 to 0.06) (Figure 8). The Cr-spinel Al/(Cr+Al) ratio shows limited variation and Fe³⁺ strongly increases from anorthosite to peridotite, troctolite, gabbro and poikilitic gabbro. Spinel grains in most poikilitic gabbros and one troctolite sample have low Mg#, TiO₂ and Cr# contents (Figures 6, 7, 8). In peridotite, and rarely troctolite, Al-poor spinel occurs as inclusion in olivine or in olivine-hosted recrystallized melt inclusions, in association with hornblende, orthopyroxene, and aspidolite (Leuthold et al., 2014a). Similar recrystallized melt inclusions have been documented in layered intrusions and oceanic lower crust gabbro (e.g. Irvine, 1975; Arai et al., 1997; Spandler et al., 2005; Renna and Tribuzio, 2011). Spinel itself hosts recrystallized melt inclusions consisting of olivine, plagioclase, apatite and Ti-spinel. The Unit 9 spinel Cr# is distinctly higher (up to 0.53 in anorthosite and 0.51 in troctolite) than the Unit 7-8 and 11-12 boundary discussed above and may have a different petrogenesis, as follows.

Olivine:

The Unit 9 profile F olivine composition is Fo₈₀₋₇₅ (Holness et al., 2007). In the profile M area, where reactive liquid flow processes have been characterized in detail (Leuthold et al., 2014a), the olivine composition varies from Fo₈₅ in peridotite to Fo₈₄₋₈₂ in troctolite, to Fo₈₄₋₈₁ in gabbro and Fo₈₂₋₇₉ in poikilitic gabbro.

Plagioclase:

The plagioclase anorthite content along profile F varies from An₇₉ to An₆₉ with normal zoning down to An₆₅. In the area studied by Leuthold et al. (2014a), the plagioclase anorthite content (An₈₅₋₈₀) shows very little variation. Along profile F (400m to the North), it is An₇₉₋₆₉ and along profile G (300m further to the North, above a peridotite lens) (Holness et al., 2007) it is An₉₀₋₈₀. The Fe₂O₃ content is 0.60 wt% for peridotite, troctolite and gabbro and 0.68 wt% for poikilitic gabbro (Leuthold et al., 2014a).

Clinopyroxene:

In Rum Unit 9, the clinopyroxene composition varies widely (Leuthold et al., 2014a). Whereas Fe-Mg cations were locally re-equilibrated, Cr and Al still record the original clinopyroxene composition obtained during precipitation from the melt (Leuthold et al., 2014a). Clinopyroxene core concentrations of Cr and Al show strong variations throughout the cumulate pile, from peridotite (Mg# = 0.89-0.86, Cr₂O₃ = 1.2-1.1 wt%, Al₂O₃ = 3.3-3.2 wt%), to troctolite (Mg# = 0.87-0.85, Cr₂O₃ = 1.2-1 wt%, Al₂O₃ = 3.7-3.2 wt%) and gabbro (Mg# = 0.86-0.80, Cr₂O₃ = 1.0-0.2 wt%, Al₂O₃ = 3.5-2.4 wt%) consistent with Cr depletion during progressive crystallisation. Clinopyroxene rims show strong zoning in peridotite (Mg# = 0.87-0.86, Cr₂O₃ = 0.86-0.85 wt%, Al₂O₃ = 3.1-2.9 wt%) and troctolite (Mg# = 0.86-0.84, Cr₂O₃ = 1.0-0.5 wt%, Al₂O₃ = 3.2-2.7 wt%) and no distinct zoning in gabbro (Mg# = 0.85-0.80, Cr₂O₃ = 1.0-0.3 wt%, Al₂O₃ = 3.2-2.4 wt%). Zoning in poikilitic gabbro is strong and complex (Mg# varies from 0.85-0.82 in the core to 0.85-0.82 in the rim, Cr₂O₃ varies from

1.2 to 0.1 wt%, Al₂O₃ varies from 3.7 to 2.3 wt%, TiO₂ varies from 0.58 to 1.2 wt%) (see Leuthold et al., 2014 for details). Clinopyroxene analyses from a single rock sampled 6m below the top of profile F show low Mg# (0.86-0.81), Cr₂O₃ (0.57-0.14 wt%) and Al₂O₃ (3.2-2.2 wt%) concentrations (unpublished data).

Discussion:

Controls on the stability and chemistry of spinel:

Because of the distinctive chemical variation in spinels from Rum and other layered intrusions and the widespread usage of spinel as a petrogenetic indicator, it is informative to use our experiments, in conjunction with published experiments (Murck and Campbell, 1986; Roeder and Reynolds, 1991), to elucidate the important controls on spinel composition. The key parameters responsible for Cr-spinel chemistry are shown schematically in Figure 10.

Liquid composition:

In order to saturate in Cr-spinel, the parental liquid must be TiO₂-poor (<2.8 wt%), have a low FeO/MgO ratio (<2.0) and contain more than 200 µg/g (ppm) Cr (Thy, 1983). Unlike the other major elements in the spinel structure, Cr acts as a trace element in the parental liquid (Ridley, 1977). Allan et al. (1988) proposed that the Cr content of spinels within a given magma has little relationship to host-liquid Cr content but instead is indirectly controlled by the host magma Al, Fe²⁺, and Mg contents. Our Cr-rich (picrite) and Cr-poor (basalt) experiments and MELTS calculations refine that proposal: MELTS calculations show that an increase in the starting liquid Cr₂O₃ results in saturation of Cr-enriched spinel at a higher temperature, but its composition at similar temperatures does not change (an addition of 0.2 wt% Cr₂O₃ to the starting picrite liquid increases Cr-spinel saturation by 150°C and Cr# from 0.41 to 0.60). Hill and Roeder (1974) also showed that the spinel liquidus is shifted to higher temperature when Cr₂O₃ is added to the starting material. The spinel saturation in Cr-poor basalt experiments is delayed in comparison to Cr-rich picrite experiments and the basalt liquid line of descent lacks Al-rich spinel. According to Kamenetsky et al. (2001), the spinel Mg# at magmatic conditions is directly linked to the parental melt Mg# and Al₂O₃ content. Murck and Campbell (1986) showed that upon cooling from 1450 to 1150°C, spinel becomes progressively less Cr-rich. This trend is consistent with our experiments, and points to the high-temperature Cr depletion of Cr₂O₃-doped melts close to their liquidus (Figure 8c).

Liquid composition directly affects mineral saturation temperatures. Our results confirm the observations by Roeder and Reynolds (1991; and references therein) that plagioclase and clinopyroxene stability plays a major role in determining spinel composition, by controlling liquid Al₂O₃ and Cr₂O₃ contents. In picrite experiments, the crystallization of abundant (up to 30 vol%, Table 2) clinopyroxene, accommodating significant amounts of Cr, effectively depletes the liquid in Cr₂O₃, thus driving the spinel chemistry towards Cr-poor composition. The Cr-spinel crystals with the lowest Al/(Cr+Al) ratio and Fe³⁺ concentration crystallize from plagioclase-rich, clinopyroxene-depleted picrite-troctolite hybrid melt (Figure 8c). A similar Fe³⁺-enrichment trend would be expected in gabbro hybrid experiments, however the selected gabbro FeO_{tot} is rather low (5.49 wt% FeO_{tot}). Hybridization with low-Fe gabbro decreases the liquid Fe content and spinel remains low in Fe over a large temperature range (Figures 6, 8c). At high temperature, in low-Fe picrite-gabbro and gabbro experiments, olivine also has a high forsterite content at high temperature. We have run additional MELTS calculations using a picrite doped with 50% plagioclase as starting composition. The chemistry of Cr-spinel is slightly more Cr-rich along

fractional liquid line of descent and slightly less Cr-rich along equilibrium liquid line of descent than for picrite-only calculations. The plagioclase abundance and increased stability balance the melt enrichment in Al_2O_3 , resulting in a minor effect on spinel chemistry.

Temperature:

The Fe-Mg exchange between spinel and olivine is temperature-sensitive, with Mg preferentially partitioning into olivine with decreasing temperature (Roeder et al., 1979) and has been used as thermometer (e.g. Irvine, 1965; Roeder et al., 1979; Engi, 1983). Diffusion (discussed below) in the Fe-Mg sites continues at sub-solidus conditions (O'Driscoll et al., 2010). Wilson (1982) concluded that geothermometers based on chromite-silicate equilibria are probably not applicable to slowly-cooled layered intrusions, but information on thermal histories may be gleaned from diffusion profiles.

Pressure and water:

Spinel is stable from mantle conditions to atmospheric pressure. Dick and Bullen (1984) proposed that Cr solubility in the melt is increased at high pressure. Fisk and Bence (1980) and Roeder and Reynolds (1991) proposed Cr# decreases at higher pressure (at conditions above the plagioclase saturation temperature), accompanied by an increase in Mg# and decrease in Fe^{3+} . Feig et al. (2006) performed oxidized experiments over a wide range of P-T- H_2O conditions on tholeiitic basalts inferring that spinel Cr# decreases as pressure increases from 100 MPa to 200 MPa, followed by a constant value up to 500 MPa. In contrast, Sisson and Grove (1993a, 1993b) showed that in calc-alkaline, high-alumina basalt experiments at NNO, water-saturated conditions, 1100°C and 100 MPa, spinel (co-saturated with olivine) has a lower Cr# than at 1050°C and 200 MPa.

Pressure or water variations have limited effect on spinel composition, but do significantly modify the stability and composition of coexisting plagioclase and clinopyroxene. At higher pressure and/or water content, plagioclase saturation is delayed and clinopyroxene stability increases, resulting in an increased spinel $\text{Al}/(\text{Cr}+\text{Al})$ ratio. In Feig et al.'s (2006) experiments, spinel stability increases at high water content (>3 wt%), whereas plagioclase stability is decreased. At such conditions, clinopyroxene saturates prior to plagioclase and coexists with Cr-spinel. In this particular case, the water content was directly and positively linked with oxygen fugacity and thus, spinel in hydrated melts resulted in higher Fe^{3+} , due to H_2 -loss. At similar water activities and temperature, spinel in high-pressure experiments is slightly more Fe^{3+} -rich and Cr-poor, because spinel saturation temperature is increased. Thus, low-pressure spinels have the capacity to attain the highest Cr# for a given bulk liquid composition. The Fe# and TiO_2 are only marginally affected by pressure and H_2O variations at a given $f\text{O}_2$.

Oxygen fugacity:

Fe^{3+} stabilizes spinel, hence increasing $f\text{O}_2$ promotes precipitation of abundant Fe^{3+} -rich spinel from basaltic liquids (Hill and Roeder, 1974; Ridley, 1977; Sharpe and Irvine, 1983; Murck and Campbell, 1986). Our experiments produce abundant (~1 vol%) Fe^{3+} -rich spinel at QFM+1.8. In the picrite, picrite-gabbro and gabbro experiments at and above QFM, spinel co-exists with olivine, plagioclase and clinopyroxene over ~40°C (Figure 4), until the liquid Cr-content is depleted to such an extent that chromite is no longer stable (Irvine 1967). This

1 contrasts with the generally accepted idea that spinel + melt would react to clinopyroxene or to olivine +
2 anorthite via peritectic reactions (Irvine, 1967; Hill and Roeder, 1974; Roeder, 1994) at low pressure (< ~0.5
3 GPa, Grove et al., 1992). This principle is adapted from the haplobasaltic, Cr- and Fe-free forsterite-anorthite-
4 diopside system where the non-ternary, spinel phase ($MgAl_2O_4$) field is terminated at a divergent peritectic point
5 followed down-temperature by the forsterite-anorthite cotectic (Morse et al., 1980; Soular et al., 1994). This
6 system cannot, however, be used to infer phase equilibria between Cr-Al-Fe-Mg spinels and silicate phases
7 where complex solid solutions exist and the degree of freedom is increased due to at least 5 additional relevant
8 components (Fe, O, Cr, Ti and Na) allowing for large stability fields wherein spinel coexists with three or more
9 silicate mineral phases plus melt. Hill and Roeder (1974) showed a gap in spinel crystallization under reduced
10 conditions, where Cr-spinel is replaced by clinopyroxene in a peritectic reaction and only reoccurs at low
11 temperature as Ti-magnetite (or ulvospinel). Our experiments confirm Fe^{3+} -poor spinel occurs only in trace
12 amounts at QFM-2.2 and temperatures in excess of 1180°C; it is absent in lower temperature runs.
13

15
16
17
18

19 Differentiation:

20
21 The 11JL33 basalt represents a fractionated liquid from a parental Rum B62/2 picrite. Crystal chemistry in
22 both liquid lines of descent follows a similar evolution, but basalt experiments lack the most primitive crystals
23 found in the picrate experiments (Figures 6, 8c). MELTS calculations show that spinels crystallized via
24 equilibrium or fractional crystallization along the QFM liquid line of descent differ little in their composition
25 (Figure 8b). Spinel obtained in the QFM cooling-rate experiments show very limited Cr-enrichment compared
26 to isothermal experiments. Conversely, MELTS fractional crystallization calculations performed under reducing
27 conditions produce more Cr-rich spinel than equilibrium crystallization (Figure 8b). Leaving the oxygen fugacity
28 free in MELTS calculations produces spinel with even higher Cr#, especially for initially reduced conditions.
29
30
31
32

33 In plagioclase-saturated experiments, spinels have a slightly lower Al/(Cr+Al) ratio and lower Fe^{3+} in
34 cooling-rate experiments (simulating inefficient fractional crystallization) than in isothermal experiments (true
35 equilibrium crystallization). The glass composition is also slightly depleted in Al_2O_3 in cooling-rate experiments.
36 The estimated plagioclase modes are not systematically higher in cooling-rate experiments, but the anorthite
37 content is. Thus, plagioclase crystallization directly influences spinel chemistry.
38
39
40

41 Irvine (1975) proposed that increased melt polymerization (NBO/T; e.g. by increased silica content) would
42 decrease the number of octahedral sites in the melt. As Cr cations have a strong preference for octahedral sites
43 (Burns, 1975), increased polymerization would significantly reduce Cr-spinel solubility in the melt, promoting
44 early Cr-spinel precipitation. According to Thy et al. (1983), local depletion in melt Cr content is due to
45 crystallization of Cr-spinel, with large spinel/melt partition coefficient for Cr (Hill and Roeder 1974). Such
46 small-scale fractionation may be responsible for grain-to-grain variation in Cr# with relatively constant Al/ Fe^{3+}
47 and a lack of correlation with Mg#. Our observations infer that the small proportion of Cr-spinel equilibrium
48 crystallization at high temperature has little effect on the spinel and liquid Cr-contents. In contrast, the
49 crystallization of abundant clinopyroxene effectively depletes both the liquid and coexisting spinel in Cr over a
50 small temperature range.
51
52
53
54
55
56

57 Re-equilibration:

58
59 Irvine (1980) pointed out that even cumulus grains whose textures do not appear to have been modified may
60
61
62
63
64
65

1 have had their composition changed extensively by reactive liquid flow processes (i.e. postcumulus
2 metasomatism, as defined by Irvine, 1982). In spinels Fe^{2+} - Mg; Cr - Al; Fe^{3+} - Cr, Al; Fe, Ti - Cr, Al cation
3 substitutions take place (Ridley, 1977). In the FeAl_2O_4 - MgAl_2O_4 system, intra-spinel and spinel-melt and spinel-
4 olivine Fe^{2+} -Mg diffusion are very fast, whereas spinel-melt Al, Cr, Fe^{3+} and Ti diffusion rates are slow (Wilson,
5 1982; Ozawa, 1984; Scowen et al., 1991; Allan, 1994; Roeder et al., 2001; Suzuki et al., 2008). Consequently
6 sub-solidus reactions only allow Fe-Mg exchanges (O'Driscoll et al., 2010). At near- and sub-solidus conditions,
7 spinel Mg# is controlled by the rate of cooling and re-equilibration with silicates (Kamenetsky et al., 2001).
8 Hoshide and Obata (2014) showed Cr-spinel Fe^{3+} -enrichment, with very limited Cr^{3+} -enrichment, when re-
9 equilibrated with evolved interstitial melt. Significant diffusion can occur through and within olivine and modify
10 spinel inclusion compositions (Scowen et al., 1991; Hoshide and Obata, 2014), which should not therefore be
11 used as indicators of original liquidus compositions. Diffusion through plagioclase is slower and the chemistry of
12 spinel inclusions is less modified as a consequence (Hoshide and Obata, 2014).
13
14
15
16
17

18 Bell and Claydon (1992) proposed that Al-rich Cr-spinel reacts with Ca-rich melt to produce plagioclase,
19 olivine and Cr-rich spinel, accompanied by a decrease in Mg# and increase in TiO_2 . This peritectic reaction
20 explains the increased amounts of intercumulus plagioclase and the small amounts of intercumulus olivine
21 associated with the more chromian spinel present in layered intrusions (e.g. O'Driscoll et al., 2009b). More Ti-
22 rich, Al-poor Rum spinel equilibrated over a long period of time at a low temperature with intercumulus melt
23 (O'Driscoll et al., 2010; Lenaz et al., 2011). O'Driscoll et al. (2010) indicate the importance of the modal
24 proportion of spinel in buffering the reaction: the more abundant it is, the less the re-equilibration.
25
26
27
28
29

30 Petrogenesis of Cr-spinel in the Rum Eastern Layered Intrusion:

31 Unit 7-8 and 11-12 boundary Al-spinel seams:

32
33 Rum spinel petrogenesis has long been discussed. Henderson and Suddaby (1971), Henderson (1975),
34 Putnis and Price (1979) and Henderson and Wood (1981) have shown that seam spinels are much more Al-rich
35 and Cr-poor and have a lower Fe# than spinels in the nearby plagioclase-rich rock and overlying peridotite.
36 Chromite Al-enrichment can result from the reaction with olivine and either plagioclase or from a melt rich in
37 plagioclase component, a reaction known as the 'Rum trend' (Barnes and Roeder, 2001 after Henderson, 1975).
38 Fe^{3+} -enrichment, on the other hand, is interpreted as progressive crystallization or reaction with evolved
39 interstitial liquid (Henderson, 1975; O'Driscoll et al., 2010). Young (1984) suggested that in Unit 7 evolved,
40 interstitial basaltic liquid migrated upward from the troctolite and anorthosite crystal mush, blended with newly
41 injected picrite and created a hybrid magma saturated with Cr-spinel (i.e. the model of Irvine, 1977). For
42 Dunham and Wadsworth (1978), the occurrence of the Unit 11-12 chromitite bands within a zone whose
43 mineralogy shows rapid changes from Fe-Na to Mg-Ca-rich minerals (i.e. a reverse of the normal magmatic
44 trend) reflects the influx of new Mg-rich magma into the system. In particular, Dunham and Wadsworth (1978)
45 suggest that the Mg- and Al-rich spinel had crystallized directly from the picrite, without subsequent reaction
46 with the crystal mush or interstitial liquid. O'Driscoll et al. (2009b, 2010) showed that the chemistry of Cr-spinel
47 at the boundary between Units 7 and 8 evolved towards a low Al concentration prior to a progressive Fe^{3+} -
48 enrichment at constant Cr# (Figure 8). They proposed a model whereby Cr-spinel crystallized in-situ, from a
49 hybrid melt produced by assimilation of troctolite cumulate into infiltrating reactive picritic liquid, one of the
50 processes simulated in our experimental study.

1 Following Irvine (1977), Roeder and Reynolds (1991) proposed that mixing of a hot, plagioclase-
2 undersaturated, primitive magma, with a plagioclase-enriched magma could produce hybrid melts that crystallize
3 chromite with low and highly variable Cr#. Magma mixing and dissolution of plagioclase could also have been
4 responsible for the so-called alumina Rum trend described above. Following these ideas, O'Driscoll et al.
5 (2009b, 2010) proposed a model whereby abundant picritic liquid (i.e. a mafic olivine-saturated liquid)
6 percolated and assimilated troctolite cumulate to produce a plagioclase-saturated melt. The hybrid melt then
7 crystallized Cr-spinel seams (~2mm thick) and anorthosite (~10-70cm thick). Our experiments show 50%-50%
8 mixing of picrite and troctolite liquids produces a hybrid melt that crystallizes Al-rich spinel and olivine at
9 liquidus temperature, thereafter fractionating abundant plagioclase (~An₈₆) from 1240°C and saturating in
10 clinopyroxene at 1160°C. The Al/(Cr+Al) ratio of high-temperature Al-spinel decreases dramatically upon
11 cooling, reaching the highest measured Cr# of 0.54 at 1180°C at QFM-1.2, before it quickly evolves towards
12 Fe³⁺-rich composition (Figure 8c). The Units 7-8 and 11-12 Al-rich spinel seams (Al/[Cr+Al] as high as 0.70)
13 are therefore consistent with crystallization from picrite-troctolite hybrid liquid, as suggested by O'Driscoll et al.
14 (2009b, 2010), at a temperature close to 1210°C and QFM condition. This temperature is higher than that
15 determined for natural grains utilising the olivine-spinel exchange thermometer of Ballhaus et al. (1991) and
16 Princivalle et al. (1999) (see O'Driscoll et al., 2009b and Lenaz et al., 2011), a fact we attribute to re-
17 equilibration during cooling.

18 In our experiments, the Al- and Cr-spinel modal proportions are low (typically 0.1-0.2 vol%) and the
19 crystallization of a 2mm thick seam with 30 vol% spinel requires effective sorting and settling of denser spinel
20 from a 30-60 cm thick magma layer, in agreement with field observations. Spinel extraction from a basaltic
21 liquid appears to be very efficient (Manoochehri and Schmidt, 2014). At ~1230 to ~1180°C, the liquid fraction
22 amounts to 60-30 vol% in picrite-troctolite hybrid magma, allowing dense crystals to settle out as long as they
23 are not part of a touching framework. This model could explain the formation of the main spinel seam, at the
24 interface between peridotite (picrite) and anorthosite/troctolite.

25 Subsidiary spinel seams are sandwiched between overlying peridotite and troctolite. Spinel often occurs in
26 indentations and embayment structures in olivine oikocrysts (see Figure 3 in O'Driscoll et al., 2009b). In our
27 reaction experiments, we have tested the effect of chemical disequilibrium between picrite and troctolite melt at
28 constant temperature, pressure and oxygen fugacity. Through picrite liquid hybridization with troctolite partial
29 melt, the glass and the spinel Al and Cr compositions vary considerably and the spinel modal abundance
30 increases markedly (up to 3.5vol%; Figure 9). Despite the low oxygen fugacity, the spinel proportion is the
31 highest we have measured. These observations corroborate the model of spinel seam formation during picrite-
32 troctolite melt hybridization. Subsequent plagioclase fractionation increases the spinel Cr#. It is curious to note
33 abundant Cr-spinel crystallized in the picrite-troctolite reaction zone, where plagioclase is absent. We
34 hypothesise that picritic liquid percolated into the troctolite crystal mush and dissolved plagioclase, which is
35 unstable at 1250°C. The melt Al-content increased, stabilizing spinel that crystallized between relict olivine
36 grains. As the picrite Cr-content is high and spinel is the only phase incorporating Cr into its structure, Al- and
37 Cr-rich spinel crystallizes. The Cr-rich picrite and Al-rich troctolite melt ratio is crucial here. Based on the
38 observation that the spinel composition in reaction experiments spans the range of spinel crystallized from
39 equilibrium experiments, we suggest that spinel with higher Cr# crystallized at lower temperature (upon cooling
40 or during reaction at lower temperature). However, evidence for reaction seems to disappear over prolonged

1 reaction time. Additionally, spinel is modally more abundant on the troctolite side of the reaction rim, at ca. 100
2 μm from the picrite contact. This observation supports in-situ spinel subsidiary seams crystallization as opposed
3 to gravitational settling of dense spinel. Upon cooling, the hybrid melt will fractionate abundant plagioclase,
4 forming the anorthosite.
5

6 7 Unit 9 Cr-spinel:

8
9 We established earlier that distinct physico-chemical parameters can increase the spinel Cr# of a single
10 magma, approaching those found in Rum Unit 9 (Figure 10): (1) Low water content increases plagioclase
11 stability and Al depletion; (2) low pressure reduces clinopyroxene stability and Cr extraction and also raises the
12 melt and spinel Cr-content, at sub-liquidus condition; (3) spinel Cr_2O_3 concentrations are higher under low $f\text{O}_2$
13 conditions, but its modal abundance is strongly reduced. The corroded texture observed at intermediate
14 temperature (1180°C, QFM-2.2) indicates a peritectic reaction with the liquid and clinopyroxene. Crystallization
15 of abundant chromite cannot be explained by low $f\text{O}_2$ conditions alone, unless crystallized over a small
16 temperature interval from a very large magma body or from a clinopyroxene-depleted magma; (4) fractional
17 crystallization has a strong effect on the spinel Cr-enrichment at low $f\text{O}_2$, but spinel becomes unstable at low
18 temperature under reduced conditions; and (5) spinel Cr# increases through re-equilibration with plagioclase +
19 melt or clinopyroxene + melt (Wilson, 1982; Bédard and Hébert, 1998).
20
21

22
23 High Cr# and Ti and low Mg# and Al spinel, with a composition very close to the Unit 9 Cr-rich spinel
24 (Figures 7, 8), crystallize from picrite-troctolite hybrid melt at QFM-1.2, 1180°C. Clinopyroxene saturation is
25 delayed in picrite-troctolite hybrid experiments, permitting the crystallization of high Cr# spinel even under
26 reduced conditions. Spinels obtained by MELTS fractionation calculations and from the cooling-rate
27 experiments have a higher Cr# than those from MELTS equilibrium calculations and from isothermal
28 experiments respectively. Olivine and plagioclase fractionation could further drive the spinel chemistry towards
29 the Unit 9 chromite composition. Also, higher Cr# spinel crystallizes from MELTS calculations where the $f\text{O}_2$ is
30 allowed to vary (especially for initially reduced conditions). Those two processes were not investigated during
31 our experiments and may account for the minor differences between experimental and natural crystals. Fe-Mg
32 diffusion occurs down to sub-solidus conditions (O'Driscoll et al., 2010) and may have lowered the Unit 9 spinel
33 Mg# (Roeder et al., 1979; Scowen et al., 1991; Kamenetsky et al., 2001). We propose the Unit 9 Cr-spinels
34 fractionated over a limited temperature range (ca.1180°C), from a reduced picrite-troctolite hybrid melt
35 fractionating olivine + plagioclase. These spinels subsequently experienced sub-solidus re-equilibration with
36 olivine.
37
38

39 40 41 42 43 44 45 46 47 48 Unit 9 and 7-8 boundary Fe^{3+} -rich spinel:

49
50 Spinel crystals in picrite and basalt cooling-rate experiments at QFM, ~1125°C and QFM+1.8 ~1180°C
51 have a similar composition to the troctolite, gabbro and poikilitic gabbro Fe^{3+} - and Ti-rich crystals suggestive of
52 crystallization at such conditions. Alternatively, equilibration of isolated Cr-spinel with evolved interstitial melt
53 would likewise increase the spinel Fe^{3+} content observed in those lithologies (Henderson, 1975; Hoshida and
54 Obata, 2014). O'Driscoll et al. (2010) inferred that the extent of spinel textural and chemical re-equilibration is
55 inversely proportional to the spinel modal abundance. Thus, re-equilibration of low modal proportions of Cr-
56 spinel with trapped melt (crystallizing abundant Fe-poor plagioclase; Lenaz et al., 2011) could induce strong
57
58
59
60
61
62
63
64
65

1 Fe³⁺-enrichment. Fe³⁺-rich spinel indeed occurs in the least compacted cumulates (i.e. gabbro and poikilitic
2 gabbro) (Leuthold et al., 2014a). Ridley (1977) suggested an extensive solid solution between Cr+Al and Ti+Fe
3 spinels. Rum Cr-spinel grains show post-cumulus Cr- and Al-increase and Fe- and Ti-decrease towards the
4 contact with ilmenite crystals (not shown), possibly produced by spinel oxidation down to ~600°C (Putnis and
5 Price, 1979; O'Driscoll et al., 2010). Finally, Bell and Claydon (1992) proposed that the spinel grains may have
6 been modified by postcumulus peritectic reaction of Al-rich spinel with melt producing low Mg# and Cr-, Fe²⁺-,
7 Fe³⁺-, Ti-rich spinel + plagioclase + olivine. This trend is similar to that in our picrite experiments. Ultimately, in
8 order to explain the Unit 9 titanomagnetite petrogenesis it is difficult to distinguish between (1) crystallization
9 from a differentiated liquid at QFM or more oxidized conditions, or (2) re-equilibration with a differentiated
10 melt. Both processes overlap when interstitial melt is not efficiently extracted.
11
12
13
14
15

16 M9 picrite accumulated spinel:

17
18 Spinel in the olivine- and spinel-phyric picritic dyke M9 (Upton et al., 2002; O'Driscoll et al., 2010) have
19 low Ti, Cr# and Fe²⁺/(Mg+Fe²⁺) in comparison to the Unit 9 grains (Figure 7). Upton et al. (2002) suggested the
20 M9 olivine and spinel primocrysts formed at high pressure in a near-Moho reservoir from a high MgO melt
21 (~20wt%) (Upton et al., 2002), prior to remobilisation by picritic liquid (~13wt% MgO) and emplacement into
22 the Rum Eastern Layered Intrusion. MELTS calculations of picrite at high pressure (0.3 GPa) predict that spinel
23 crystallized at sub-liquidus temperature from a Cr-rich liquid, or under reduced conditions, has a high Cr#
24 similar to natural grains (Figure 8). The melt Cr₂O₃ content determines the Cr# of the first spinel to saturate,
25 directly influencing the saturation temperature. Looking at Figures 8b and c, spinel Cr# is high at very high
26 temperature, prior to Al-increase. Thus, M9 spinel primocrysts may have crystallized at very high temperature
27 and lower crustal pressure from a more mafic melt than the Unit 9 crystals (i.e. less TiO₂ and FeO and more
28 MgO and Cr₂O₃; Fisk and Bence, 1980) prior to emplacement. It is probable that a few Unit 9 spinels were
29 inherited from an M9-type dyke, and then re-equilibrated during hybridization with partially molten mafic
30 crystal mushes.

39 Petrogenesis of the Rum Unit 9 cumulates:

40
41 Using our picrite and basalt experiments together with the large dataset of natural crystals compositions
42 (Holness et al., 2007; Leuthold et al., 2014a), we attempt to determine the physico-chemical conditions for the
43 formation of the Rum Unit 9 cumulates. In the Appendix table 3, we present correspondences based on the
44 Figure 6. We will first compare the natural grains with the Rum picrite and basalt equilibrium liquid lines of
45 descent. Leuthold et al. (2014a) proposed the phase abundance, saturation temperature and chemistry were
46 shifted from the equilibrium liquid line of descent though *reactive liquid flow* (Figure 1). We then test the
47 hypothesis that the Unit 9 cumulates were modified by gabbro and/or troctolite assimilation. It is believed that
48 cumulates in the profile F area (see Appendix figure 1), where the discordant peridotite sill is absent, were not
49 modified by late-stage crystal-melt reactions, thus still showing the original composition.
50
51
52
53
54
55

56 Olivine

57 Olivines in profile F are distinctly more fayalitic (Fo₈₂₋₇₄) than along other Unit 9 profiles E, G, H and I
58 (Fo₈₇₋₈₀) sampled by Holness et al. (2007). Although we cannot exclude the possibility that the Rum olivine
59
60
61
62
63
64
65

1 composition was not fully re-equilibrated, the olivine compositions obtained in the picrite (for all fO_2
2 conditions), picrite-gabbro and picrite-troctolite experiments overlap with the range of Unit 9 crystals overlying
3 peridotite sills (Figure 6). Olivine in basalt experiments is more Fe-rich, consistent with the down-temperature
4 extension of the picrite experiments. Thus profile F olivines are consistent with low temperature picrite and/or
5 hot basalt parental liquids.
6

7 8 9 Plagioclase

10 Plagioclase in Rum Unit 9 shows lateral chemical variability, ranging from An_{85-80} in the area studied by
11 Leuthold et al. (2014a) to An_{79-69} 400m to the North, along profile F of Holness et al. (2007) and An_{90-80} along
12 profile G 300m further North. While the chemistry of profile F crystals is well reproduced by picrite experiments
13 and corresponds to the range from the point of plagioclase saturation to the solidus, the high anorthite content of
14 Leuthold et al. (2014a) and profile G (Holness et al., 2007) can only be reproduced by hybrid experiments.
15 Alternatively, crystallization from a water-bearing magma would lower the plagioclase liquidus temperature and
16 crystallise plagioclases that are higher in An content (Kuritani, 1998). MELTS calculations at the maximal
17 estimated crystallization pressure of 50 MPa (Holness, 1999) reveal little effect on the anorthite composition
18 compared to 0.001 MPa. Along a fractional crystallization liquid line of descent, the anorthite content would
19 become even lower (e.g. Toplis and Carroll, 1996). Anhedral cores, also described by Young (1984) and
20 O'Driscoll et al. (2009b) in the Unit 7, are An_{68-58} , similarly to the 11JL33 basaltic dyke experiments. Anhedral
21 sodic cores certainly crystallized from a basaltic parental magma or from a fractionating dry picritic liquid.
22

23 The Unit 9 plagioclase Fe_2O_3 content varies from 0.4 to 0.8 wt%, with no distinction between core, rim and
24 anhedral core (profiles F and G in Holness et al., 2007; Leuthold et al., 2014a). In picrite and basalt experiments,
25 plagioclase Fe_2O_3 increases from ~0.6 to ~1.8 wt% at QFM and is <0.7 wt% under more reduced conditions.
26 Plagioclase crystallized from hybrid experiments have Fe_2O_3 concentration ranging from 0 to 1.5wt%. Thus,
27 unmodified profile F natural plagioclase grains are consistent with crystallization from a hot (~1140°C), wet,
28 reduced (~QFM-1.2, possibly up to QFM) basalt. Conversely, the more An-rich crystals above peridotite sills
29 crystallized either from a hot water-bearing reduced picritic melt or a hybrid melt.

31
32
33
34
35
36
37
38
39
40

41 Clinopyroxene

42 The Mg# of cumulate crystals (0.89-0.80 in the profile M area, ~0.86-0.79 along profile F) is higher than
43 those in experiments, except for the high-temperature, reduced picrite, picrite-gabbro and gabbro experiments.
44 According to Leuthold et al. (2014a), divalent cations were frequently partly re-equilibrated (at least within the
45 individual grains) but trivalent cations were unmodified. The Cr_2O_3 concentration of the experimental
46 clinopyroxene overlaps with the clinopyroxene core composition from all lithologies, except for the Cr_2O_3 -poor
47 basalt experiments. Profile F clinopyroxene has low Cr-contents identical to basalt and low-temperature picrite
48 experiments. Only clinopyroxene crystallized from reduced experiments at high temperature (picrite, basalt,
49 picrite-gabbro, gabbro and picrite-troctolite) have low Al_2O_3 , close to natural Unit 9 grains in the profile M area.
50
51
52
53
54
55

56 Synthesis

57 Comparing olivine, plagioclase and clinopyroxene to experimental crystals shows the Unit 9 profile F
58 gabbro crystallized from a hot (~1140°C), wet, reduced basalt at QFM-1.2, possibly up to QFM). Clinopyroxene
59
60
61
62
63
64
65

1 cores, plagioclase and olivine in the profiles M, G, H, E area crystallized from a hot (~1180°C), reduced (~QFM-
2 1.2) picrite. Lateral variations may be explained by local accumulation of high temperature crystals and the
3 segregation of interstitial melt that will fractionate down-temperature. Also gravity currents (Emeleus et al.,
4 1996; Tepley and Davidson, 2003; O'Driscoll et al., 2007) may transport and juxtapose grains crystallized at
5 different conditions.
6

7 Picrite or basalt liquid lines of descent fail to reproduce the profile M area crystal cumulates. The most
8 likely parental melts are picrite-gabbro, gabbro or picrite-troctolite crystallizing at ~1170°C and reduced
9 conditions. Subsequent to hot reactive picrite intrusion, the chemistry and composition of the overlying
10 cumulative rocks was modified during *reactive liquid flow*. Where low-degree gabbro partial melting was
11 achieved (a few decametres from the sill, according to Leuthold et al., 2014), clinopyroxene crystallized around
12 pre-existing, partially molten crystals from a reduced gabbro melt, or reduced picrite-gabbro hybrid melt where
13 porosity was sufficient for both melts to mix, forming complex poikilitic gabbro. Closer to the peridotite sill, the
14 high-An, low Fe₂O₃ troctolite plagioclase indicates crystallization from a reduced hybrid picrite-troctolite melt.
15 This is consistent with the low abundance of clinopyroxene, depleted by troctolite assimilation and the chemical
16 constraints from spinel. Our experiments highlight an increased melting proportion of plagioclase versus
17 clinopyroxene towards the peridotite sill. Based on successive crystallization-dissolution stages in
18 clinopyroxene, Leuthold et al. (2014a) have demonstrated consecutive partial melting episodes. This suggests
19 most clinopyroxene close to the hot intrusive sill was molten and expelled, leaving a troctolite restite that was
20 intruded and partially melted next to a second hot picrite intrusion. Spinel, An-rich plagioclase and sparse
21 clinopyroxene crystallized from this later, hot, reduced hybrid picrite-troctolite melt at ~1190-1160°C. Exact
22 temperature estimates may vary slightly vary (not more than ~20°C), when considering different picrite-gabbro
23 and picrite-troctolite proportions.

33 **Conclusions:**

34 We have determined the Rum parental magma liquid line of descent over a wide range of oxygen fugacity,
35 from liquidus to solidus conditions. The plagioclase saturation temperature is only slightly higher than that of
36 clinopyroxene. We observe excellent agreement with MELTS calculations (Ghiorso and Sack, 1995; Asimow
37 and Ghiorso, 1998) in terms of crystal saturation temperatures and modal abundances increasing confidence in
38 this algorithm for understanding Rum petrogenesis. The temperatures and modes used in the reactive liquid flow
39 model by Leuthold et al. (2014a) are thus corroborated. Using the plagioclase and clinopyroxene chemistry in
40 Unit 9 and in experiments, we propose that the Rum parental magma was slightly reduced (around QFM-1.2).
41
42
43
44
45
46

47 We have studied experimentally the effect of mafic cumulate (gabbro and troctolite) melting by cogenetic
48 picrite liquid and melts hybridization. The liquidus and solidus temperatures are shifted from the picrite liquid
49 line of descent in hybrid experiments, in accordance with the cumulate equilibrium temperature. Mineral modes
50 are strongly modified. The plagioclase fraction, in particular, is increased significantly. Assimilation of mafic
51 crystals by mafic melt has a minor, but distinct, effect on the chemistry of the new crystal generation. High
52 temperature troctolite assimilation decreases spinel Fe#, Cr# and TiO₂ concentration. This is best explained by
53 olivine and plagioclase dissolution, releasing MgO and Al₂O₃ to the hybrid melt. Down-temperature, abundant
54 plagioclase crystallization strongly depletes the residual melt in Al₂O₃, driving the spinel towards low
55 Al/(Cr+Al). Clinopyroxene removes Cr₂O₃ from the melt, but its stability is reduced in such compositions,
56
57
58
59

65

1 favouring crystallization of high Cr# spinel. Chromites from Rum Unit 9 are best explained by troctolite
2 assimilation into invading reactive picrite and crystallization from a hybrid melt. Clinopyroxene and plagioclase
3 compositions cannot be explained simply by crystallization from pure picrite or basalt liquid and also require
4 hybridization with various proportions of gabbro and/or troctolite. Our observations confirm the model of Cr-
5 and Al-spinel precipitation from a hybrid picrite-troctolite melt, proposed by O'Driscoll et al. (2009b, 2010) and
6 Leuthold et al. (2014a). Our combination of natural observations and experiments allowed us to determine the
7 crystallization temperature and parental melt chemistry of the complex Rum Eastern Layered Intrusion
8 cumulates.

1 **Figure captions:**

2 Figure 1: Schematic representation of the complex reactive liquid flow process (modified from Leuthold et al.,
3 2014). Percolation of reactive liquid within crystal mush/cumulate has important consequences: crystal
4 chemistry and textures are modified by dissolution-recrystallization and re-equilibration; the rock structure is
5 changed by compaction and modification of the mineral mode; and the percolating liquid chemistry is modified
6 by assimilation, mixing and mingling, perturbing the normal liquid line of descent.
7
8
9

10
11 Figure 2: Experimentally-determined liquid compositions. Picrite 1atm, anhydrous, QFM; MELTS (Ghiorso and
12 Sack, 1995; Asimow and Ghiorso, 1998) calculations and Rum aphyric dykes are shown for reference. B62/2
13 picrite and 11JL33 basalt were used as starting material in the experiments. Grey areas delimit the composition
14 of Iceland plume mafic lavas (Hémond et al., 1993). The Rum picrite liquid line of descent is very similar to the
15 trend defined by the Rum dykes and Icelandic alkaline basalt. Through clinopyroxene-rich cumulate
16 assimilation, the experimental glass SiO₂ content is distinctly increased. Through clinopyroxene- and/or olivine-
17 rich cumulate assimilation, the liquid Mg# is increased. ¹McClurg, 1982 unpublished PhD thesis, ²Leuthold et
18 al., 2014a
19

24

25 Figure 3: BSE images of representative experimental run products (see Tables 2 to 5 for conditions). a) Picrite at
26 1210°C, QFM (run#87), illustrating few olivine and Cr-spinel crystals. Spinel grains are ~3µm in diameter and
27 require high spatial-resolution FEG-EMPA analysis. b) Picrite at 1170°C, QFM (run#51), showing the first
28 occurrence of clinopyroxene. c) Picrite at 1125°C, QFM (run #63), with 30 vol% glass. Crystallization of large
29 euhedral crystals in figures *b* and *c* was achieved by slow cooling (Heber et al., 2007) and temperature
30 oscillation (Mills et al., 2011; Mills and Gardner, 2013). The mineral modes in slowly cooled experiments are
31 indistinguishable from isothermal experiments. Olivine crystals show zoning (especially at low temperature). d)
32 Picrite-troctolite hybrid (50-50%) at 1190°C, QFM (run #78). The melt fraction is lower than in picrite at similar
33 temperatures. Cr-spinel mode is higher than in picrite and clinopyroxene saturation temperature is lowered to
34 ~1160°C. e) Picrite at 1180°C, QFM+2.8 (run #99). Under more oxidized conditions, spinel mode is enhanced
35 and its composition is more Fe³⁺-rich. f) Picrite at 1180°C, QFM-2.2 (run #61). Under more reducing conditions,
36 spinel is distinctly Fe³⁺-poor and becomes unstable at high temperature, as evidenced by corroded texture.
37 Abbreviations: Ol: olivine; Cr-spl: Cr-spinel; Plg: plagioclase; Cpx: clinopyroxene. Scale bar is 100µm.

47 Figure 4: Schematic representation of equilibrium mineral parageneses (filled grey fields in boxes) in picrite
48 (B62/2, Upton et al., 2002) (QFM+1.8, QFM and QFM-2.2), picrite-troctolite, picrite-gabbro and gabbro
49 experiments (see Table 1 for starting compositions and Tables 2 to 5 for run conditions and modal abundances),
50 as a function of temperature and Mg# of starting material. Spinel is stable in most experiments. Cr-spl: Cr and
51 Al-spinel; Spl: magnetite and titanomagnetite Ol: olivine; Plg: plagioclase; Cpx: clinopyroxene.
52
53
54
55

56 Figure 5: Mineral mode (vol%) in 0.1 MPa experiments. The liquid fraction is high until plagioclase
57 fractionation starts and strongly decreases thereafter. Clinopyroxene saturation temperature is systematically
58 lower than plagioclase one. Calculations using the MELTS (Ghiorso and Sack, 1995; Asimow and Ghiorso,
59
60
61
62
63
64
65

1998) algorithm at identical conditions show a good correspondence in mineral modes and saturation temperatures. Modal estimates have uncertainties of less than ± 5 vol%.

Figure 6: Glass and mineral chemistry as a function of temperature. The vertical bars indicate the variation of mineral compositions of Rum aphyric dykes and Unit 9 minerals (data from Holness et al., 2007 and Leuthold et al., 2014a). Spinel, olivine and clinopyroxene chemistry is strongly dependent on fO_2 . At identical temperature (i.e. lower melt fractions), the plagioclase anorthite content is higher in hybrid picrite-troctolite and picrite-gabbro experiments compared to picrite experiments. High temperature olivine and clinopyroxene (when present) have a higher Mg# in hybrid experiments. ¹McClurg (1982, unpublished PhD thesis), ²Leuthold et al. (2014a), ³Holness et al. (2007)

Figure 7: Spinel chemistry (averaged compositions). a) Fe# ($Fe\# = Fe^{2+}/[Mg+Fe^{2+}]$) progressively increases upon cooling, while $Al/(Cr+Al)$ decreases. The experimental data reveal systematically higher $Al/(Cr+Al)$ than the Rum Unit 9 grains. Spinel chemistry in picrite-troctolite experiments is highly variable in $Al/(Cr+Al)$, ranging from low ratio at high temperature to higher ratio than in picrite experiments at intermediate temperature. Through rapid re-equilibration with olivine down to sub-solidus conditions, spinel becomes Fe^{2+} -rich and Mg-poor (Roeder et al., 1979; Scowen et al., 1991; Kamenetsky et al., 2001, O'Driscoll et al., 2010). b) Down-temperature, spinel becomes Ti-rich. Prior to plagioclase saturation, spinel Al-content increases slightly. Spinel crystallized from Ti-poor and Al-rich hybrid melts have lower Ti and higher Al contents than spinels in picrite experiments (at the same melt fraction). ¹Holness et al. (2007), ²Leuthold et al. (2014b), ³O'Driscoll et al. (2009b), ⁴O'Driscoll et al. (2010), ⁵Upton et al. (2002)

Figure 8: Spinel trivalent cations chemistry (individual analyses). a) Natural spinels from the Rum Eastern Layered Intrusion (Units 7-8 and 11-12 boundaries, Unit 9 and picritic dykes [M9 and B62/2]) (modified after Leuthold et al., 2014 and O'Driscoll et al., 2010 and references therein). b) Calculations using MELTS (Ghiorso and Sack, 1995; Asimow and Ghiorso, 1998) covering a wide range of P-T-X- fO_2 conditions at which the Rum cumulates may have formed. QFM and oxidized picrite fail to reproduce the Rum Unit 9 Cr-rich spinels. Intermediate temperature spinel crystallized under reduced conditions should have high Cr#. Fractional crystallization, especially under reduced conditions, produces higher Cr# spinel. The $Al/(Al+Cr)$ ratio is lowered when the fO_2 is left free. Spinel crystallizing at moderate pressure or from hydrous melt results in even lower Cr#. Picrite-troctolite and plagioclase-doped picrite (not shown) spinels show a large $Al/(Cr+Al)$ scatter. Fractional crystallization under reduced conditions best reproduces the Unit 9 chromite. High temperature Cr-rich spinels are absent along the basalt liquid line of descent. c) Spinel equilibrated at 0.1 MPa from anhydrous picritic liquid variously affected by hybridization with mafic cumulate (gabbro, troctolite) (see Table 1 for compositions). Along the picritic liquid line of descent, spinel Al_2O_3 concentration increases up to the point of plagioclase saturation. Upon plagioclase crystallization, spinel Cr# increases until clinopyroxene saturates. With subsequent cooling, spinel rapidly evolves to magnetite and titanomagnetite compositions. Abundant Fe^{3+} -rich spinel crystallizes under oxidized conditions. Conversely, Fe^{3+} -poor spinel is rare under reduced conditions and becomes unstable following clinopyroxene saturation. Gabbro assimilation results in very limited variation of Cr-spinel chemistry during cooling. In contrast, troctolite assimilation strongly modifies spinel chemistry,

generating Al-rich spinels at high temperature, Cr-rich spinel at ~1180°C and Fe³⁺-rich spinels at lower temperature. The Rum Unit 9 chromites are best reproduced by picrite-troctolite experiments at 1180°C, QFM-1.2. Selected experimental temperatures [°C] are shown for reference. The grey shaded area delimits the Rum Unit 9 Cr-spinel compositional field. ¹Holness et al. (2007), ²Leuthold et al. (2014a), ³O'Driscoll et al. (2009b), ⁴O'Driscoll et al. (2010), ⁵Dunham and Wilkinson (1985), ⁶Upton et al. (2002).

Figure 9: BSE image and Al and Cr X-ray maps of the interface between a synthetic picrite and a troctolite initially equilibrated at 1250°C and QFM-1.2, left to react for 5 hours at similar conditions (run #154). Note the high abundance of Al- and Cr-spinel (up to 3.5 vol%) in the troctolite side of the hybrid reaction zone, where plagioclase is absent.

Figure 10: Schematic diagram illustrating potential modification of Cr-spinel chemistry by common magmatic processes. The diamond symbol indicates the Cr-spinel composition crystallized from B62/2 picrite starting material at 1180°C, QFM. The arrows show isothermal chemistry modifications and will change according to different temperatures (e.g. hot mafic, intermediate or cool differentiated interstitial melt). See text for discussions and references. ¹Henderson (1975), ²Bell and Claydon (1992).

Appendix figure 1: Geological map of the Hallival region, Eastern Layered Intrusion (ELI), from Emeleus (2004) (WLI: Western Layered Intrusion; CC: Central Complex). Units 8, 9, 10 and 11 allivalite are indicated. Note the discontinuous nature of the Unit 9 peridotite, attributed to formation from a sill-like intrusion of picrite (Bédard et al. 1988). Traverses F, G, H and E show the location of the traverses of Holness et al. (2007). Traverse M and its surroundings were described by Sides (2008, unpublished PhD thesis) and Leuthold et al. (2014a). Unit 7-8 and 11-12 boundaries were studied by O'Driscoll et al. (2009b, 2010). The brown cross in the inset shows the location of picritic dyke B62/2 sampled by McClurg (1982, unpublished PhD thesis) and analysed by Upton et al. (2002).

Appendix figure 2: Schematic examples of different experimental cooling paths used. Isothermal experiments (a,b) were set at the equilibrium conditions and quenched. The goal was to accurately determine the phase assemblage, proportions and major element chemistry. We used temperature oscillation (generally ±10°C) to grow coarser crystals with fewer inclusions, following Mills et al. (2011) and Mills and Gardner (2013). Following Fisk and Bence (1980), we ran cooling-rate experiments (c,d,e,f) to grow large crystals. Upon cooling, the *f*O₂ was constantly adjusted along a buffer. Crystals (mostly olivine ± clinopyroxene) in such experiments show little zoning, especially when equilibrated at low temperature (*F*<0.4). Undercooling was sometimes observed, evidenced by the absence of low temperature phases. In a few runs (c), samples were initially heated to 1260°C, where they became saturated in olivine and spinel, representing an already differentiated, crystal-bearing magma. Combining temperature oscillation to progressive cooling (e,f) contributes to growth of even larger crystals. Temperature oscillation (±10°C) 15°C below the saturation temperature of a new phase (f) is especially efficient in growing large crystals.

Appendix figure 3: Picrite (1), picrite-troctolite (2) and picrite-gabbro (3) cotectic compositions and

1 temperatures, plotted in the Forsterite – Diopside – Anorthite ternary projection using the algorithm of Grove
2 (1993). The clinopyroxene stability field increases at the expense of the plagioclase in hybrid picrite-gabbro
3 experiments and is significantly decreased in picrite-troctolite experiments. Basalt, troctolite and gabbro liquidus
4 glasses are shown for comparison.

Appendix Figure 2

Glass composition	
◆	picrite B62/2, QFM, 1atm, 1280-1110°C (cooling + equilibrium)
★	picrite B62/2 + troctolite, QFM, 1atm, 1370-1160°C
●	picrite B62/2 + gabbro, QFM, 1atm, 1235-1170°C
×	basalt 11JL33, QFM, 1 atm, liquidus
■	troctolite 11JL16, QFM-1.2, 1 atm, liquidus
▲	gabbro 11JL27, QFM, 1atm, liquidus
Mineral assemblages	
◇	> liquidus
◊	olivine-saturated
◈	olivine- + plagioclase-saturated
◑	olivine- + plagioclase- + clinopyroxene-saturated
