Abstract

Schumpeterian arguments related to creative destruction place small, entrepreneurial firms at the centre of the innovation process. The exclusion of micro-enterprises (with less than 10 employees) from most innovation surveys means, however, that we know relatively little about innovation among this group of firms. Here, using new survey data on a thousand micro-enterprises we explore the determinants of new-to-the-market innovation, the basis for the Schumpeterian creative destruction (CD) process. Our results provide strong support for the interactive nature of micro-enterprise innovation, and suggest the potential value of a model of interactive creative destruction (ICD). Contrary to some other recent evidence, market-based and supplier-based collaboration both prove important for new-to-the-market innovation. Our results suggest the importance of micro-enterprises as sources of new-to-the-market innovation and the potential value of including such firms in future innovation studies.

Acknowledgements: We are grateful to the Department of Trade, Enterprise and Investment, Belfast for allowing us to use the data on which this paper is based. Valuable comments on earlier drafts were received from participants in a Regional Studies Association seminar in Brussels, June 2015; a seminar held in Queen's University Belfast in September 2015 and the Institute for Small Business and Entrepreneurship conference in Glasgow, November 2015. Valuable comments were also received from two referees and the editor of this journal. Errors remain our own.

Investigating a neglected part of Schumpeter's creative army: What drives new-to-the-market innovation in micro-enterprises?

1. Introduction

Schumpeterian arguments related to Creative Destruction (CD) place small, entrepreneurial firms at the centre of the innovation process. Here, opportunistic entrepreneurs, invest in new technology and commercialisation and, for a limited time, through innovation, achieve a position of market leadership. In reality such processes are hard to observe systematically, both due to the dynamic nature and potential rapidity of the process of creative destruction itself but also due to practical difficulties associated with identifying the firms involved. Studies of emergent clusters or industries (Diaz Perez, Alarcon Ozuna, and Ayala Arriaga 2011; Sydow, Lerch, and Staber 2010) and those focussed on start-ups probably come closest (Ganotakis and Love 2011) although, even here, the creative destruction process tends to be observed as a historical rather than current phenomena. More generally, innovation studies, many of which are based on data sets such as the EU Community Innovation Survey, exclude micro-enterprises with less than 10 employees as these are excluded from EU surveys.

While a focus on larger firms in innovation surveys may be regarded as a pragmatic decision it means we have very little robust evidence on the drivers of innovation in micro-firms (Tu et al. 2014). A priori, however, we might anticipate that micro-businesses operate very differently to larger firms in terms of their innovation process (Cohen and Klepper, 1996), investment in R&D (Baumann et al. 2016), and particularly in relation to partnering (Kim and Vonortas 2014). Micro-businesses owners may, for example, over-estimate the risks associated with pursuing growth and innovation (Allinson et al. 2006). Innovation partnerships with other organisations may help micro-firms share these risks, overcome any innate conservatism, and make positive strategic decisions. Internal resource constraints, reflected in arguments about the liability of smallness (Carroll 1983), may also shape how micro-firms innovate, forcing firms with an ambition to innovate to access external resources for innovation through collaboration. Lack of scale may also make appropriating the benefits of innovation more difficult for micro-businesses, and here too partnering with larger organisations may yield significant benefits.

The potential importance of partnering for micro-business innovation suggests the value of augmenting the traditional CD model in which firms introducing new-to-the-market innovations gain a position of market leadership. In the original CD model, the process of technological change and innovation is seen as atomistic, undertaken by individual firms, where innovation is based primarily on firms' internal capabilities. This 'closed', and essentially linear, view of innovation today seems rather naïve. Instead, we increasingly understand innovation as an interactive or social process, shaped strongly by firms' external relationships (Metcalf 1997), something which may be particularly important for innovating micro-businesses. These relationships may be interactive – partnerships or formal R&D collaborations – or non-interactive – involving copying, reverse engineering or imitation (Glückler 2013). Either way, the evidence from studies of innovation in small and medium enterprises (SMEs) emphasises the importance of external knowledge in contributing to firms' innovation success (Vahter, Love, and Roper 2014)¹. This emphasises the role of absorptive capacity and firms' capabilities in integrating external and internal knowledge in what we refer to as Interactive CD or ICD.

Empirically, we have little evidence on the nature of micro-business innovation. Two recent studies, both based on bespoke surveys and relatively small samples (c. 150 firms), provide some insights, examining the impact of internal factors on innovation in Spanish micro-enterprises (Benito-Hernandez, Platero-Jaime, and Rodriguez-Duarte 2012), and of supply chain co-operation in Chinese night markets (Tu, Hwang, and Wong 2014). Here, we add to this very limited evidence base using data from a large-scale survey of 1,000 micro-businesses in Northern Ireland (Department of Enterprise 2014). We make three main empirical contributions. First, our data is unusual in providing detailed information on the innovative activities of a large group of micro-firms, and this provides new insights into the creative destruction process for this under-studied group of firms. What proportion of micro-enterprises, for example, are introducing new-to-the-market innovations of the type envisaged in the creative destruction model? Second, as our data includes a range of innovation metrics in common with the EU Community Innovation Surveys we are able to make comparisons with larger firms. This enables us to examine whether new-to-the-market innovation is more

¹ Little is known about the role of external connectivity in shaping innovation in micro-enterprises although see Tu, Hwang and Wong (2014).

common among micro-enterprises than larger firms as the CD model might suggest. Finally, reflecting the entrepreneurial nature of micro-firms, we are able to examine how the leadership and ownership characteristics of micro-businesses influence which micro-enterprises take the lead in the creative destruction process (Kellermanns et al. 2012; Kotlar et al. 2014; Kraus, Pohjola, and Koponen 2012).

The remainder of our paper is organised as follows. Section 2 outlines our conceptual perspective focussing on interaction and its role in stimulating new-to-the-market innovation. Section 3 specifies our hypotheses drawing on what is known about the drivers of small business innovation. Data sources are described in Section 4 which also profiles our estimation approach. Our analysis makes use of a standard innovation production function which relates innovative outputs to knowledge inputs and resources from within the firm alongside the firm's acquisition of external knowledge (Leiponen and Byma 2009; Roper, Du, and Love 2008). Section 5 describes our main empirical results.

2. Conceptual foundations – towards an interactive CD model

In creative destruction 'the creation is usually accomplished by invaders – new firms or entrants from other industries – while the destruction is suffered by the incumbents'². Two types of destructive impacts have been identified: competence destroying innovations which undermine or eliminate the value of the assets or technology of incumbents within an existing market paradigm; and, disruptive innovations which change the market paradigm itself (Bergek et al. 2013). Both require innovation which is (at least) new-to-the-market, and both threaten the market position of incumbents which may also be influenced by core-rigidities (Leonard-Barton 1992) and inertia (Christensen 1997; Lucas and Goh 2009). New entrants may then benefit from 'attackers advantage' and the innovators' potential opportunity to set the ground rules for future competition (Leenders and Voermans 2007; Foster 1986).

² Rosenbloom and Christensen (1994, p. 656) as quoted in Bergek et al. (2013).

Achieving market leading or disruptive innovation, however, requires resources and a willingness to bear risk. The risk associated with any innovation project will depend on both the technological complexity of the project as well as commercial concerns about sales, profitability and potential competition (Keizer and Halman 2007; Roper, Du, and Love 2008; Cabrales et al. 2008). Technological risks are associated primarily with the potential failure of development projects to achieve the desired technological or performance outcomes, an inability to develop a solution which is cost-effective to manufacture/deliver (Astebro and Michela 2005), or issues around project development time (Menon, Chowdhury, and Lukas 2002; Von Stamm 2003). Each may have implications for innovations' subsequent market success or viability. In terms of development time, for example, it has been suggested that compressed development time may necessitate overly rapid decision making, reducing innovation quality (Zhang, Chen, and Ma 2007) with potentially negative effects on post-innovation returns (Bower and Hout 1988).

The extent to which enterprise size may alter the technological risk of innovation has been the focus of considerable research interest, specifically in relation to R&D investment. It is accepted that for micro-enterprises, the resources available for investment in R&D and innovation are more limited than for larger enterprises (Vossen 1998; Dickson et al. 2006). Baumann and Kritikos (2016) highlight three reasons why this may be the case, relating to threshold levels of R&D investment (Cohen and Klepper 1996), sunk and fixed costs of conducting formal R&D (Peters et al. 2013), and information asymmetries (Stiglitz and Weiss, 1981) which reduce access to external finance and may be particularly acute for micro-enterprises with limited accumulated profits (Conte and Vivarelli, 2014).

Beyond the technological risks, market-related innovation risks have a commercial dimension linked directly to the demand for the innovation, but may also involve issues around rivalry or appropriability conditions. Astebro and Michela (2005), for example, emphasise demand instability as one of three main factors linked to reduced innovation survival in their analysis of 37 innovations supported by the Canadian Inventors Assistance Programme³. Market rivalry

³ The other predictors of innovation survival identified by Astebro and Michela (2005) are 'technical product maturity' and 'entry cost and price'.

and competitors' responses may also play a critical role in shaping market-related innovation risks. Rivals' new product announcements may reduce returns (Fosfuri and Giarratana 2009), for example, while appropriability conditions may shape firms' ability to benefit from new innovations (Leiponen and Byma 2009). Moreover, as Keizer and Holman (2007) suggest: 'Radical innovation life cycles are longer, more unpredictable, have more stops and starts, are more context-dependent in that strategic considerations can accelerate, retard or terminate progress, and more often include cross-functional and or cross-unit teamwork. Incremental projects are more linear and predictable, with fewer resource uncertainties, including simpler collaboration relationships' (p. 30)⁴. As with technological risks, market-related risks may also be disproportionately large for micro-enterprises. Larger, mature, enterprises are likely to have an established market position which brings with it structural capital, such as supplier and distribution channels, cognitive capital in terms of industry and consumer norms and values, and relational capital as reflected in established reputation and trust (Powell and DiMaggio 1991). Mature micro-enterprises are unlikely to have the same stock of structural, cognitive and relational capital as larger firms. This deficit is likely to be greater for younger, or newly established, micro-businesses, increasing the market-related risks of innovation (Hargadon and Douglas 2001).

Innovating through partnering – seeking knowledge and resources outside the firm – may be one way to offset such innovation risks (Caroll, 1983). For example, Powell (1998) stresses the potential value of collaboration in reducing risk in the innovation process, accelerating or upgrading the quality of the innovations made, and signalling the quality of firms' innovation activities. External innovation linkages may also increase firms' access to external resources and technology developed elsewhere. Further, having more extensive networks of external relationships, or more different types of relationships, is likely to increase the probability of obtaining useful knowledge from outside of the firm (Leiponen and Helfat 2010). Empirical evidence also points to the conclusion that knowledge gained from alternative external sources tends to be complementary, and also complementary with firms' internal knowledge in shaping innovation performance (Roper, Du, and Love 2008). However, as Chesborough (2010) suggests, collaborative innovation poses particular challenges for smaller firms because of their

⁴ See also Leifer et al. (2000).

relative lack of capacity to both seek and absorb external knowledge as well as their ability to protect knowledge and appropriate its returns (Laursen and Salter 2014)

The potential importance of innovation partnering for micro-firms suggests the value of considering a model of interactive creative destruction, which retains the creative and destructive dynamics of Schumpeter's original CD model but in which we acknowledge that innovation often occurs through partnerships or collaborations. Partnerships may, for example, enable firms working together to establish joint positions of market dominance or lead to merger or acquisition activity. In either case, the extent, and potentially the nature of firms' innovation collaboration, is likely to be an important determinant of innovation outcomes.

3. Hypotheses

Small – and particularly micro-enterprises - are commonly thought to have advantages in terms of flexibility but disadvantages in terms of their resource base (Vossen 1998). There is a substantial literature, however, linking the strength and scale of firms' internal resources positively to innovation. R&D capacity and investment for example, have been shown to be important in shaping innovation outcomes in numerous studies (Belderbos, Carree, and Lokshin 2004; Czarnitzki, Ebersberger, and Fier 2007; Graziadio and Zawislak 1997; Harris and Trainor 1995; Hoffman et al. 1998), as well as contributing to firms' absorptive capacity (Griffith, Redding, and Van Reenan 2003; Xia and Roper 2008). Similarly, firms' investments in intangibles such as design (Filipetti 2010; Fridenson 2009; Marion and Meyer 2011; Moultrie and Livesey 2013), advanced manufacturing technologies (Cardoso, de Lima, and Gouvea da Costa 2012; Hewitt-Dundas 2004) and quality improvement (Adam, Flores, and Macias 2001) have also been shown to link strongly to innovation outcomes. Labour quality and training investment have also been linked to stronger innovation outcomes in small firms (Freel 2005; Leiponen 2005). Public support for R&D and innovation may also create slack within an organisation, allowing greater investments in innovation than would otherwise have been possible (Ballesteros and Rico 2001; Buiseret, Cameron, and Georgiou 1995; Czarnitzki and Licht 2006).

Evidence on the effect of firm size on R&D investment is mixed, with early work suggesting that larger firms invest more in R&D (Schumpeter, 1942; Galbraith 1952; Arrow 1962) due to the presence of threshold effects, sunk- and fixed-costs and imperfections in capital markets, all of which disadvantage the smaller firm. Empirically, the positive relationship between firm size and R&D investment has been questioned (for a review see Symeonidis 1996), with some evidence that size effects may be more evident at the early stages of the industry life cycle (Klepper and Simons 1997). For micro-enterprises, a recent Germany study found that despite smaller firms being less likely to undertake innovation, for those that do, R&D intensity increases as firm size decreases. Further, R&D intensity was found to be positively correlated with the probability of innovating (Baumann and Kritikos 2016).

The evidence therefore suggests that despite constraints on R&D investments by smaller firms, where R&D investments do occur, this has a positive effect on innovation outputs and specifically product innovation. Here, we take this a step further and suggest that for micro-firms, investing in R&D will be related to the entry into new markets as opposed to reinforcing existing capabilities and market position through incremental innovation.

Hypothesis 1: Resources

The probability of micro-enterprises introducing new-to-the-market innovation will increase as their investment in knowledge creation increases.

In addition to their internal resources, previous studies have suggested the importance of external knowledge and resources for innovation outputs (Oerlemans, Meeus, and Boekema 1998; Love, Roper, and Vahter 2014). While it is clear that for micro-firms the process of seeking knowledge outside the firm presents particular problems, recent empirical evidence does, however, suggest that some SMEs do purposively engage in collaborative innovation, and that the prevalence of collaboration among SMEs has increased in recent years (van de Vrande et al. 2009). For micro-enterprises seeking to enter new markets and faced with higher relative R&D costs and risk compared to larger firms, forming external connections may be an efficient strategy to overcoming these constraints. Further, micro-enterprises may be better positioned to access external knowledge and resources (Audretsch and Vivarelli 1996) due to their flexibility in organisational structure and ability to respond quickly to technological and market changes (Dean et al. 1998).

At its simplest, the innovation impact of external relationships might depend on a firm's number of connections. Having more connections increases the probability of obtaining useful external knowledge that can be combined with the firm's internal knowledge to produce innovation (Leiponen and Helfat 2010; de Leeuw, Lokshin, and Duysters 2014; Love et al, 2014). The extent or breadth of a firm's portfolio of external connections may also have significant network benefits, reducing the risk of 'lock-in' where firms are either less receptive to knowledge from outside their own region (Boschma 2005), or where firms in a region are highly specialised in certain industries (Camagni 1991). However, the capacity of management to pay attention to, and cognitively process, many sources of information is not infinite particularly in micro-enterprises (Simon 1947). This cognitive constraint means that while the returns to additional connections may at first be positive, eventually the firm will reach a point at which an additional connection actually diminishes the innovation returns. This is reflected in an extensive empirical literature which suggests an inverted U-shaped relationship between innovation performance and the extent of firms' external networks (Laursen and Salter 2006; Leiponen and Helfat 2010; Grimpe and Sofka 2009; Garriga, von Krogh, and Spaeth 2013). Hence:

Hypothesis 2: Co-operation breadth

As the breadth of firms' network of external innovation partners increases the probability of micro-enterprises introducing new-to-the-market innovation outputs will also increase but with diminishing returns.

Aside from the number and diversity of firms' innovation partnerships, significant attention has focussed on the types of partnerships which impact most directly on innovation. Process innovation in manufacturing, for example, may be most strongly linked to collaboration with universities and suppliers (Un and Asakawa 2015). This suggests the need for firms, and particularly micro-enterprises with limited relationship management capacity and managerial cognition, to adopt a strategic approach to partner choice (Bengtsson et al. 2015). Kohler et al. (2012), in particular, identify those partner types most strongly associated with success in

introducing new-to-the-market innovation for a large group of European firms. Their findings suggest that ‘science-driven search’ with universities and research institutes and ‘supplier-driven’ search with suppliers are most strongly associated with new-to-the-market innovation. Conversely, ‘market-driven’ search with customers is most strongly linked to, more imitative, new-to-the-firm innovation. This suggests our final hypothesis that:

Hypothesis 3: Exploratory partnerships

Collaboration by micro-enterprises with universities, research institutes or suppliers will result in new-to-the-market innovation.

4. Data and methods

4.1 Data and measures

Our analysis is based on a survey of innovation among micro-enterprises (with 1-9 employees) conducted in Northern Ireland and relating to firms’ innovation activity during the three year period 1st January 2010 to 31st December 2012. The survey closely follows the definitions and questions used in the EU Community Innovation Survey and the UK Innovation Survey but uses a different survey methodology being conducted by telephone rather than post. In each firm the most senior person in the business was the respondent. The survey targeted 1,000 businesses, quota sampled to be representative of the Northern Ireland micro-enterprise population. Of the 1,000 respondents around 240 firms indicated that they had had no need to innovate over the last three years due either to prior innovation or the nature of the markets in which they operated. Our analysis focuses on the remaining 761 firms which did identify a need for innovation. Within this group missing values limit our maximum estimation sample to 735 firms of which 462 were non-innovators, 173 were new-to-the-firm innovators only, and 100 were new-to-the-market innovators⁵.

⁵ The sectoral coverage of the estimation sample was as follows in terms of SIC 2007 (n=735): SIC 15-33 Manufacturing 7.48 per cent; SIC 41-43 Construction, 19.73 per cent; SIC 45-46 Wholesale trade, 12.93 per cent; SIC 47 Retail trade, 13.61 per cent; SIC 49-53, 61 Transport, storage, 3.95 per cent; SIC 55-56 Hotels and restaurants, 6.8 per cent; SIC 58, 62, 63, 68-82 Real estate, 29.93 per cent; All other sectors, 5.57 per cent.

Northern Ireland itself is the smallest of the devolved territories of the UK with a population of 1.8m in 2012 at the time of the survey⁶. Linked by a land border with the Irish Republic, Northern Ireland has a long history as a centre for heavy engineering and textile manufacture. However, in common with the rest of the UK, significant industrial restructuring has taken place over recent decades with a loss of manufacturing activity and a growth in creative industries and other services. Around 1:6 of the workforce are now employed in manufacturing, with the economy dominated by micro, small and medium-sized companies. Labour productivity per hour worked has remained around 79-85 per cent of the UK average over the 2000-2010 period and was 17.2 per cent below the UK average in 2012⁷.

The proportion of firms introducing either new or significantly improved products/services or processes in Northern Ireland and the whole of the UK can be compared using data from the UK Innovation Survey 2013. From 2010-12, 18 per cent of UK firms introduced new products or services compared to 14.6 per cent in Northern Ireland. A more significant difference was evident between the proportion of revenue derived from new-to-the-market innovation in the UK (7.5 per cent) and Northern Ireland (3.2 per cent). Conversely, Northern Ireland firms derived 12.4 per cent of revenues from new-to-the-firm innovations compared to 10.7 per cent in the UK⁸. Product innovators in Northern Ireland (52.1 per cent) were also less likely to be collaborating with other partners than similar firms in the UK (62.7 per cent). Possible explanations for this relatively low level of collaborative innovation activity in Northern Ireland are suggested by previous analyses of Northern Ireland's innovation capabilities. One study of absorptive capacity, for example, places Northern Ireland below the UK average on each of the dimensions measured (NESTA 2008). Another recent study of the innovation systems of Northern Ireland and Ireland also suggests that: "Despite numerous agents and supports available to support collaboration and networking, it would appear that the full breadth of the ecosystem is not being fully exploited either at local level or beyond and opportunities

⁶ Source: Region and Country Profiles – Population and Migration, Office of National Statistics, 30 May 2012.

⁷ Source: Region and Country Profiles: Economy, Office of National Statistics, 30 May 2012. Regional Economic Indicators, July 2014, ONS.

exist to increase the relevance of and connections to the other innovation partners”⁹. In terms of the ICD framework outlined earlier this suggests that the potential for collaborative innovation in Northern Ireland may be under-developed at present, perhaps accounting for the lower than average level of new-to-market innovation.

Consistent with the ICD model our interest here is in what shapes micro-enterprises’ ability to introduce new-to-the-market products or services. In the micro-enterprise survey this is reflected in a binary indicator of whether or not firms introduced new-to-the-market products or services over the 2010 to 2012 period. While this type of innovation is clearly important in driving the type of competitive process envisaged in the ICD model, three caveats relating to this measure are worth highlighting. First, the measure is subjective in the sense that it relies on micro-enterprises’ own judgement of what is and what is not new-to-the-market innovation. It is difficult to be clear about the scale of any likely bias in this measure but the probability is that this overstates the proportion of innovations described as new-to-the-market. In this context it is interesting that in the micro-business survey 13.7 per cent of firms reported introducing new-to-the-market innovations in our estimation sample (Table 1) compared to only 7.9 per cent in the UK Innovation Survey which provides representative figures for all UK businesses¹⁰. Second, the question arises of which market the innovation is new to. For the majority of micro-enterprises in the sample this is the UK and Irish market as only 5.9 per cent of micro-businesses were exporting. Third, the binary indicator provided gives us little idea of the commercial success of the innovation itself. In the UK Innovation Survey, for example, and other EU Community Innovation Surveys, firms are asked what proportion of their sales are derived from new-to-the-market innovation, however, this question was not asked in the micro-enterprise survey.

To address our first Hypothesis we measure the resources available for micro-enterprises’ innovation activity using three indicators. First, we include a binary variable to reflect the engagement of the business in R&D, which is generally associated positively with new product development (Roper and Hewitt-Dundas, 2015). Second, we include a variable to reflect micro-

⁹ See IntertradeIreland (2012) Leveraging the innovation ecosystem for business advantage: a cross border study, October 2012.

¹⁰ As the original survey report makes clear, however, ‘higher [micro-business] innovation rates compared to the UKIS ... are a likely consequence of differences in survey methodology. For example, respondents are the most senior person in the business and therefore more likely both to be aware of, and recall, innovation related activity’.

enterprises' investment in other aspects of innovation such as design, training for innovation etc.¹¹. We anticipate this variable having a positive impact on innovation given evidence from other studies that, for example, investments in design and machinery are associated with higher innovation outputs (Marsili and Salter, 2006). Third, we include a variable indicating whether or not the micro-enterprise received public support from either local, national or supranational agencies to support its innovation activity. Such support has been shown in the past to be positively linked to innovation outputs (Smith 1989; Hewitt-Dundas and Roper 2009; Gongora, Garcia, and Madrid 2010).

To address our second and third Hypothesis we measure the extent of micro-enterprises' external co-operation for innovation using two different approaches. First, we use the now standard measure of the 'breadth' of firms' set of innovation linkages (Laursen and Salter 2006). This relates to the number of partner types with which a firm is engaging whether those partners are local, national or international. In the survey, seven different partner types are identified and this variable therefore takes values 0 to 7¹². Previous studies have highlighted an inverted-U shape relationship between this measure and innovation outputs and we therefore include a square of this variable in all models to capture the potential for this non-linear effect (Vahter, Love, and Roper 2014). Second, to capture the innovation value of different types of linkage we split the overall breadth of firms' innovation co-operation into three sub-categories: science-driven links involving commercial labs or private R&D institutes, universities and government or public research institutes; market-driven links to customers from the private sector and public sectors; and, supplier-driven links to suppliers of equipment, competitors and consultants. Our division of overall search breadth into these three components is suggested by the analysis of Kohler et al. (2012).

¹¹ Ten types of innovation investment are identified in the micro-business questionnaire. This variable therefore takes values between 0 and 10. The options were: Advanced machinery and equipment; Computer hardware; Computer software; Purchase of licensing of patents and non-patented inventions, know-how and other types of knowledge from other businesses or organisations; Internal or external training for your personnel, specifically for the development and/or introduction of innovations; Engagement in all design activities, including strategic, for the development or implementation of new or improved goods, services and processes; Changes to product or service design; Market research; Changes to marketing methods; Launch advertising.

¹² These are: Suppliers of equipment, materials, services or software; Clients or customers from the private sector; Clients or customers from the public sector; Competitors or other businesses in your industry; Consultants, commercial labs or private R&D institutes; Universities or other higher education institutions; Government or public research institutes.

We also include in our estimation a number of firm-level control variables which previous studies have linked to innovation outputs. First, we include variables related to whether or not the owner-manager of the firm has a science or technology background and whether she or he is a graduate. Both we anticipate will be positively related to innovation. Employment in the firm is also included which again we expect to be positively related to innovation. Second, an indicator of the independence of the firm is also included to reflect any potential resource advantage accruing to firms which are group members (Choi, Il Park, and Hong 2012). Third, firm age is included to capture any accumulated resource advantages (Balasubramanian and Lee 2008). Fourth, we include an exporting variable to capture any benefit which firms derive from selling in international markets (Love and Roper 2015). Fifth, we include a binary variable to indicate whether firms are family-owned¹³. Previous studies have suggested that family firms may be more risk averse, keener on preserving wealth rather than undertaking the type of risky investments implicit in new-to-the-market innovation (Kotlar et al. 2014; Matzler et al. 2015; Sciascia et al. 2015)¹⁴. Overall, 81.0 per cent of micro-enterprises in our estimation sample indicated that the business was family-owned (Table 1). Finally we, include an indicator to capture any ‘value of diversity’ associated with a more diverse workforce (Diaz-Garcia, Gonzalez-Moreno, and Saez-Martinez 2013)¹⁵ following Ostergaard, Timmermans and Kristinsson (2011) and include both the proportion of female owners, partners and directors and a squared term to allow for any non-linear effects of gender balance.

4.2 Analytical approach

Our analysis is based on the concept of the innovation production function, which relates micro-enterprises’ innovation outputs to the knowledge inputs to their innovation process (Griliches, 1995; Love and Roper, 2001; Laursen and Salter, 2006). Adopting the innovation production function also allows us to take into account firm characteristics and other elements of micro-enterprises’ innovation strategies – e.g. investments in R&D, design and innovation

¹³ The categorisation of businesses as family-owned and controlled has received substantial attention in the research literature and generated significant debate. In the current context we are limited to a single question in the micro-enterprise survey which directly asked: ‘Is the business family-owned?’ and required a binary response. We have no information in the survey on whether a business is both family-owned and family-run.

¹⁴ Although see Craig et al (2014) who find no significant differences in the propensity to take risks among a large sample of Finnish family and non-family firms.

¹⁵ In the survey, micro-enterprises were asked how many ‘owners, partners and directors were there in day-to-day control of the business’ and then ‘how many of these owners, partners and directors (OPDs) were female?’ On average around a quarter of all OPDs were female (Table 1), a figure strongly consistent with other studies of UK businesses (Martin et al. 2008).

partnerships – alongside firms’ ownership and leadership profile. Furthermore, it enables us to identify any contingent factors, which might be associated with aspects of firms’ operating environment (e.g. sector) or other dimensions of firms’ innovation activity (e.g. size). We investigate two different forms of the innovation production function relating to the different hypotheses. Let IO_i be an indicator of the probability that a micro-business will be doing new-to-the-market innovation, then to investigate Hypothesis 1 and 2 we estimate

$$IO_i = \alpha + \beta_0 RES_i + \beta_1 XT_i + \beta_2 XT_i * XT_i + \beta_3 CONT_i + \varepsilon_i \quad (1)$$

Where RES_i is a vector of resource indicators, XT_i are the number of external connections and $CONT_i$ is a series of firm-level controls. Hypothesis 1 requires that $\beta_0 > 0$, Hypothesis 2 requires that $\beta_1 > 0$ and $\beta_2 < 0$.

To investigate the value of different types of external linkages for new-to-the-market activity – Hypothesis 3 – we divide firms’ external linkages into those relating to the science-base ($XTSC_i$), those to suppliers ($XTSU_i$) and those to other market based partners ($XTMB_i$). This implies:

$$IO_i = \alpha + \beta_0 RES_i + \beta_1 XTSC_i + \beta_2 XTSU_i + \beta_3 XTMB_i + \beta_4 XT_i + \beta_5 CONT_i + \varepsilon_i \quad (2)$$

Where Hypothesis 3 requires that $\beta_1 > 0$, $\beta_2 > 0$ and $\beta_3 = 0$.

We use two different modelling approaches to explore each hypothesis. The first reports a series of bivariate probit models focussed on the probability that micro-enterprises will make new-to-the-market innovations. For comparison we also report models for the probability of undertaking new-to-the-firm innovation. Second, we use ordered probit models reflecting the progression from no innovation, through new-to-the-firm innovation to new-to-the-market innovation. The results from each estimation approach prove very similar.

5. Empirical Results

We report probit models for the probability that firms will undertake new-to-the-firm innovation in Table 2. In addition to the variables of interest and the controls, all models include sectoral dummies at the two digit level. In each case the reference group is the group of 462 non-innovating firms, i.e. the models for new-to-the-market innovation exclude those (173)

firms doing only new-to-the-firm innovation¹⁶. Models (2), (4) and (6) relate to new-to-the-market innovation and, for comparison, models (1), (3) and (5) relate to new-to-the-firm innovation in products or services. The first two models in the table include only control variables. Model fit improves significantly when the main independent variables are added. Average VIF statistics are 3.41 for models (5) and (6) well below the conventional cut-off (10) for serious multi-collinearity.

Hypothesis 1 suggests a positive link between firms' resources and their probability of undertaking new-to-the-market innovation. This is supported in the case of R&D activity and innovation investment but, contrary to other studies of larger firms, we find no evidence that public support for innovation has any positive output effect. Indeed, R&D itself only has a significant association with new-to-the-market innovation but no significant link to new-to-the-firm innovation. It is also notable that the marginal coefficient on other types of innovation investment (i.e. design, market research, IT etc.) is more than twice that for new-to-the-firm innovation than new-to-the-market (Table 2). This suggests the rather different nature of the investments underlying new-to-the-firm and new-to-the-market innovation, with the former relying more heavily on externally acquired knowledge or expertise, and new-to-the-market innovation with its higher degree of novelty linked more strongly to in-house R&D activity. For example, licensed-in technology previously used elsewhere would require an investment by the firm and may lead only to a new-to-the-firm innovation. R&D investments are likely to be linked to more exploratory activity helping firms to introduce more novel new-to-the-market innovations.

Central to the notion of the ICD model is inter-organisational co-operation and Hypothesis 2 argues that the breadth of firms' co-operation will be important for new-to-the-market innovation. In the estimated models we include both a level and quadratic term to reflect earlier studies of an inverted-U shape relationship between the breadth of firms' co-operation and innovation outputs. This resolves to a single marginal effect (measured at variable means) for the relationship between breadth and innovation outputs which is positive and significant in

¹⁶ In the case of the new-to-the-firm innovation models some observations were also dropped due to sectoral dummies being perfectly correlated with the dependent variable. This reduced the estimation sample from a possible 562 (462 non innovators and 100 new-to-the-market innovators) to 547.

each model (Table 2). This provides strong support for Hypothesis 2. Estimates of the marginal effects of co-operation on innovation at different levels of breadth where all other variables are held at variable means are included in Figure 1. The marginal benefits of extending co-operation are clearly strongest for micro-firms' first two connections and then fall – particularly for new-to-the-firm innovation - as the number of connections increases beyond this. Negative marginal effects where breadth is largest suggest the normal inverted-U shape relationship which characterises the contribution of external connectivity to innovative outputs (Figure 1). Notably, these negative marginal returns are encountered at lower levels of breadth for new-to-the-firm innovation than for the potentially more complex new-to-the-market innovation (Figure 1). Overall, our results provide strong support for Hypothesis 2, and the importance of external collaboration for new-to-the-market innovation. As a robustness check on this result we also investigated potential absorptive capacity effects, interacting our measure of connectivity with R&D and the control variable indicating whether the owner-manager of the business was a graduate. The external connectivity effects remain the same with neither interaction measure proving significant for either new-to-the-market or new-to-the-firm innovation.

Our final hypothesis relates to the nature of micro-enterprises' innovation collaboration and suggests that links to suppliers, universities and research institutes are most likely to be associated with new-to-the-market innovation (Kohler, Sofka, and Grimpe 2012). We find only partial support for this hypothesis, with both supplier-based co-operation and market-based co-operation having beneficial effects for both new-to-the-firm and new-to-the-market innovation. Unlike Kohler et al. (2012) we find no positive association between science-based co-operation – with universities or research laboratories – and new-to-the-market innovation. It is possible that this may reflect either the paucity of links between micro-enterprises and universities or the more limited absorptive capacity of micro-businesses. Including interaction effects with R&D in these models to test this idea changes little, with the interaction effects largely insignificant. Where a firms' owner-manager is a graduate there is, however, a positive interaction effect with science-based co-operation for both new-to-the-market and new-to-the-firm innovation. Graduate status has no significant interaction with either supplier or market-based collaboration. This perhaps suggests the specificity of absorptive capacity required for different types of external collaboration (Schmidt 2010).

Our control variables largely take the anticipated signs. One notable exception is the unanticipated positive effect of family ownership on new-to-the-market innovation: family-owned firms are 8.3-8.4 per cent more likely to introduce new-to-the-market innovations than non-family owned firms. This suggests the long term perspective and patient capital of family-owned firms outweighs any greater risk aversion among family-owned firms (Matzler et al. 2015; Sciascia et al. 2015). Interestingly this effect is only evident for new-to-the-market innovation with no significant family ownership effect for more incremental product or service change.

In Table 3 partly as a robustness check we report ordered probit models estimated across the whole group of non-innovators, new-to-the-firm and new-to-the-market innovators. Table 4 reports the marginal values for the two ordered probit models. The ordered probit models largely re-emphasise the importance of those variables identified earlier: R&D and innovation investment are important as is external supplier-based and market-based co-operation (Table 3). There is again evidence of a significant family ownership effect linked to the greater novelty of innovation activity (Table 3). The marginal values are confirmatory suggesting, for example, that firms are less likely to be in the non-innovator group when they are R&D active and more likely to be in either the new-to-the-firm or new-to-the-market groups. As we might anticipate, the marginal effects of R&D, innovation investment and co-operation activity are largest for new-to-the-market innovation (Table 4).

6. Discussion

Our conceptual discussion focuses on the potential role of co-operation or interaction in driving new-to-the-market innovation – and hence a creative destruction process – among micro-enterprises. We find strong support for this central proposition – particularly in terms of supplier and market-based co-operation - and for the important role of other types of innovation investment and R&D in shaping the probability of new-to-the-market innovation (Table 2). These inputs to the innovation process may be playing complementary roles, with firms' in-house R&D capabilities helping to identify and perhaps absorb externally acquired knowledge (Cohen and Levinthal 1989). This confirms previous empirical findings that R&D is positively

correlated with innovation activity in micro-enterprises (Baumann and Kritikos 2016). Yet, our findings refine this further with R&D investment in micro-enterprises positively associated with the new-to-the-market innovation and not new-to-the-firm innovation. Innovation investments may also be playing a complementary role, providing an alternative to co-operation for accessing externally available knowledge. We also find some evidence that family businesses are more likely to introduce new-to-the-market innovation.

How does the importance of innovation co-operation suggested by our empirical analysis, and the role of firms' internal complementary knowledge assets, change the competitive dynamics of the CD model among micro-enterprises? In the rather specific context of pharmaceuticals, for example, Rothaermel (2001) shows that incumbents derive performance benefits from developing alliances with new technology providers in a process which is mutually beneficial: through alliance formation the incumbent neutralises any competitive threat from the new entrant at the cost of internalising any commercial or technical risk; the new entrant benefits from the resource advantages and market legitimacy of the incumbent. This is especially advantageous for micro-enterprises where R&D investment is more difficult (Conte and Vivarelli 2014), and new market entry is hindered by issues of legitimacy (Lévesque & Shepherd 2004). Where industries are more atomistic, these strategic advantages to both parties – incumbents and new entrants - will be less pronounced, and motivations for alliance or partnership may instead emphasise resource acquisition and/or risk mitigation. This may influence both firms' alliance portfolios and strategy in terms of each individual partnership. There is mounting evidence, for example, that for smaller firms the breadth of firms' alliance portfolios contributes both to innovative outputs and organisational performance albeit with a declining marginal benefit for each added partner type (Beck and Schenker-Wicki 2014; Vahter, Love, and Roper 2014). Alongside the technological leadership capabilities required for success in the traditional CD model, the need for small firms to carefully select partners also emphasises the importance of firms' organisational capabilities around partner search, partnership management and learning capabilities (Love, Roper, and Vahter 2014; Zhu 2006). This links into on-going debates about ambidexterity in innovation, and firms' ability to effectively explore and develop new technologies through partnerships and then effectively exploit the innovations developed (Chang and Hughes 2012).

The implication is that to be successful in the ICD model micro-enterprises require a rather different – and broader - profile of internal capabilities than in a more traditional CD setting. In the CD model, internal innovation dominates and the emphasis is on firms’ internal ambidexterity – their ability to develop and effectively exploit technological innovation based on their internal resources, typically R&D investment. In the ICD model the picture is more complex with firms needing to achieve partnership ambidexterity – developing relationships which effectively combine internal and external resources to achieve technological leadership (Tiwana 2008). This is emphasised in our analysis by the simultaneous importance of what are potentially exploratory relationships to suppliers and potentially exploitative relationships to customers.

The importance of co-operation in driving new-to-the-market innovation in micro-enterprises may also contradict to some extent the fluid competitive dynamics of the CD model with its emphasis on the temporary technological leadership of individual firms. Instead as Rahman and Korn (2014, 257) suggest ‘many promising alliances fail to produce satisfactory results because of their inadequate longevity ... greater longevity may translate to more time to work on the alliance to yield satisfactory results’. On the other hand, alliances of longer duration may allow the development of deeper, more complementary, relationships between firms yielding more positive outcomes (Pangarkar 2003). In the ICD model this suggests two possible innovation strategies for micro-enterprises seeking to introduce new-to-the-market innovation – that of closed or solo innovation and that of collaborative innovation. Interestingly, in our sample of micro-enterprises the latter strategy predominates with 74.8 per cent of new-to-the-market innovators collaborating with (often multiple) external partners and only 25.2 per cent being solo innovators. Moreover, new-to-the-market innovators were typically working with 2.8 types of partner compared to 0.99 among all firms in the estimation sample.

Alongside collaboration our analysis also highlights the positive role of family ownership on micro-enterprises’ introduction of new-to-the-market innovation (Table 2). On first sight this result appears to contradict the majority of existing evidence which suggests a negative relationship between family ownership and R&D investment (Matzler et al. 2015; Sciascia et al. 2015), although our results are similar to those of a recent German study linking family ownership positively to innovation outputs (Matzler et al. 2015). One possibility consistent

with both this wider evidence and our analysis would be that family firms have higher levels of external collaboration and are therefore able to economise on internal R&D expenditure. In our sample, however, among new-to-the-market innovators, levels of external collaboration are actually lower among family-owned firms (an average of 2.57 external partner types) than among non-family owned firms (3.9 partner types on average). This is consistent with evidence from other studies which suggests that in order to preserve control over their innovation activities family-owned firms are reluctant to engage in innovation partnerships (Kotlar et al. 2014). More persuasive therefore are arguments which suggest that, all else being equal, family-owned firms may be more effective innovators due to deeply embedded knowledge of the company and its operation, close relations between family members and shared business objectives (Chrisman et al. 2012). It may also be the case that these attributes reduce the search costs of external relationships and enhance the contribution of such relationships to family-owned firms' innovation outputs.

In managerial terms our study emphasises the range of capabilities necessary for micro-enterprises to undertake new-to-the-market innovation and so contribute to the CD process. Managerial attitudes, resource co-ordination, appropriability strategies and partnering skills may be equally important as more technological competencies (Laursen and Salter 2014), although our results do suggest that new-to-the-market innovation is more likely where the owner-manager of a firm has a science or technical background (Table 2). In policy terms it is perhaps of interest to consider the barriers to innovation cited by those micro-enterprises which were making new-to-the-market innovations. Factors which were said to be 'very influential constraints' on innovation were: excessive economic risk, 45.4 per cent of firms; availability of finance, 42.7 per cent; costs of finance, 36.9 per cent and direct innovation costs being too high, 35.9 per cent of firms. Other factors like regulatory issues (24.2 per cent), a lack of information about partners (19.4 per cent) and uncertain demand (21.4 per cent) were less commonly cited. The dominance of risk and finance related constraints on innovation here is common to most innovation surveys, however, perhaps less common is the finding that 33.9 per cent of new-to-the-market innovators felt that a major constraint was a lack of information on the potential support available for innovation. This may explain in part the lack of any significant policy effect in our innovation models, although this result is consistent with other recent findings (Conte and Vivarelli 2014).

7. Conclusions

Relatively little is known about the nature of innovation among micro-enterprises with less than 10 employees due to their exclusion from the majority of innovation surveys. Here, we draw on a regional survey explicitly targeted at micro-enterprises to consider the drivers of new-to-the-market innovation and the related process of creative destruction. We find strong support for the interactive nature of new-to-the-market innovation activity among micro-enterprises suggesting the need for a re-definition of the Schumpeterian creative destruction model. The fundamental impetus remains - competition drives innovation – but the process through which innovation and market leadership emerge is interactive rather than atomistic, and socially-embedded rather than acontextual. Alongside micro-enterprises' internal capabilities, collaboration plays a key role in firms' ability to develop new-to-the-market innovations. Family ownership matters too, increasing the probability that firms will engage in new-to-the-market innovation and drive the creative destruction process.

While, our study provides some new insights into micro-enterprise innovation it has a number of limitations. First, it is based on a cross-sectional survey from a single UK region, Northern Ireland. Both factors limit the generalisability and causal interpretation of the results. Replication with data with broader geographical coverage and a stronger temporal dimension would be valuable. Second, there are some specific limitations to our survey data. In particular we have no information on the perceived importance of different types of collaboration to each firm or on the specific number of collaborating partners of each type. This limits our analysis of the innovation benefits of collaboration and means we have no insight into the importance of the 'depth' of firms' collaboration (Laursen and Salter, 2006). Our data is also limited in terms of the information it provides in terms of the success of the innovations introduced. We are unable to say, for example, whether the new-to-the-market innovations reported proved to be truly disruptive and what implications this had for the innovating firm. Third, although combining some novel leadership and innovation measures our study remains limited by its econometric and reductionist methodology. Complementary case-study evidence would be a valuable and insightful addition. Finally, while our study does suggest some of the direct influences of factors such as family-ownership and co-operation on innovation outputs we have yet to consider the potential interactions between these influences. Our data shows, for

example, that in general family-owned firms have fewer external innovation partnerships, but it may be that the longer time horizons of family-owned firms allow more complementary partnerships to develop increasing their innovation value. This is for future work.

Table 1: Sample Descriptives

	Obs	Mean	Std. Dev.
