12 **Abstract**

13 New numerical and analytical modeling shows that the growth of a volcanic umbrella cloud,
14 expressed as the increase of radius with time, proceeds through regimes, dominated by
15 different force balances. Four regimes are identified: Regime Ia is the long-time behavior
16 of continuously-supplied intrusions in the buoyancy-inertial regime; Regime IIa is the long-
17 time behavior of continuously-supplied, turbulent drag-dominated intrusions; Regime Ib is
18 the long-time behavior of buoyancy-inertial intrusions of constant volume; and Regime IIb
19 that of turbulent drag-dominated intrusions of constant volume. Power-law exponents for
20 spreading time in each regime are $3/4$ (Ia), $5/9$ (IIa), $1/3$ (Ib) and $2/9$ (IIb). Both numerical
21 modeling and observations indicate that transition periods between the regimes can be long-
22 lasting, and during these transitions the spreading rate does not follow a simple power law.
23 Predictions of the new model are consistent with satellite data from seven eruptions and,
24 together with observations of umbrella cloud structure and morphological evolution, support
25 the existence of multiple spreading regimes.

28 volcanic eruption.

29 1. Introduction

30 When ash is injected into the atmosphere, its dispersal has been modeled using two
31 different approaches. By using a Volcanic Ash Transport and Dispersal Model (VATDM)
32 to disperse the ash in the atmosphere (e.g., [Heffter and Stunder, 1993](#); [Folch , 2012](#)), the
33 assumption is generally made that ash originates from a simple, arbitrary source region
34 and will propagate as a function of the windfield and other atmospheric variables alone.
35 By coupling an eruption column model to provide initial conditions to a VATDM ([Barsotti](#)
36 [et al. , 2008](#); [Bursik et al., 2012](#)), the assumption is made that no phase of lateral ash
37 spreading exists between eruption column rise and wind dispersal. Both of these approaches
38 lack a key aspect of the dynamics, namely the behavior and spread as an atmospheric
39 intrusion driven by gravity ([Woods and Kienle, 1994](#)). It has been hypothesized that the
40 gravitational spreading of an umbrella cloud can be the driving force, depending on the
41 intensity of the eruption, over tens to thousands of kilometers from the source (e.g., [Bursik,](#)
42 [Carey and Sparks, 1992](#); [Sparks et al., 1997](#); [Bonadonna and Phillips , 2003](#); [Costa, Folch](#)
43 [and Macedonio, 2013](#)). Lack of inclusion of gravitational spreading of ash could lead to
44 significant mischaracterization of its transport in the atmosphere.

45 The goal of the present contribution is to test a new model for radial, gravity-driven
46 intrusion of volcanic ash and gas into the atmosphere in the umbrella cloud. The model
47 suggests the existence of distinct fluid dynamical regimes as the umbrella cloud grows with
48 time. We test the model by careful measurement of umbrella cloud growth from satellite
49 imagery, and comparing that growth with model output. We seek to understand whether the
50 different fluid dynamical regimes can be observed in the data, and if so, what they imply for

51 the dynamics of cloud growth, the quantitative values of parameters controlling that growth,
52 and the time and distance to which gravity-driven growth can be recognized.

53 In the following sections, we summarize research on gravity-driven interflow within a
54 stratified fluid, introduce the eruptions to be studied and the newly developed model of
55 intrusion (Johnson *et al.*, 2015), which improves upon past efforts. We test the model
56 predictions against observations for umbrella clouds produced by seven different eruptions,
57 which allows us to assess the values of the different parameters influencing gravity flow,
58 and the magnitude and duration of release of material into the atmosphere. Finally, we
59 discuss implications for ash transport modeling. We also include an appendix in which a
60 new similarity solution for the radial intrusion of a finite volume of fluid through a linearly
61 stratified environment is constructed, in the regime where the driving gravitational forces
62 are balance by drag.

63 2. Background

64 A buoyant plume rises vertically through an otherwise motionless environment, mixing
65 with the surrounding fluid and eventually intrudes horizontally at its level of neutral buoy-
66 ancy, where it spreads radially to form an axisymmetric cloud (see Fig. 1 and Morton *et al.*
67 (1956)). Our study is concerned with the way in which the horizontal motion is driven by
68 gravitational forces. This class of flow is that of a ‘gravity current,’ the term used for the
69 predominantly horizontal motion of fluid of one density through surrounding fluid of another
70 density; such motions have been widely researched for the past 60 years (see, for example,
71 the textbooks of Simpson (1997) and Ungarish (2009), and the studies of Chen (1980) and
72 Lemckert and Imberger (1993), which are of particular relevance for the current work).

73 Most previous work has used scaling techniques to identify different spreading behaviors
74 of intrusions (Chen, 1980; Ivey and Blake, 1985; Woods and Kienle, 1994; Kotsovinos, 2000),

75 and a small number of recent studies have used numerical modeling to better understand
76 umbrella cloud growth (Suzuki and Koyaguchi, 2009). Several workers have compared results
77 with data obtained from laboratory experiments (Didden and Maxworthy, 1982; Ivey and
78 Blake, 1985; Kotsovinos, 2000), but there has been only limited comparison to full-scale
79 natural events, notably including the study of Holasek, Self and Woods (1996), who found
80 good agreement between a simple scaling relation and the spread of the 1991 Pinatubo
81 (Phillipines) umbrella cloud. In general, these studies identified a power-law relationship
82 between the radius of the intrusion and time as the intrusion grew, however, the particular
83 value of the power-law exponent differed between studies, even for similar driving forces, and
84 for instantaneous or continuous releases.

85 To summarize the fluid dynamical relationships that have been discussed by previous
86 workers, the driving force acting on the flow is predominantly *buoyancy* (the flows are
87 gravitationally-driven), and the resisting forces are *inertial* or *turbulent* drag. (Tables 1
88 and 2 show the flow regimes arising from the different combinations of these forces.) In the
89 earliest stages of development flows may also be *momentum driven* (Chen, 1980). By *gravity*
90 *driven flow*, we refer to the stage in which the flow is propagating due to gravitational effects
91 at the level of neutral buoyancy. This stage can be divided into two phases. First, the phase
92 in which the dominant force resisting spreading is the inertia of the displaced fluid, which we
93 will call *inertial drag*. This regime arises in the early stage of intrusion, when the greatest
94 difficulty in driving the relatively deep flow forward is the inertia of the air that needs to
95 be moved out of the way. In this case, the drag force is primarily a function of the velocity
96 of the flow front and the density of the fluid being intruded. The second regime is that
97 in which the dominant resisting force is the drag along the interfaces (top and bottom) of
98 the spreading current; it will be called *turbulent drag*. This regime corresponds to a flow in
99 which the drag is a function of the velocity and the coefficient of eddy viscosity. *No drag*

100 corresponds to the case in which the magnitude of the drag force is negligible compared to
101 that of the driving force.

102 **3. Data**

103 For the purpose of this study, umbrella clouds (volcanic, radially driven intrusions into
104 a relatively still atmosphere) from seven eruptions were studied in the visible and infrared
105 bands in satellite images. The eruptions were chosen due to their characteristics (e.g., du-
106 ration of eruption, wind speed) and availability of good quality observations (i.e., satellite
107 imagery). On the daytime images, the diameter of the umbrella cloud was measured in
108 eleven different directions to obtain a mean and standard deviation for the radius. The
109 edge of the cloud was determined first by outlining from the visible band image, and then
110 refining that outline using the brightness temperature or the infrared bands, when available
111 (further details on this technique can be found in [Pouget *et al.* \(2013\)](#)). The duration of the
112 eruption (start to cessation) was estimated from time, $t = t_0 = 0$, taken to be the start of
113 the generation of the eruption column, using seismic and infrasound data, and ground obser-
114 vations when available. If the first observation consisted of satellite or ground observation
115 of a rising plume, the time of acquisition of this image was used for the eruption start time.
116 The difference between the time the first image was acquired after the umbrella cloud began
117 to spread and the start of the eruption was used to estimate the uncertainty in start time,
118 i.e., the size of the error bar in time.

119 The eruptions were initially divided into two groups based on eruption duration (the time
120 during which material was injected into the atmosphere without major interruptions, not
121 the duration of continued emissions of any type, nor the lifetime of the plume as a distinct
122 entity in the atmosphere):

123 1. Group 1 – short-lived eruptions: Redoubt, 1990; Shishaldin, 1999 and Sarychev Peak,

124 2009.

125 2. Group 2 – long-lived eruptions: Pinatubo, 1991; Okmok, 2008, Grímsvötn, 2011 and
126 Kelut, 2014.

127 A short-lived eruption here is defined by an injection of material into the atmosphere sus-
128 tained for less than the time over which satellite observations of the plume were made, i.e.,
129 the eruption ceased before the last satellite images were acquired. A long-lived eruption
130 lasted longer than the time of satellite acquisition. This division is important, because the
131 intruding mass can be driven by the continued addition of new mass, as well as the gravi-
132 tational forces. Long-lived eruptions cannot therefore be approximated by an instantaneous
133 release of material. The characteristics of each eruption within its group can be found in
134 Table 3.

135 3.1. Eruptions

136 3.1.1. Redoubt, 21 April 1990

137 Mount Redoubt (Alaska, USA) was active from 15 December 1989 to 21 April 1990.
138 On that last day, at 14:12 UTC, a relatively small explosive eruption – four-minutes long,
139 based on seismic data (Power *et al.*, 1994) – generated a pyroclastic flow that formed a large
140 buoyant ash cloud (Woods and Kienle, 1994). The cloud was observed to rise and spread
141 into an umbrella cloud at an altitude of 12 km ASL, by videocamera and still photography
142 (Kienle *et al.*, 1992), with a cloud deck, top height centered around 14.6 km. The umbrella
143 cloud tripled its radius in less than 10 minutes, and rose to its maximum altitude in about 3
144 minutes (Woods and Kienle, 1994). Total mass of ash in the cloud was estimated by Woods
145 and Kienle (1994) and Pouget *et al.* (2013) as $\sim 2 \times 10^9$ kg at a temperature of 300 K.
146 The series of photographs shows that the cloud grew with no major asymmetry, but that it
147 had two intruding discs. The discs may be the result of a natural stratification within the

148 cloud due to particle diffusive convection (Bursik, 1998; Carazzo and Jellinek, 2013), wherein
149 particles concentrate at different levels based on their settling speed. We used the sketch of
150 the outlines of the upper, more particle rich, cloud made from the original photographs and
151 scaled by Woods and Kienle (1994).

152 3.1.2. Pinatubo, 15 June 1991

153 The eruption of Pinatubo (Luzon, Philippines) was the most intense eruption occurring
154 during the modern satellite era. After weeks of precursory activity, a paroxysmal phase was
155 reached on 15 June 1991 (Koyaguchi and Tokuno, 1993), which resulted in the observation of
156 ash injected in the atmosphere for 14 hours from a plume that rose to nearly 40 km initially,
157 but settled down to 20–25 km for an extended period, with a total of 16 h over 20 km
158 height (Holasek, Self and Woods, 1996). Due to the powerful nature of this eruption, winds
159 had little influence on the intruding material, therefore a large circular umbrella cloud was
160 observed. It is uncertain when the eruption column of the paroxysmal phase started rising,
161 since direct observations were not possible and meteorological clouds limited the observations
162 from satellites. Based on seismic data, the first observation of a plume from the paroxysmal
163 phase at 22:41 UTC could be the result of an eruption that produced high-amplitude tremor
164 beginning at 22:15 UTC. Visible and infrared GMS data were available every hour, and were
165 analyzed by Holasek, Self and Woods (1996) to show the growth of the umbrella cloud. They
166 found that the umbrella cloud spread symmetrically for the first 4 to 5 hours before slight
167 stretching in the East-West direction by a wind of average speed 4-5 m/s. The images used
168 by Holasek, Self and Woods (1996) were used in this study.

169 3.1.3. Shishaldin, 19 April 1999

170 During the summer of 1998, Shishaldin (Aleutian Islands, USA) became seismically ac-
171 tive. This activity increased until 19 April 1999, when 80 minutes of strong seismicity,

172 starting at 19:30 UTC, was associated with a subplinian eruption ([Thompson, McNutt and](#)
173 [Tytgat, 2002](#)). The eruption column rose to a maximum height of 16 km before dissipating
174 within a few hours, presumably because of the high sedimentation rate of coarse particles.
175 The spreading umbrella cloud was observed on Geostationary Operational Environmental
176 Satellite (GOES) ([Nye et al., 2002](#)).

177 *3.1.4. Okmok, 12 July 2008*

178 Okmok volcano (Aleutian Islands, USA) erupted on 12 July 2008 with little seismic
179 warning. Seismic studies put the eruption start time at 19:43 UTC ([Arnoult et al., 2010](#);
180 [Johnson et al., 2010](#)). The eruption was most intense and continuous in the first ten hours
181 ([Arnoult et al., 2010](#)). A dark ash-rich plume was noticed first on GOES images at 20:00
182 UTC ([Neal et al., 2008](#)), with an initial height of 16 km ASL ([Larsen et al., 2009](#)), and which
183 was followed an hour later by a white, vapor-rich plume. Both of these grew together into a
184 large umbrella cloud that started being distorted by the wind at about 23:00 UTC.

185 *3.1.5. Sarychev Peak, 14 June 2009*

186 A MODIS image at 00:31 UTC showed a thermal anomaly and a possible weak plume
187 at Sarychev Peak (Kurile Islands, Russia) on 11 June 2009. Later images confirmed the
188 release of ash into the atmosphere ([Rybin et al., 2012](#)). The activity, which lasted for 9
189 days, consisted of 23 separate explosions leading to the emission of ash plumes ([Rybin et al.,](#)
190 [2009](#)). The ash plume studied here was emitted from an eruption that began on 14 June at
191 18:51 UTC ([Pouget et al., 2013](#)). The infrasonic data suggest eruptive activity lasting 1 h
192 19 min ([Matoza et al., 2011](#)). The umbrella cloud grew undisturbed until 21:30 UTC, when
193 it reached a maximum height of 16 km, before being elongated in both western and eastern
194 directions ([Levin et al., 2010](#)).

195 *3.1.6. Grímsvötn, 21 May 2011*

196 On 21 May 2011, at 19:00 UTC, Grímsvötn (Iceland), entered into a week-long explosive
197 subglacial eruption (Petersen *et al.*, 2012). Activity was most intense during the first 10
198 hours, when the plume reached a momentary, maximum height of 25 km, with a sustained
199 height of 11-19 km for 12 h. The plume eventually decreased to a 10-km height on 23
200 May, and finally a 5-km height on 24 May, before the end of the eruption on 28 May at
201 07:00 UTC (Tesché *et al.*, 2012). The umbrella cloud can first be seen at 19:15 UTC on a
202 EUMETSAT Meteosat-9 satellite image. However, the signature of the eruption column can
203 be observed on a satellite image taken 15 minutes earlier, and an initial explosive burst 30
204 minutes earlier. GOES passed over Iceland at 18:45 UTC, when no activity was observed
205 by this lower-resolution platform, as well as 30 minutes later, when the cloud was clearly
206 visible. During the first four hours of the eruption, four ash-rich pulses have been identified
207 (peaks in bursts at 18:45, 19:45, 20:30 and 21:00 UTC) on imagery. Each of these pulses
208 contributed to an umbrella cloud until 22:00 UTC, when the ash cloud became a downwind
209 plume propagating to the south-east.

210 *3.1.7. Kelut, 13 February 2014*

211 On 13 February 2014, around 16:15 UTC, Kelut volcano erupted in Eastern Java, Indone-
212 sia. Access to satellite imagery at 10-minute intervals allowed a close study of the evolution
213 of the eruption. During the first three hours, an umbrella cloud grew, but then quickly dis-
214 persed. The plume reached a maximum altitude of 26 km, and spread laterally at an altitude
215 of 18 km (S. Carn, personal communication, 2014). Even though the eruption took place
216 during the night, features interpreted to be gravity waves were observed on the upper surface
217 of the umbrella cloud in infra-red images (E. Jansson, personal communication, 2014).

218 *3.2. Cloud mapping*

219 The fluid dynamical structures on satellite imagery of three of the eruptions, Okmok,
220 Sarychev Peak and Grímsvötn, were mapped in detail, to ascertain whether any features in
221 the eruption clouds corresponded with fluid dynamical regime. These qualitative observa-
222 tions in fact allowed us to recognize different dynamical behaviors during the evolution of
223 each cloud.

224 On the first image from the eruption of Sarychev Peak at 18:57 UTC on 14 June, the
225 umbrella cloud had risen above the meteorological cloud cover in a subspherical and contained
226 (or well-defined) shape, with several irregularities identified as eddies (Fig. 2). This stage
227 will be referred to as the *mushroom* stage, given the observed geometry of the cloud. By
228 19:30 UTC, the umbrella cloud had lost its subspherical shape and appeared to be wider and
229 more flattened. This state is identified as being near the beginning of horizontal spreading.
230 At this time, most of the umbrella cloud was still affected by eddies, particularly close to the
231 intrusion origin. However, the distal umbrella cloud fringe was characterized by a smooth
232 appearance (fewer eddies) and radial, finger-like edges. The smoothness is attributed to
233 loss of turbulent energy due to loss of buoyancy, and the impact of the drag force. Gravity
234 waves started appearing in this outer part of the umbrella, with a wavelength between 10
235 and 40 km around the intrusion point, and between 2 and 8 km from the intrusion point
236 to the edge of the cloud. In this and all other imagery, wave breaking was not observed,
237 suggesting that entrainment throughout the umbrella cloud was minimal. As time went
238 by, the umbrella cloud became more homogeneous as eddies were less pronounced (e.g. at
239 19:57 UTC). The cloud became completely smooth except for gravity waves visible on the
240 upper surface. On the last image at 20:30 UTC, only a few eddies are seen, but many
241 concentric gravity waves are visible across the surface of the umbrella cloud, as well as in
242 the surrounding meteorological clouds.

243 The first two images (18:45 and 19:00 UTC) of Grímsvötn show the rise of the eruptive
244 column above the meteorological cloud cover (Fig. 3). At 19:15 UTC, an umbrella cloud, still
245 attached to a visible eruptive column, started to spread horizontally. This umbrella cloud
246 was subspherical, dark and well-contained, with an irregular surface, which is consistent with
247 the 'mushroom' stage. Irregularities in short wave-length color suggest the presence of eddies.
248 At 19:30, the umbrella was larger and remained subspherical, but did appear to be evolving
249 between the mushroom and the later, "classical" umbrella stages. It was elongated in the
250 horizontal dimensions rather than vertically. Several eddies were visible on the surface of
251 the cloud. By 19:45 UTC, the umbrella cloud was larger and slightly less turbulent. Eddies
252 were still visible, but the edges of the umbrella appeared to be smoother, although some
253 radial, finger-like edges started to appear. From 20:00 to 21:00 UTC, the umbrella cloud
254 enlarged and smoothed with time, with a possible thickening toward the leading edge. The
255 proportion of the umbrella affected by eddies diminished, and these became confined to the
256 area above the vent, where material continued to be intruded into the atmosphere by new
257 bursts from the eruptive column. These new bursts were observed in images at 19:45, 20:00,
258 20:15 and 20:30 UTC. As the umbrella grew, gravity waves started appearing; unfortunately,
259 a shadow obscured further observations.

260 The eruptive cloud from Okmok observed in the first available image at 20:00 UTC was
261 already a large, spreading umbrella cloud, with finger-like edges; the mushroom stage was
262 not observed (Fig. 4). The edges were quite smooth, and even though there was a small
263 region around the intrusion point with several irregularities (i.e., eddies), most of the cloud
264 appeared smooth, and thus, far from the mushroom stage. From 20:30 to 23:00 UTC, the
265 umbrella cloud grew larger and wider, and gravity waves started to be visible. At 21:00, a
266 new burst of vapor-rich material was seen intruding above the upper deck of the umbrella
267 cloud.

268 4. Model

269 We model volcanic clouds as axisymmetric intrusions of well-mixed fluid into an otherwise
270 quiescent, stratified atmosphere. Initially, as the rising eruption column begins to spread at
271 the neutral buoyancy level, the flow is complex and highly turbulent with several potential
272 mechanisms affecting the rate of spreading, including momentum-driven flow (Chen, 1980;
273 Kotsovinos, 2000) resulting from the collapse of plume fluid that has risen above the neutral
274 buoyancy level. This early phase we believe to correspond to our observational ‘mushroom’
275 phase or stage, as seen in the cloud mapping. However, as the cloud spreads the dynamics
276 becomes driven by horizontal pressure gradients resulting from variations in the thickness of
277 the intrusion. These pressure gradients are referred to by the more general term “buoyancy.”

278 Previous studies of the buoyancy-driven spreading mechanism for intrusions are based on
279 a box model, in which a single, characteristic cloud thickness is assumed, allowing equations
280 of motion to be derived using force balances or scaling arguments (Lemckert and Imberger,
281 1993; Woods and Kienle, 1994; Costa, Folch and Macedonio, 2013). These approaches lead
282 to the prediction that the radius of a continuously supplied plume grows as $t^{2/3}$ (Woods
283 and Kienle, 1994), which has become widely used (Sparks *et al.*, 1997; Pouget *et al.*, 2013).
284 However, the underlying assumption that it is possible to capture the unsteady evolution
285 of the thickness of the cloud through a single characteristic variable is inappropriate (see
286 Johnson *et al.* (2015)). Instead we use the analytical and numerical modeling of a buoyancy-
287 driven intrusion developed by Johnson *et al.* (2015), which solves a complete system of
288 ‘shallow-water’ equations to give the evolution of the ash cloud radius with time, as well as
289 its thickness and radial velocity as functions of space and time. This model shows that the
290 buoyancy-dominated state forms two distinct dynamic regimes, with different behavior close
291 to the front from what is observed in the interior. Asymptotic solutions at late times show
292 that the buoyancy-inertial regime in fact predict that the radius grows as $t^{3/4}$. Full numerical

293 solutions allow us to study quantitatively the transition between different flow regimes as
 294 indicated by different asymptotic behavior, such as the onset of significant drag effects late
 295 in spread, as the buoyancy force decreases.

296 Full details of the modeling are reported by [Johnson *et al.* \(2015\)](#), but in essence the
 297 buoyancy-driven intrusion is shallow (with horizontal length scales much larger than vertical
 298 ones), implying that vertical fluid accelerations are negligible and therefore that, except near
 299 the flow front, the pressure is hydrostatic. We assume that the suspended ash is sufficiently
 300 dilute and fine that sedimentation does not cause density changes, and therefore plays no
 301 dynamic role in the radial spread of the plume. Furthermore, we assume that entrainment
 302 of air into the intrusion is negligible, once gravity-driven flow is established. We therefore
 303 consider neither sedimentation nor entrainment in this paper, although the incorporation of
 304 these is a straightforward extension to the model.

305 We describe the axisymmetric flow in terms of its thickness h and radial velocity u , both
 306 functions of the radial distance from source r and time t (note that h represents the thick-
 307 ness of the intrusion, not its altitude above the ground). These are governed by equations
 308 representing the conservation of mass and the balance of radial momentum,

$$\frac{\partial h}{\partial t} + \frac{1}{r} \frac{\partial}{\partial r} (ruh) = 0 \quad (1)$$

309 and

$$\frac{\partial}{\partial t} (uh) + \frac{1}{r} \frac{\partial}{\partial r} (ru^2h) + \frac{\partial}{\partial r} \left(\frac{N^2 h^3}{12} \right) = -C_D u |u|, \quad (2)$$

310 respectively ([Ungarish and Huppert, 2002](#); [Johnson *et al.*, 2015](#)). In (2), N denotes the buoy-
 311 ancy frequency of the atmosphere and the spread of the intrusion is resisted by a turbulent
 312 drag, parameterized with the coefficient C_D .

313 Where momentum-driven flow ends and buoyancy-driven flow begins, we must specify
 314 not only the volume flux per unit radian, $Q = ruh$, but an additional boundary condition,

315 r_0 , the radius at which the flow is critical, i.e., the radius at which the Froude number,
 316 $Fr \equiv 2u/(Nh) = 1$. This source condition is imposed from $t = 0$ to some time t_c at which
 317 the eruption ceases; thereafter the condition applied at the source is that no further fluid
 318 enters the intrusion ($hu = 0$). At the front of the intrusion $r = r_f(t)$, vertical accelerations
 319 of fluid are non-negligible, and the forces resulting from the corresponding non-hydrostatic
 320 pressure are represented by the boundary condition $u = Fr_f Nh/2$, where Fr_f is a constant
 321 Froude number of order unity (see [Ungarish, 2006](#), and references therein).

322 The governing equations (1) and (2) are hyperbolic, and may therefore develop discon-
 323 tinuities in the solution, here termed ‘shocks’. We assume that relatively little mass or
 324 momentum is transferred between the intrusion and the ambient atmosphere at these shocks
 325 (compared with the mass and momentum fluxes of the intrusion itself), leading to the jump
 326 conditions:

$$[h(u - c)]_+^+ = 0 \quad \text{and} \quad [hu(u - c) + N^2 h^3 / 12]_+^+ = 0, \quad (3)$$

327 where c is the radial speed of the shock and $[\dots]_+^+$ denotes the difference between quanti-
 328 ties either side of the shock. We use a non-oscillatory shock-capturing numerical method
 329 ([Kurganov and Tadmor, 2000](#)) to ensure that these conditions are satisfied in the numerical
 330 solutions.

331 By nondimensionalizing the equations and boundary conditions above with respect to the
 332 timescale N^{-1} and the lengthscale $(Q/N)^{1/3}$, the parameters Q and N are scaled out of the
 333 problem for numerical solution. Four parameters remain: the frontal Froude number, Fr_f ,
 334 the dimensionless duration of the eruption, t_c , the drag coefficient, C_D , and the dimensionless
 335 source radius at which the flow is critical, r_0 , which is the initial condition for the radius of
 336 the cloud. After [Ungarish \(2006\)](#), we set $Fr_f = 1.19$.

337 Our modelling of the intrusion does not include the significant vertical motions that exist
 338 within the intrusion very close to the source. For this reason we model the spreading only

339 from the source radius onward $r \geq r_0$, and define $t = 0$ as the time when $r = r_0$.

340 The equations of motion (Eq 1 to 3) were solved by numerical integration. A total of 204
341 computational runs were performed to cover a broad range of values for the parameters and
342 scales influencing the model output (Table 4). The values were chosen not only to assess the
343 influence of the parameters on the result but also to reflect as much as possible the values
344 during each of the eruptions studied for this research. It is important to remember that
345 “duration,” t_c , and “source radius,” r_0 , are dimensionless parameters, and their dimensional
346 equivalents, D and R , can be calculated using the value of the timescale, i.e., $D = t_c/N$ and
347 $R = r_0(Q/N)^{1/3}$.

348 5. Results

349 We focus first on numerical results for the theoretical growth of radius with time, and
350 investigate the behavior with different input parameter values. Next, we compare the radial
351 growth of the umbrella cloud according to the new numerical model with data. Finally, we
352 investigate whether any particular power-law relationship (hence asymptotic behavior) can
353 be seen in any given dataset.

354 5.1. Theoretical growth of radius with time

355 The radius is plotted against time in Figure 5a, for four sets of parameters: intrusions
356 with and without drag ($C_D = 0$, $C_D = 0.01$, where 0.01 is a typical value inferred from
357 observations; see Baines (2013)), and intrusions of short and long duration ($D = 20$ minutes
358 and $D = 12$ hours). As plotted on logarithmic axes, a straight line of gradient α indicates
359 a power-law relationship $r_f \sim t^\alpha$. To identify the regimes of power-law behavior, we plot
360 the gradient of the four curves in Figure 5b. Power-law behavior is indicated on this graph
361 by a horizontal line. We highlight with dotted lines the four regimes of power-law cloud
362 growth, each corresponding to a long-time, asymptotic solution of the model. These regimes

363 are: regime Ia, $r_f \sim t^{3/4}$ (upper red line), the long-time behavior of continuously-supplied,
 364 intrusions in the buoyancy-inertial regime; regime IIa, $t^{5/9}$ (upper green line), the long-
 365 time behavior of continuously-supplied, turbulent drag-dominated intrusions; regime Ib, $t^{1/3}$
 366 (lower red line), the long-time behavior of buoyancy-inertial intrusions of constant volume,
 367 i.e., those continuing for a substantial time after the eruption has ceased, $t > D$ (Ungarish
 368 and Zemach, 2007); and regime IIb, $t^{2/9}$ (lower green line) for turbulent drag-dominated
 369 intrusions of constant volume, again at $t > D$, described in Appendix A.

370 Vertical lines in Figure 5 indicate the times at which the eruption stops (D), and the
 371 feeding of the intrusion ceases, i.e., volume becomes constant at that time. The rapid decrease
 372 in growth exponent shortly after these times (figure 5b) represents the slowing effect that
 373 eruption cessation has on cloud growth.

374 It is evident from Figure 5b that, while the behavior of the model does indeed approach
 375 these four regimes at large time, for much of the duration of the eruption, the flow is not fully
 376 in any particular asymptotic regime, and thus its effective exponent α varies with time. Of
 377 particular note is the effect of drag, which results in a slow decay of α towards its asymptotic,
 378 regime IIa value of $5/9 = 0.55\dots$, and a lengthy period during which the cloud grows at
 379 a rate between $t^{0.6}$ and $t^{0.7}$. Observations of umbrella clouds that appear to be consistent
 380 with a $t^{2/3}$ growth rate (Woods and Kienle, 1994) may well in fact be undergoing this long
 381 transition to drag-dominated flow, with an eventual growth rate of $t^{5/9}$.

382 5.2. Influence of parameters

383 To evaluate the influence of the values of the three parameters (C_D , t_c and r_0), compu-
 384 tations were made in which the value of one of these was changed while the values of the
 385 others were fixed (Table 4; Fig. 6). The resulting informal exploration of the parameter
 386 space, using the 204 model runs, allowed for comparison of three to ten separate outputs for
 387 each parameter. The number of outputs per parameter varied depending on ease of inter-

388 preting the resulting trends in the change in shape or position of the umbrella growth curve
389 in (t, r) -space.

390 In all model runs, the cloud radius predicted by the model increases with time. At very
391 early times, ($t \lesssim 10^2$), the spreading is strongly affected by the precise conditions at the
392 source. Thereafter the radial spreading adopts a more universal behavior, with the fastest
393 expansion occurring early on, before progressively slowing at later times. Two asymptotic
394 regimes are evident from the log-log plots: a regime of relatively rapid growth while the
395 eruption is ongoing (Regime Ia), followed by a regime after the eruption has ceased, in
396 which the growth rate is slower (Regime Ib). These are separated by a regime transition
397 (Fig. 5).

398 For comparison, we begin by looking at the effect of the buoyancy frequency, N (Fig.
399 6a), which is one of the primitive, dimensional variables used in the analysis. Three different
400 values of N were tested — 0.001, 0.01 and 0.1 s^{-1} . Since N occurs in the model only through
401 the nondimensionalization, variations of N simply result in a translation of the growth curve;
402 a similar translation would occur with variation of V or Q . For a larger buoyancy frequency,
403 intrusion starts sooner and the radius of the umbrella cloud with time is smaller, since the
404 eruption column reaches the level of neutral buoyancy earlier.

405 Four different values of the coefficient of drag, C_D , were tested — 0.0, 0.1, 0.01 and 0.001
406 (Fig. 6b). The *shape* of the curve is affected by changes in C_D , and in particular a new regime
407 is introduced (Regime IIa), in which the spreading of the cloud is dominated by turbulent
408 drag, which becomes increasingly significant at late times. An increase in the coefficient
409 of drag results in an earlier onset of the drag-dominated spreading regime, reducing the
410 duration of the more rapid buoyancy-inertial spreading regime. Larger coefficients of drag
411 diminish the growth of the umbrella cloud, both while the cloud is still growing and later,
412 once the eruption has ceased.

413 The duration, t_c , of the eruption emission (Fig. 6c) directly controls the duration of the
414 first regime of spreading (Ia). The cessation of the eruption causes the expansion rate of the
415 cloud to decrease rapidly (towards Regime Ib), although it continues to spread. The (final)
416 cloud volume, after the eruption has ceased, is proportional to the duration of eruption,
417 which then acts as a scale for the radius in Regime Ib.

418 The last parameter was the initial, nondimensional radius of the intrusion, which was
419 tested with three different, nondimensional values — 1, 1.5 and 2 (Fig. 6d), which are of
420 similar magnitude to the value suggested by Baines (2013). Changes to the initial radius
421 mainly affect the cloud radius at early times (within the first few minutes of an eruption),
422 and rapidly become negligible as the intrusion grows to much larger radii.

423 At early times, the log-log plots shown here become sensitive to small offsets of the
424 radius r or time t , which become negligible as soon as the intrusion expands to a width
425 much greater than that of the source. The difficulty with obtaining precise predictions of
426 the cloud behaviour at early times is compounded by the likelihood of a time-varying flux
427 supplying the intrusion, as the plume first reaches the neutral buoyancy layer. For this
428 reason, interpreting model results during the first few minutes of an eruption is likely to be
429 difficult.

430 *5.3. Fitting the new numerical model to observations*

431 Given that a complete exploration of the parameter space for the numerical model was
432 beyond the scope of the present contribution, output from the numerical model is directly
433 compared with observational data for a subset of the eruptions for which reasonable fits
434 with the numerical model were found. This constitutes a straightforward and qualitative
435 exploration of the model, and its transitions between different flow regimes. Note there is
436 not a unique solution in such model fitting. Here, a reasonable, illustrative set of parameters
437 was used to estimate the conditions of the intrusion of the material in the atmosphere and

438 its spreading by gravity (Table 5). For each of the eruptions, several outputs from the model
439 were then explored for goodness of fit. The parameter ranges being explored in each case
440 were chosen according to the characteristics of the eruption.

441 Considering the eruption of Shishaldin (Fig. 7a), fitting of the model suggests that the
442 data are consistent with the initiation of an asymptotic flow regime. Over much of the period
443 of observation, this umbrella cloud can be characterized by spreading as a gravity current
444 with turbulent drag as the main resisting force in regime IIa (Table 1; Fig. 5). The growth of
445 the umbrella cloud of Okmok is within Regime 1a (Fig. 7b), corresponding to inertial drag
446 being the main resisting force. The model results are consistent with a drag coefficient of
447 0.01, and $D = 9$ hr (Table 5. The observed duration was 10 hr (Table 3). For the eruptions
448 of both Sarychev Peak and Grímsvötn (Fig. 7c, d), a convergence from early times can be
449 observed into Regime Ia. This suggests that the Sarychev Peak eruption was continuously
450 fed during the period of observation. It appears there are insufficient observations to see a
451 transition to Regime Ib. The data suggest the eruption duration for Sarychev Peak to be
452 ~ 4740 s (Table 3), while the model is consistent with $D \sim 6000$ s. For Grímsvötn, model
453 duration (9 hr) is likewise similar to observed (10 hr). Data from Kelut suggest a progressive
454 transition from Regime Ia to Ib or IIa (Fig. 7e). The model eruption duration of ~ 6000 s
455 can be compared with an observed value of ~ 10800 s. The final three observations show a
456 decrease in radius with time within the error bars. If real, it is presumably due to dispersal
457 of the cloud, which is not captured by the model.

458 For those eruptions with cloud mapping (Sarychev Peak, Okmok and Grímsvötn), the
459 earliest time a smooth cloud top is seen in satellite imagery is indicated in Figure 7. In the
460 case of Sarychev Peak and Okmok, asymptotic, gravity current behavior is indeed seen in
461 the growth rate data after this time. In the case of Sarychev Peak, we can furthermore say
462 that asymptotic behavior is not seen in imagery before this time. For Grímsvötn, however,

463 asymptotic behavior is achieved before the appearance of the smooth cloud top. The data
464 therefore suggest that a smooth cloud top may provide an indicator of asymptotic gravity-
465 inertial flow.

466 In this set of eruptions with reasonable fits of numerical model outputs to data, non-
467 asymptotic behavior in cloud growth, and several growth regimes, are consistent with data.
468 For three of the eruptions, model eruption duration is quite close to observed. These results
469 suggests that inverse modeling may yield a wealth of information about both the atmosphere
470 and the volcanic eruption from satellite imagery. For example, volumetric flux into the um-
471 brella cloud can be estimated ($2\pi Q$ from Table 5). The product of the pyroclast volumetric
472 density and the integral of volumetric flux over time from 0 to D yields, of course, particle
473 mass loading.

474 *5.4. Asymptotic, power-law relationships observable in the data*

475 We now explore the data further by looking for sections of growth curves for all eruptions,
476 in which asymptotic behavior might be occurring. We then estimate best-fit asymptotes to
477 those sections of the growth curves. This is a process fraught with uncertainty, as the
478 numerical model suggests that asymptotic behavior can be difficult to achieve. Previous
479 studies have assumed power-law behavior; the present study represents the first time that
480 data are explored in sufficient detail to determine the true growth behavior. We begin by
481 exploring the short-lived eruptions, and then look into the long-lived ones. Our goal in this
482 section is to explore in what way the data are consistent with power-law behavior, and if so,
483 whether there are consistent flow regimes indicated for different eruptions. Power-law fits
484 were applied to the data after logarithmic transformation, using a least-squares regression,
485 and the mean and standard deviation of the power-law exponent were calculated.

486 *5.4.1. Short-lived eruptions*

487 The power-law relationships for growth of intrusions into stratified fluids have been tested
488 against the data (Fig. 8). Because it is not clear where exactly lies the temporal dividing
489 line between an instantaneous and a continuous release, power-law relationships for both
490 cases have been investigated for the short-lived group, and each relationship was tested to
491 see whether it was a good match to the data.

492 For Redoubt, the first data point has large temporal error bars due to the ambiguity
493 in eruption start time. Excluding this point, the best power-law fit has an exponent of
494 0.48 ± 0.04 . For Shishaldin, all the points were considered, and the exponent of the best-
495 fit curve is 0.22 ± 0.02 , although these sparse data may be consistent with a transition in
496 exponent towards $2/9$, as suggested by the numerical results (Fig. 7a). For Sarychev Peak
497 the exponent is 0.72 ± 0.06 .

498 The exponents for these three short-lived eruptions are dramatically different, and are, at
499 face value, difficult to interpret. In considering carefully that interpretation in the discussion
500 section, we offer some potential explanations for this disparity. Here, we only conclude that
501 no single power-law exponent is consistent with all data.

502 *5.4.2. Long-lived eruptions*

503 Since all these eruptions lasted for more than three hours, they cannot be approximated
504 as an instantaneous release of material.

505 If the earliest point is ignored, data from Pinatubo have a best-fit power-law exponent
506 of 0.72 ± 0.01 (Fig. 9). However, looking into the data more carefully, it appears that the
507 general trend can be divided into two segments. From data point 2 to data point 8, the best
508 power-law fit is 0.69 ± 0.02 , and from data point 5 to data point 12, the best power-law fit
509 is 0.75 ± 0.02 . Note that we use overlapping data points, since the onset time of a particular
510 flow regime is not well-defined.

511 The growth of the umbrella cloud of Okmok is difficult to divide into different segments.
512 From data point 2 and lasting until the end, 0.73 ± 0.04 is the best fit.

513 In the case of Grímsvötn, the first data points are associated with a high value of the
514 power-law exponent. From data point 2 to 9, the best power-law fit is 0.67 ± 0.02 . If only
515 points 2 to 5 are considered, the best power-law fit is 0.68 ± 0.05 , and from data point 6 to
516 data point 9, the best power-law fit is 0.58 ± 0.05 . This decrease in power law exponent is
517 consistent with the onset of drag (Figure 5).

518 Considering the eruption of Kelut, the best power-law fit for all the data is 0.54 ± 0.02 .
519 However several trends can be observed. From data point 2 to 4, the best power-law fit is
520 0.69 ± 0.02 , then from data points 8 to 13, the power-law exponent changes to 0.40 ± 0.04 ,
521 before decreasing as the result of plume dissipation.

522 From these observations, in addition to the idea that consistent asymptotic behavior
523 is not necessarily the norm, it can be seen that the relationship between the radius of an
524 umbrella cloud and time gradually evolves, as predicted by the new model. For Pinatubo
525 and Okmok, the long-term asymptote is closest to the fraction $3/4$ (Regime Ia), and for
526 Grímsvötn and Kelut, it is closest to $5/9$ (Regime IIa), after passing through $3/4$.

527 **6. Discussion**

528 *6.1. Dynamics of spreading*

529 For short-lived eruptions, that of Redoubt is somewhat different from the others, as it
530 originates from a distributed pyroclastic flow source rather than a point source vent. All
531 observations for Redoubt, being taken by ground-based photography, are from much earlier
532 in the eruption than are the satellite data acquired for the other eruptions. The best power-
533 law fit (0.48 ± 0.04) lies between the power-laws associated with clouds of a constant volume
534 and those associated with clouds that are continually supplied with material. This may be

535 due to a decay of the flux being supplied to the cloud from the coignimbrite plume.

536 The eruptions of Sarychev Peak and Shishaldin have release durations as well as maximum
537 plume heights and wind speeds similar to one another. However, the Shishaldin eruption
538 was subplinian, with a powerful initial phase and decreasing mass eruption rate until the
539 last satellite image was acquired (Caplan-Auerbach and McNutt, 2003). The entire eruption
540 lasted for 79 min, with the first 14 min being the most intense. The single asymptotic
541 power-law obtained for Shishaldin (0.22 ± 0.02) indicates an umbrella cloud that is no longer
542 fed, being driven by gravity against turbulent drag (power-law of $2/9$). This implies that,
543 although at first the eruption was intense, as it weakened, negligible additional material
544 was being added and intruding in the atmosphere. This may explain the low value of the
545 modeled duration (Table 5). In the case of Sarychev Peak, the power-law relationship is
546 consistent with a continuously-fed umbrella cloud spreading as a gravity current dominated
547 by inertial drag (power-law of $3/4$). It appears that on the time-scale of the available satellite
548 imagery, this particular eruption continued to be fed substantially from the vent, and that
549 the difference with Shishaldin is therefore that the intensity of the release was more or less
550 constant over the time, suggesting that it is perhaps better classified with the continuous
551 eruptions.

552 Among the eruptions that were more clearly continuous, the results for Pinatubo are
553 ambiguous, being consistent with either the previously accepted or the present model. The
554 best-fit (single) power-law exponent of 0.72 ± 0.01 is between that for the previously accepted
555 model ($2/3 \sim 0.667 \dots$) and the present model ($3/4 = 0.75$) for the buoyancy-inertial regime
556 (Ia).

557 For Okmok and Grímsvötn, the best fit is consistent with a slope changing to $r_f \sim t^{3/4}$,
558 then to $r_f \sim t^{5/9}$ with time (regime Ia to IIa). This corresponds to a transition between
559 a gravity current spreading in the ‘buoyancy-inertial’ regime with inertial drag as the main

560 resisting force, to one in which turbulent drag resists buoyancy forces. For both eruptions,
561 it is found that $r_f \sim t^{2/3}$ is a good approximation for the entire trend, as $2/3 \approx 0.67$
562 lies between $3/4 = 0.75$ and $5/9 \approx 0.56$. We suggest that this approximation is not the
563 result of the presence of a separate asymptotic regime, as suggested by [Woods and Kienle](#)
564 (1994), but results from a transition between the inertial $t^{3/4}$ and turbulent drag-dominated
565 $t^{5/9}$ regimes. This means that although observational data may best be described by the
566 transition in behavior as predicted by our numerical model, the agreement of observations
567 with the $t^{2/3}$ trend may be expected, given typical measurement errors (e.g. [Holasek, Self](#)
568 [and Woods, 1996](#)). Using a $t^{2/3}$ regime to fit the data would, however, result in degraded
569 estimation of values of the eruption parameters.

570 For the 2014 eruption of Kelut, with a greater number of observations, best fits indicate
571 the establishment of a $r_f \sim t^{3/4}$ regime (Ia), changing to $r_f \sim t^{5/9}$ (regime IIa). The higher-
572 quality data for Kelut are inconsistent with a relationship of $r_f \sim t^{2/3}$. Note that the last
573 observations of the Kelut eruption indicate a reduction in radius, corresponding to rapid
574 dispersion of the umbrella cloud.

575 Comparing the evolution of the radius with time for different eruptions, we conclude
576 that there is not just one relationship between radius and time and that the relationship
577 changes gradually. Thus, the use of the new model, capable of reproducing the transitions
578 in spreading rate, is potentially important, as the model predicts times of transition, as
579 well as the progression from one type of power-law behavior to another, based on different
580 parameter values. Model curve-fitting should thus provide an estimate for the values of the
581 parameters.

582 *6.2. Regime transitions and cloud maps*

583 For a typical isolated volcanic thermal or starting plume, a rise height of 12 km is reached
584 after c. 400 seconds from the beginning of the eruption ([Sparks et al., 1997](#)). Therefore, in

585 the case of Sarychev Peak, Okmok and Grímsvötn, it is expected that the plume would take
586 more than five minutes to rise, before beginning to intrude laterally into the atmosphere. The
587 clouds from both Sarychev Peak and Grímsvötn were observed on the first satellite image
588 one to five minutes from the beginning of the eruption, at 360 and 90 seconds, respectively
589 (Fig. 2, 3). As a result, these first observations are not of an umbrella cloud spreading as
590 a gravity current, but of an earlier, potentially momentum-dominated spread. This growth
591 phase corresponds to a 'mushroom' structure with (turbulence related) irregularities (Figs.
592 2, 3, 4).

593 Following the 'mushroom' phase, the buoyancy-driven intrusion phase develops. On
594 satellite imagery, the transition to gravity driven flow is not extremely well-defined, as the
595 subspherical cloud turns into a spreading umbrella. This might be the result of the acquisition
596 time between images. For Okmok and Sarychev Peak, a satellite image was available every
597 30 min during the eruption, and for Grímsvötn, it was every 15 min. Good agreement with
598 our model after the first observation suggests that the spreading becomes predominantly
599 buoyancy-driven in less than 15 min for the examples of Sarychev Peak and Grímsvötn (Fig.
600 7).

601 The buoyancy-driven growth phase corresponds to the time when the umbrella cloud
602 is observed to smooth and widen. This phase of spreading can be divided in two periods,
603 given the structures observed in the umbrella. In the first period, the umbrella has several
604 irregularities due to the presence of eddies, and the irregularities of the edges are defined as
605 being finger-like. In the second period, the umbrella cloud develops a smooth appearance,
606 with non-fingering edges and gravity waves on the upper surface. The first period is observed
607 for the eruptions of Okmok, from 20:00 to about 20:30 UTC, for Sarychev Peak from 19:30
608 to 19:57 UTC and for Grímsvötn from 19:30 to about 19:45 UTC. This timing corresponds
609 to the gradual transition between the different regimes, in which $r_f \sim t^{3/4}$ (Regime Ia) is

610 reached for the eruptions of Okmok from about 20:30 to 23:00 UTC, for Sarychev Peak from
611 19:57 to 20:57 UTC and for Grímsvötn from about 19:45 to 20:45 UTC.

612 After this, another transition occurs as turbulent drag begins to dominate. The effect
613 of turbulent drag is characterized by a relationship of either $r_f \sim t^{2/9}$ (Regime IIb) for
614 instantaneous eruptions, or $r_f \sim t^{5/9}$ (Regime IIa) for long-lived eruptions.

615 Transition to Regime II is observed on the satellite images by an enlarged and smoothed
616 umbrella cloud surface affected by numerous concentric gravity waves (e.g. Fig. 3). These
617 gravity waves can also affect the surrounding meteorological clouds (Fig. 2). In this regime,
618 eddies are not detected, as they are disappearing from the cloud. Although the Regime II
619 power-law exponents from the numerical model runs are consistent with the data for several
620 eruptions, only those data for Shishaldin captured transition to this behavior, given the
621 parameter values explored and the duration of the transition from one regime to another.

622 *6.3. Implications for ash clouds and forecasting*

623 The new model captures the evolution of the radius with time when an ash cloud intrudes
624 in the atmosphere, and the transition from one spreading regime to another. This has a
625 rather important implication for ash cloud forecasting. The way ash clouds are simulated at
626 the operational level in near-real time is either by dispersing the ash once it is introduced
627 at height, using one of several VATDMs, such as HYSPLIT or NAME (Folch , 2012), or by
628 simulating first the injection of the ash into the atmosphere using a column model and then
629 using a VATDM, such as in VOLCALPUFF or puffin (Barsotti *et al.* , 2008; Bursik *et al.*,
630 2012). Neither of these two standard procedures includes the spread of the ash in a gravity
631 current. This could be an issue, since it has been shown that the spreading as a gravity
632 current can occur hundreds to thousands of kilometers from the source, depending on the
633 mass eruption rate and the column height (Bursik, Carey and Sparks, 1992; Pouget *et al.*,
634 2013; Costa, Folch and Macedonio, 2013). The results of the present contribution suggest

635 that the refinements introduced herein would provide an improved basis for the physics of the
636 gravity current. Adding an implementation of the new model into a dispersion model would
637 enable the behavior of ash in the atmosphere to be better captured, and a better estimation
638 of parameters needed for the atmospheric dispersal calculation, such as mass loading, spatial
639 distribution of ash, effective buoyancy frequency, and atmospheric level of spreading.

640 7. Conclusions

641 We tested a new numerical model of a spreading volcanic umbrella cloud. The model is
642 based on careful consideration of the spreading cloud front, and predicts the occurrence of
643 different spreading regimes. Data for seven different eruptions are consistent with the new
644 model. Each of the spreading regimes can be expressed with a different power-law exponent
645 in asymptotic analysis, although numerical modeling suggests that these asymptotic flows
646 can take considerable time to develop. We have shown that a simpler model, based on a
647 single velocity scaling relationship, does not capture this behavior, and cannot fit all available
648 data, being consistent with only a single spreading regime and a single power-law exponent.
649 Using least-squares fitting, we have shown that the new numerical model fits all available
650 satellite data. Perhaps more importantly, we have shown strong support for the model and
651 the existence of the flow regimes by creating histories for the growth of umbrella clouds from
652 numerous eruptions consistent with known timing information, measured growth rates, and
653 cloud mapping. Furthermore, the detailed growth curve for a spreading umbrella cloud is
654 sensitive to a number of parameters, including mass eruption rate and eruption duration.
655 Limited numerical curve fitting suggests that both atmospheric and volcanic parameters can
656 be estimated from cloud growth curves.

657 Future research should include effects of sedimentation and entrainment of air. [Nye et](#)
658 [al. \(2002\)](#) show, e.g., that the cloud of Shishaldin dissipated rapidly because of sedimentation

659 of coarse pyroclasts. Intuitively, entrainment should be important in some situations where
660 the breaking jump at the back of the intrusion head brings in substantial mass relative to
661 the starting mass of the intrusion.

662 *Acknowledgments.* This research was supported by NSF-IDR CMMI grant number 1131074
663 to E. B. Pitman, and by AFOSR grant number FA9550-11-1-0336 to A.K. Patra. All results
664 and opinions expressed in the foregoing are those of the authors and do not reflect opinions
665 of NSF or AFOSR. CGJ, AJH, JCP and RSJS acknowledge support from NERC (UK)
666 through the Vanaheim project “Characterisation of the near-field Eyjafjallajokull volcanic
667 plume and its long-range influence” (NE/I01554X/1). AJH and JCP were additionally
668 funded by the European Union Seventh Framework Programme (FP7, 2007-2013) under
669 grant agreement number 208377, FutureVolc, and AJH and CGJ by EPSRC (UK) through
670 grant EP/G066353/1. The authors would like to thank Peter Webley, Jon Dehn, Emile
671 Jansons and Andrew Tupper for giving us access to satellite imagery. We would like to
672 thank Greg Valentine and the reviewers (Tak Koyaguchi and an anonymous reviewer) for
673 their useful comments, which greatly improved the manuscript. The paper is dedicated to
674 the memory of Solène Pouget, an exemplary young scientist and human being.

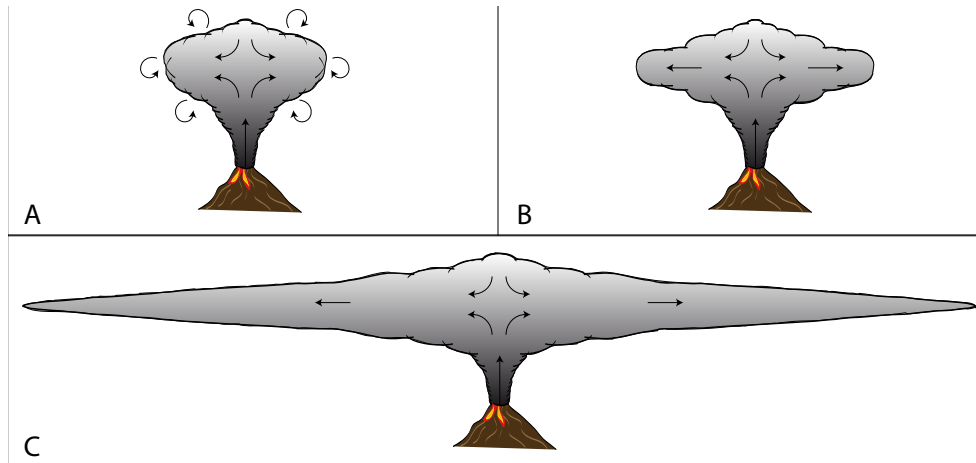

Figure 1: Sketch of intruding volcanic umbrella cloud spreading as a gravity current in a stratified environment with no or negligible winds. (a) The intruding cloud with momentum as driver is represented by large and numerous eddies, as well as entrainment. After this, umbrella cloud spreading is driven by buoyancy. (b) First phase of buoyant spreading is resisted by inertial drag, with fewer eddies. (c) The second phase is resisted by drag, in which umbrella spreads as a thin, laminar layer.

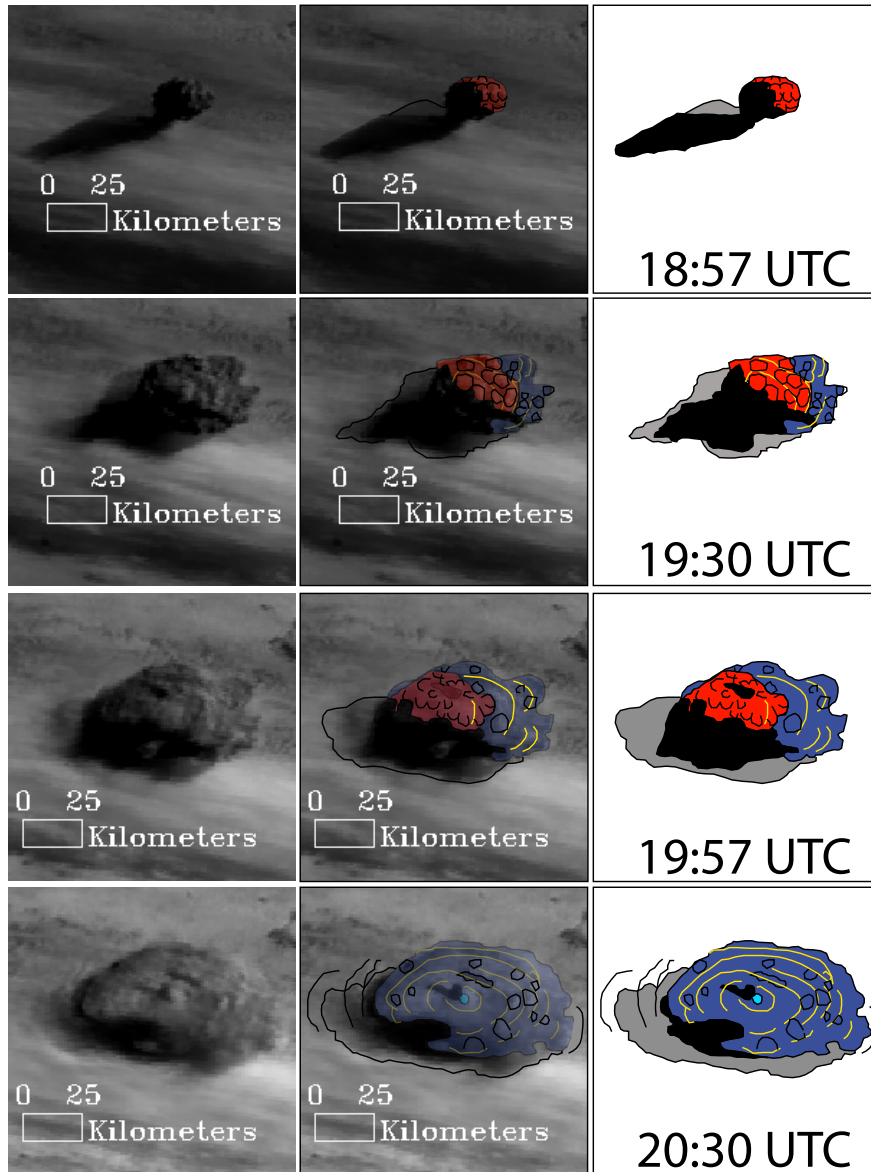

Figure 2: Evolution of the Sarychev Peak eruptive cloud with time in visible band, visible band with mapping overlaid, and mapping (from left to right). Eddies visible in the umbrella are outlined in black, gravity waves are mapped by a bright yellow line placed at the wave trough. New bursts into the cloud are represented with light blue. The part of the umbrella with eddies is colored in red, while the part with few to no eddies is coloured in dark blue. Any dense shadow is coloured in black, and light shadow is grey.

Figure 3: Evolution of the Grímsvötn eruptive cloud with time in visible band from low viewing angle (causing cloud to appear elongated), visible band with mapping overlaid, and mapping (from left to right). Eddies visible in the umbrella are outlined in black, gravity waves are mapped by a bright yellow line placed at the wave trough. New bursts into the cloud are represented with light blue. The part of the umbrella with eddies is colored in red, while the part with few to no eddies is coloured in dark blue. Any dense shadow is coloured in black, and light shadow is grey.

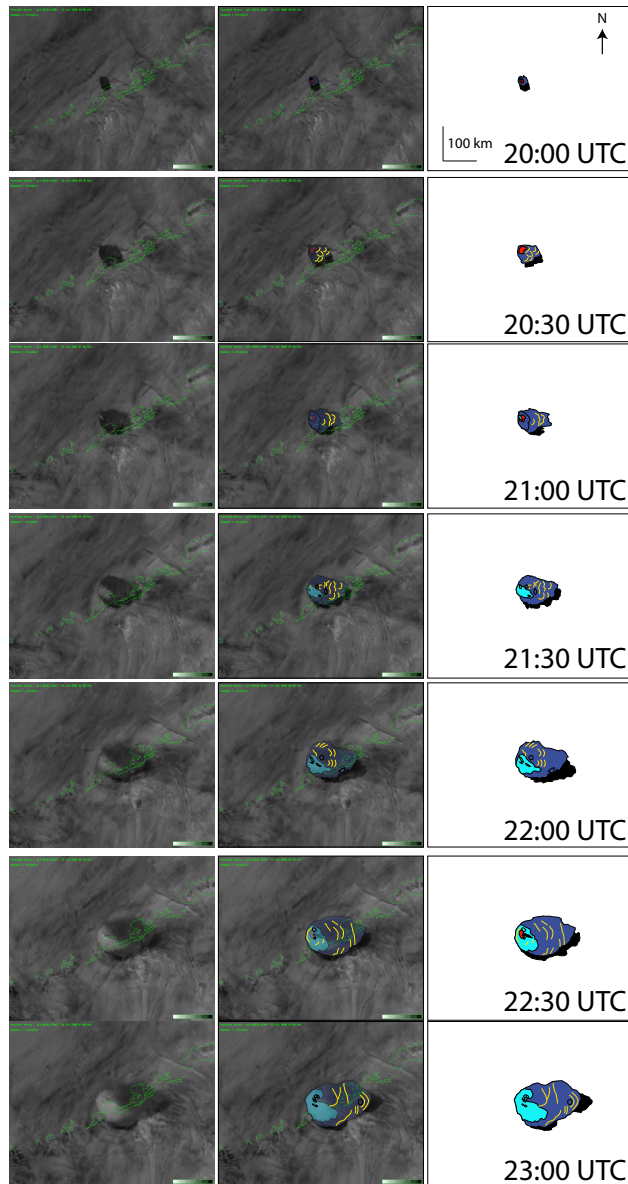

Figure 4: Evolution of the Okmok eruptive cloud with time in visible band, visible band with mapping overlaid, and mapping (from left to right). Eddies visible in the umbrella are outlined in black, gravity waves are mapped by a bright yellow line placed at the wave trough. New bursts into the cloud are represented with light blue. The part of the umbrella with eddies is colored in red, while the part with few to no eddies is coloured in dark blue. Any dense shadow is coloured in black, and light shadow is grey.

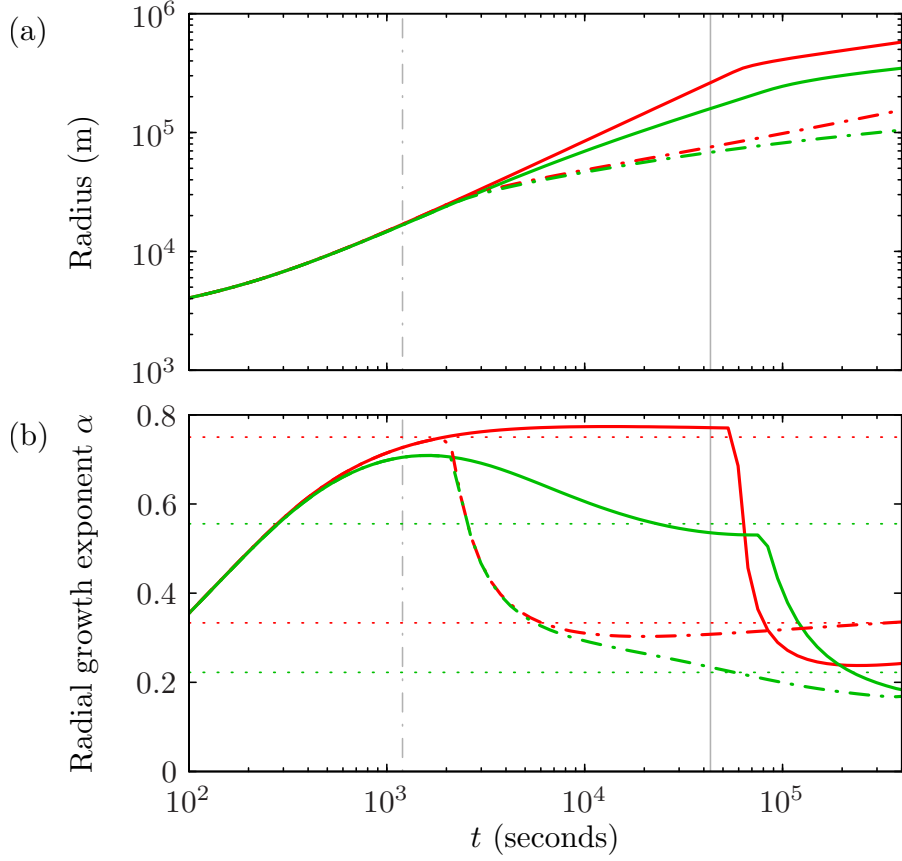

Figure 5: (a) Plots of current radius r_f as a function of time, determined from numerical solution of Eqns (1) and (2). (b) Plots of $d \log(r_f)/d \log(t)$, gradient of r_f against t on logarithmic axes. Regimes where curves in (b) take a constant value indicate straight-line regimes of curves in (a), hence regimes where radial growth with time is well matched by a power law, $r_f \sim t^\alpha$. Results for four sets of parameters are plotted, each with $N = 0.01 \text{ s}^{-1}$ and $2\pi Q = 10^9 \text{ m}^3 \text{ s}^{-1}$. Red curves indicate solutions with no drag ($C_D = 0$), and green curves indicate those with $C_D = 0.01$. For solid curves, the intrusion is supplied between $t = 0$ and $t_c = 432$ nondimensional units, corresponding to an eruption duration, $D = 12$ hours; for dash-dotted curves, source is turned off at $t_c = 12$ nondimensional units, corresponding to an eruption duration, $D = 20$ minutes. These times are represented by vertical grey solid and dash-dotted lines, respectively. Horizontal dotted lines in (b) indicate the long-time asymptotes for r_f of $t^{3/4}$ (upper red line), $t^{5/9}$ (upper green line), $t^{1/3}$ (lower red line) and $t^{2/9}$ (lower green line). The numerical results asymptote to these curves at times much greater than those shown.

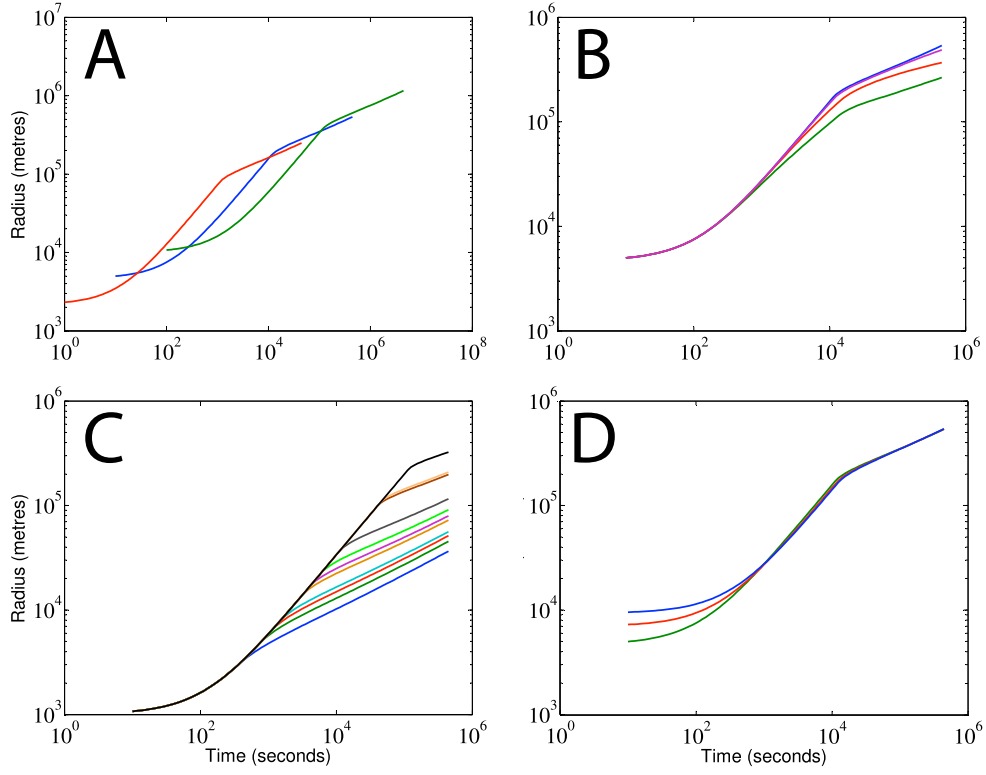

Figure 6: Effect of each of five parameters on results produced by the model. For each case, parameters not tested were fixed as follows: $N = 0.01 \text{ s}^{-1}$, $C_D = 0$, Duration $D = 2$ hours, $Q = 10^9 \text{ m}^3 \text{ s}^{-1}$ and $r_0 = 1 \text{ km}$. (a) Variation of buoyancy frequency, $N = 0.001 \text{ s}^{-1}$ (green line), $N = 0.01 \text{ s}^{-1}$ (blue line) and $N = 0.1 \text{ s}^{-1}$ (red line). (b) Variation of drag coefficient, $C_D = 0$ (blue line), $C_D = 0.001$ (purple line), $C_D = 0.01$ (red line) and $C_D = 0.1$ (green line). (c) Variation of duration of eruption, since $N = 0.01$ then $D = 3 \text{ min}$ (blue line), $D = 6 \text{ min}$ (green line), $D = 10 \text{ min}$ (red line), $D = 13 \text{ min}$ (light blue line), $D = 30 \text{ min}$ (orange line), $D = 40 \text{ min}$ (purple line), $D = 1 \text{ h}$ (light green line), $D = 2 \text{ h}$ (grey line), $D = 8 \text{ h}$ (dark brown line), $D = 9 \text{ h}$ (pink line) and $D = 24 \text{ h}$ (black line). (d) Variation of volumetric flux/radian, $Q = 10^5 \text{ m}^3 \text{ s}^{-1}$ (black line), $Q = 10^6 \text{ m}^3 \text{ s}^{-1}$ (purple line), $Q = 10^7 \text{ m}^3 \text{ s}^{-1}$ (green line), $Q = 10^8 \text{ m}^3 \text{ s}^{-1}$ (red line) and $Q = 10^9 \text{ m}^3 \text{ s}^{-1}$ (blue line). (e) Variation of the initial, nondimensional radius of intrusion, $r_0 = 1$ (green line), $r_0 = 1.5$ (red line) and $r_0 = 2$ (blue line). Slopes (power-law exponent) same as those shown in Fig. 5.

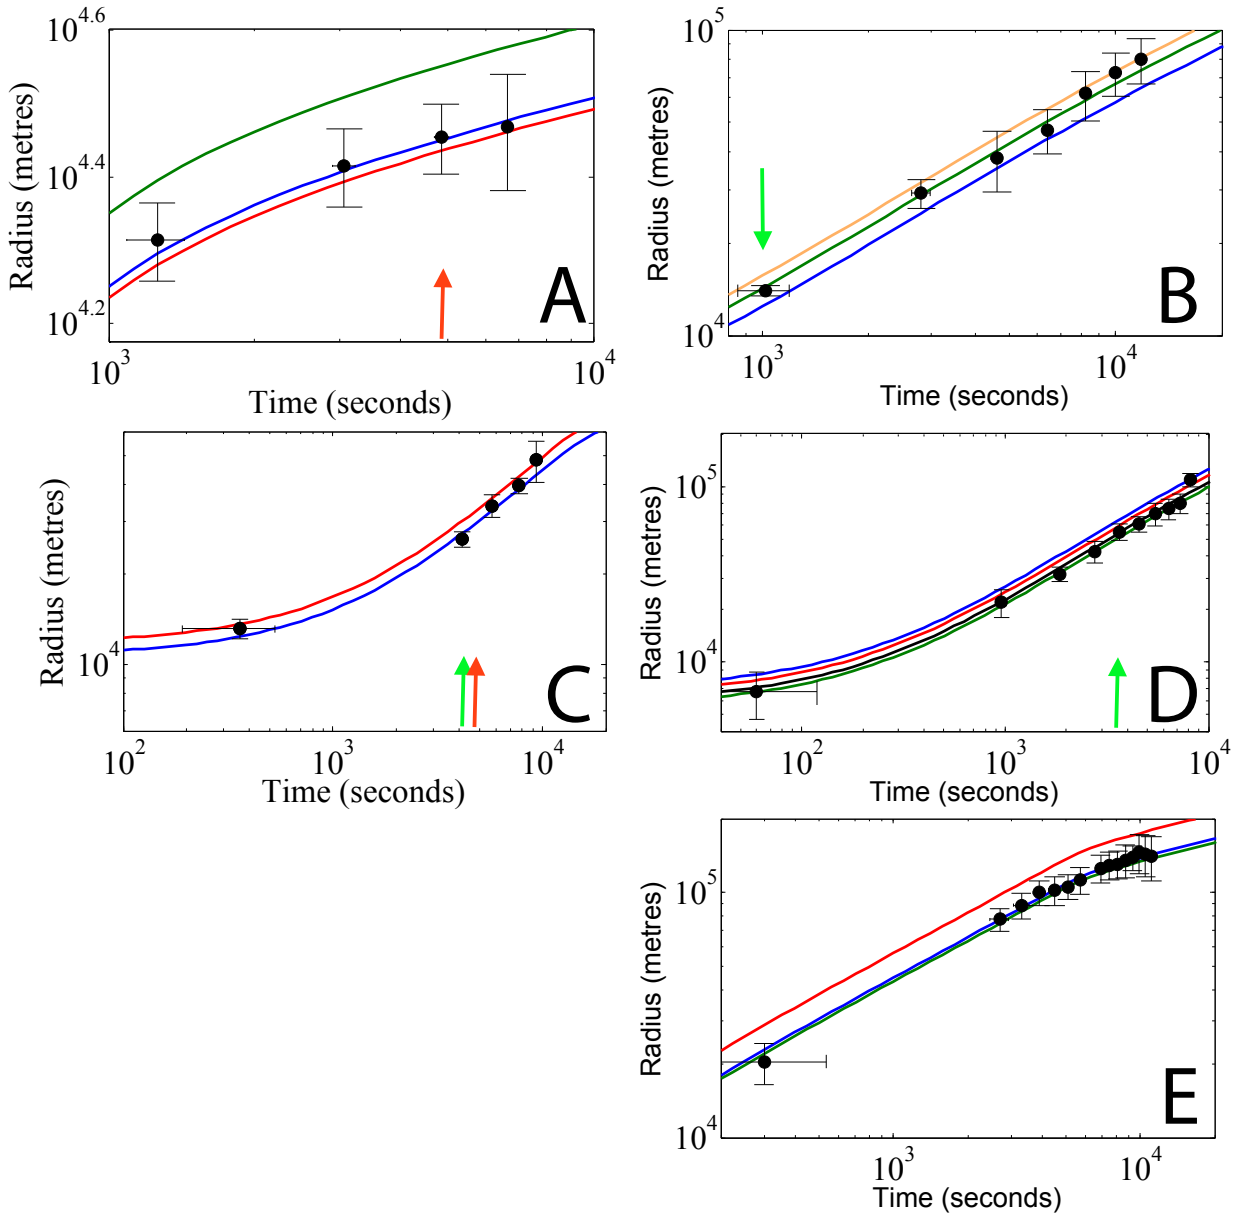

Figure 7: Comparison of cloud growth curves produced by model (full lines of different colors) and data measured from observed umbrella clouds (closed circles) with errorbars. (a) Shishaldin, 1999 ; (b) Okmok, 2008; (c) Sarychev Peak, 2009; (d) Grímsvötn, 2011 and (e) Kelut, 2014. Characteristics of each model run producing different colored curves given in Table 5. Green arrow, first satellite image in which smooth cloud appears (hypothesized start of gravity current flow); red arrow, end of eruption (D reached)

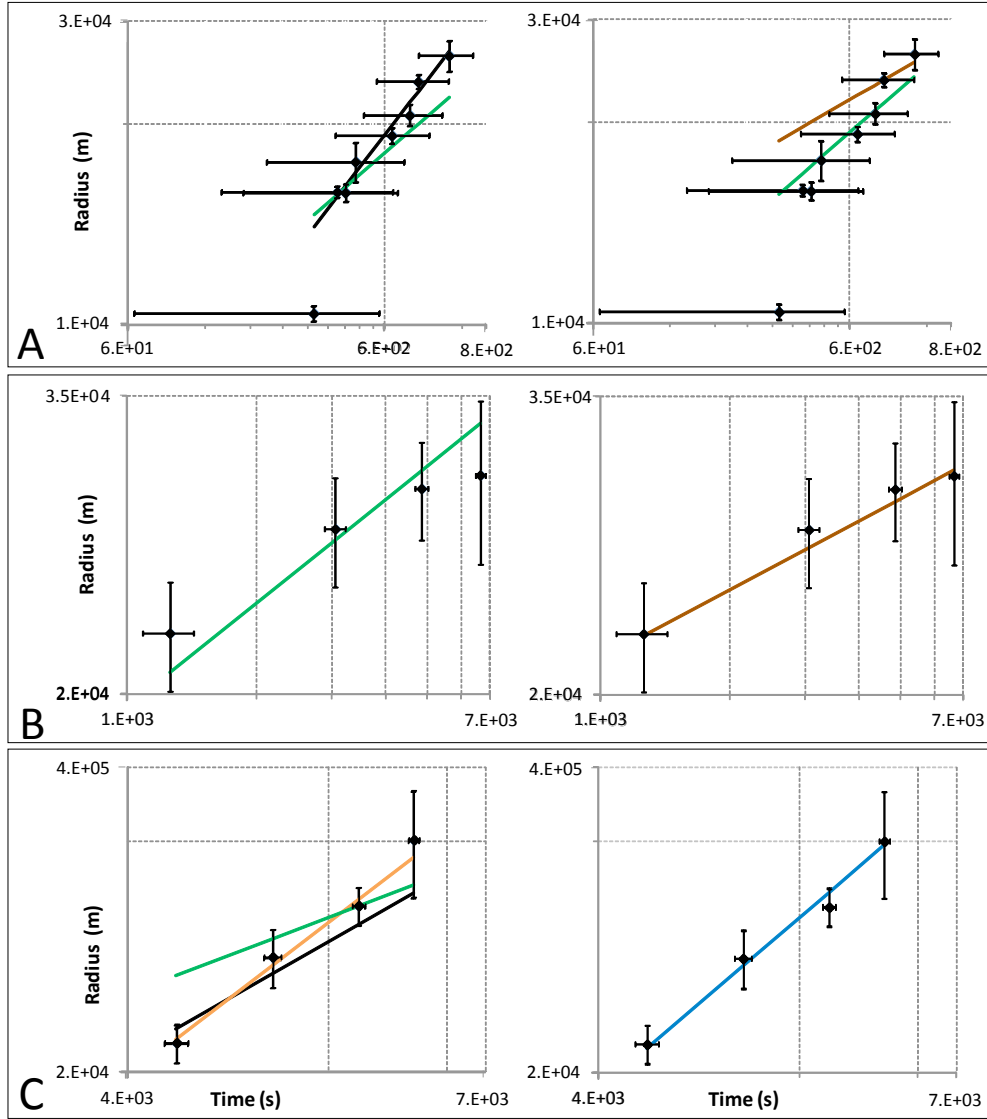

Figure 8: Evolution of the umbrella cloud radius with time (black diamonds) with associated error bars for short-lived eruptions using relationships from previous workers (left; Table 1) and from this work (right). (a) Redoubt, 1990; (b) Shishaldin, 1999; (c) Sarychev, 2009. First data point from Figure 7c removed as inconsistent with asymptotic behavior. Asymptotes are: $r_f \sim t^{2/9}$ (brown line), $r_f \sim t^{1/3}$ (green line), $r_f \sim t^{1/2}$ (black line), $r_f \sim t^{2/3}$ (orange line), $r_f \sim t^{3/4}$ (light blue line). Power-law curves from previous studies are on left side of figure, and power-law curves from present model on right side.

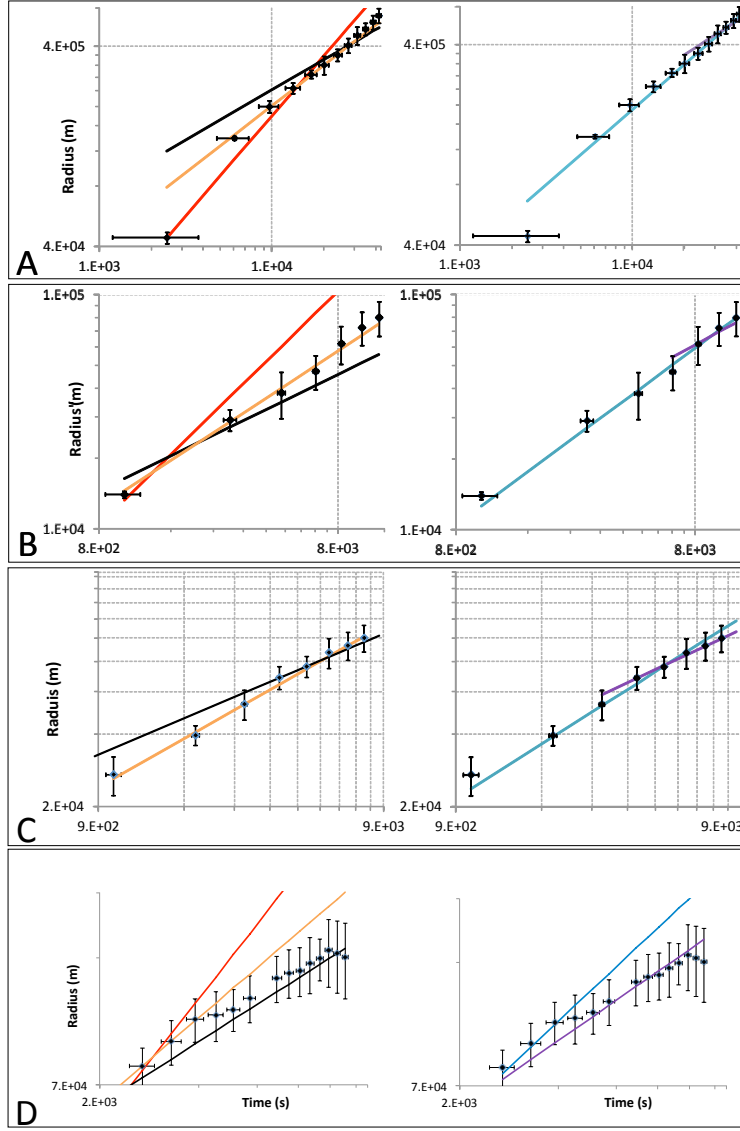

Figure 9: Evolution of umbrella cloud radius with time (black diamonds) with associated error bars for a long-lived eruption using relationships from previous workers (left; Table 2) and from this work (right). (a) Pinatubo, 1991; (b) Okmok, 2008; (c) Grímsvötn, 2011. First two data points from Figure 7d have been removed as potentially inconsistent with asymptotic behavior, (d) Kelut, 2014. First data point from Figure 7e removed for clarity. Asymptotes are: $r_f \sim t^{2/9}$ (brown line), curves $r_f \sim t^{1/2}$ (black line), $r_f \sim t^{5/9}$ (purple line), $r_f \sim t^{2/3}$ (orange line), $r_f \sim t^{3/4}$ (light blue line), $r_f \sim t$ (red line). Theoretical curves from previous studies are on left side of figure, and curves from present model on right side.

815 **Appendix A. Drag-dominated intrusions of constant volume**

816 After the cessation of an eruption, the volume of fluid in the plume remains approxi-
 817 mately constant (increasingly only slowly due to entrainment), but buoyancy forces result in
 818 continued spreading. In the absence of drag, a buoyancy-inertial spreading regime becomes
 819 established [Ungarish and Zemach \(2007\)](#), with a radial growth rate of $t^{1/3}$. However, our
 820 numerical results (Fig. [A.10](#)) indicate that turbulent drag has often become significant by
 821 the point at which an eruption ceases, meaning that spreading of the plume will be drag-
 822 dominated. We calculate a similarity solution to the governing equations in this regime,
 823 which exhibits a radial growth rate of $r_f \sim t^{2/9}$. This derivation is analogous to that in
 824 ([Johnson *et al.*, 2015](#)) for the drag-dominated spread of an intrusion supplied by a constant
 825 flux.

826 After the eruption has ceased, there is no longer a volume flux per radian Q feeding
 827 the intrusion, so we nondimensionalize by scaling lengths to $V^{1/3}$, where V is the intrusion
 828 volume per radian, and times to N^{-1} , as before. At late times the governing equations (2)
 829 form a dominant balance in which buoyancy spreading forces are balanced by turbulent drag.
 830 In this regime, the governing equations become (in nondimensional form)

$$\frac{\partial h}{\partial t} + \frac{1}{r} \frac{\partial}{\partial r} (ruh) = 0 \quad \text{and} \quad \frac{h^2}{4} \frac{\partial h}{\partial r} = -C_D |u|u, \quad (\text{A.1a,b})$$

respectively. We seek a similarity solution for these equations, and therefore first look for
 scalings. Integrating (A.1a) across the intrusion we find that $r_f^2 h \sim 1$, while from (A.1b)
 the balance between driving buoyancy forces and drag results in $h^3/r_f \sim C_D r_f^2/t^2$. These
 scalings suggest that $r_f \sim C_D^{-1/9} t^{2/9}$, and that a similarity solution may exist in which

$$h = \kappa C_D^{2/9} t^{-4/9} \mathcal{H}(\eta), \quad u = \kappa C_D^{-1/9} t^{-7/9} \mathcal{U}(\eta), \quad \text{and} \quad r_f = \kappa C_D^{-1/9} t^{2/9}, \quad (\text{A.2})$$

where $\eta = r/r_f(t)$ and κ is a dimensionless constant to be determined. On substitution of

(A.2) into the governing equations (A.1), we obtain

$$\frac{1}{\eta}(\eta\mathcal{U}\mathcal{H})' - \frac{2\eta}{9}\mathcal{H}' - \frac{4}{9}\mathcal{H} = 0 \quad \text{and} \quad \frac{\mathcal{H}^2}{4}\mathcal{H}' = -\mathcal{U}|\mathcal{U}|. \quad (\text{A.3a,b})$$

831 where the prime denotes differentiation with respect to η . These are subject to boundary
 832 conditions $\mathcal{U}(1) = 2/9$, representing the kinematic condition at the front, and $\mathcal{H}(1) = 0$,
 833 which is the frontal Froude number condition in the drag-dominated regime. Integrating
 834 (A.3a), and applying the kinematic condition, we find

$$\eta \left(\mathcal{U} - \frac{2\eta}{9} \right) \mathcal{H} = 0 \quad (\text{A.4})$$

835 from which we deduce that $\mathcal{U} = 2\eta/9$. From (A.3b) we then find

$$\mathcal{H} = \left[\frac{16}{81} (1 - \eta^3) \right]^{1/3}. \quad (\text{A.5})$$

836 Profiles of the thickness and velocity of the plume, \mathcal{H} and \mathcal{U} , are illustrated in Figure A.10.
 837 Equating the total volume of the intrusion per radian (expressed as a volume of revolution)
 838 with V , we obtain

$$\kappa^3 \int_0^1 \eta \mathcal{H} d\eta = 1. \quad (\text{A.6})$$

839 Evaluating (A.6) using (A.5), we find that $\kappa = 1.62\dots$. Thus, in dimensional variables, the
 840 long time asymptotic radius of the intrusion is $r_f = 1.62(N^2V^3t^2/C_D)^{1/9}$.

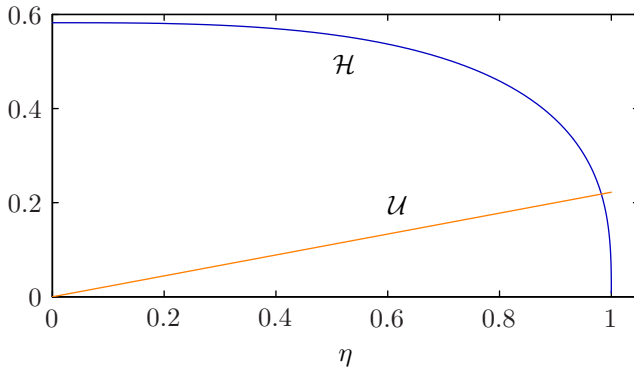

Figure A.10: Profiles of intrusion thickness \mathcal{H} and radial velocity \mathcal{U} for an intrusion of constant volume in a turbulent-drag dominated spreading regime.
