## Abstract

Physical activity is an important facilitator for health and wellbeing, especially for late middle-aged adults, who are more susceptible to cardiovascular diseases. Physical activity performed in green areas is supposed to be particularly beneficial, so we studied whether late middle-aged adults are more active in green areas than in non-green areas and how this is influenced by individual characteristics and the level of neighbourhood greenness. We tracked 180 late middle-aged (58 to 65 years) adults using global positioning system and accelerometer

data to know whether and where they were sedentary or active. These data were combined with information on land use to obtain information on the greenness of sedentary and active hotspots. We found that late middle-aged adults are more physically active when spending more time in green areas than in non-green areas. Spending more time at home and in non-green areas was found to be associated with more sedentary behaviour. Time spent in non-green areas was found to be related to more moderate-to-vigorous physical activity (MVPA) for males and to less MVPA for females. The positive association between time spent in green areas and MVPA was the strongest for highly educated people and for those living in a green neighbourhood. This study shows that the combined use of global positioning system and accelerometer data facilitates understanding of where people are sedentary or physically active, which can help policy makers encourage activity in this age cohort.

## Introduction

Aging is often associated with physical frailty and increased health problems (Rockwood *et al.*, 2004; Landi *et al.*, 2010). With increasing life expectancy and an expected increased number of middle-aged (45 to 65 years) and older adults ( $\geq 65$  years) in the future, health care costs are expected to rise globally (Department of Health, 2004; OECD, 2006). Sufficient physical activity and limited sedentary behaviour can prevent certain diseases, especially in middle-aged and older adults, who are more susceptible to cardiovascular diseases than younger people (Warburton *et al.*, 2006; Cavill *et al.*, 2008; US Department of Health and Human Services, 2008; King and Guralnik, 2010; Warburton *et al.*, 2006; Hamilton *et al.*, 2012).

Theoretically, late middle-aged adults (58 to 65 years) have more leisure time to spend on recreational physical activity (PA) or active transport than younger adults and could thus be more physically active or spend more time away from home (Banister and Bowling, 2004). However, with increasing age people seem to spend more time at home (Kerr *et al.*, 2012), their sedentary behaviour increases (Clark *et al.*, 2014; Ortlieb *et al.*, 2014), and they are less physically active (Bauman and Bull, 2007; Troiano *et al.*, 2008; Ortlieb *et al.*, 2014). In most developed countries, 60 to 70% of adults aged 65 and more do not reach 150 minutes of moderate-to-vigorous PA (MVPA) per week, which is recommended to benefit positive health effects (Centers for Disease and Control Prevention, 1996; WHO, 2010).

The presence of green areas can have a positive impact on achieving these health effects. Several publications demonstrate that a higher availability of accessible green spaces is associated with a higher amount of PA (Van Cauwenberg *et al.*, 2011; Van Holle *et al.*, 2012,

2014). On the other hand, when PA occurs in green areas (*e.g.* parks; Coombes *et al.*, 2013), it can have positive effects on both physical (*e.g.* less exposure to pollution) and mental (*e.g.* wellbeing) health (Frumkin, 2001; St Leger, 2003; Sugiyama *et al.*, 2008; Mackay and Neill, 2010; Fan *et al.*, 2011; Thompson *et al.*, 2011). It has also been demonstrated that performing PA in non-green areas, especially along-side urban roads, increases inhalation levels and hence exposure to air pollution (Int Panis *et al.*, 2010). Providing a sufficient amount of accessible green areas in urban areas is potentially a cost effective way to improve health and wellbeing. However, the relationships between greenness and health are complex and further exploration is needed. The research presented here explores the link between PA levels of late middle-aged adults and the presence of green areas. Not only do we focus on where PA mainly takes place as this significantly influences health impacts, but also on the general relationship between the amount of available greenness and the level of PA. To better understand time-activity patterns and PA of late middle-aged adults, it is important to know if and where they are mostly active. Global positioning system (GPS) devices in combination with accelerometers have been previously used to analyse the location-specific PA in children (Elgethun *et al.*, 2003; Almanza *et al.*, 2012; Lachowycz *et al.*, 2012; Oreskovic *et al.*, 2012; Coombes *et al.*, 2013). Knowing where people are can give insights into their exposure to different attributes of the environment (*e.g.* air pollution, noise, greenness) and related health effects (Seeger *et al.*, 2007; Dons *et al.*, 2013; Bekö *et al.*, 2015; Dewulf *et al.*, 2016). Knowing where people are physically active (in terms of location or greenness) can also provide policy makers with insights into people's needs.

There are numerous factors influencing both PA itself and the association between greenness, location (*i.e.* at home, in the neighbourhood or further away) and PA, which need to be known to further promote PA. Several individual characteristics are correlates of PA. Males with a higher income and normal weight tend to be more physically active than their counterparts (Bauman and Bull, 2007; Ortlieb *et al.*, 2014). For older adults, *being confident to be physically active and having social support* is positively correlated with PA, while *feeling too old* has an adverse effect (Bauman and Bull, 2007; Carlson *et al.*, 2012). Next to individual characteristics, the relation of neighbourhood built environment factors and PA has been widely studied in the past, mainly showing that people living in highly *walkable* neighbourhoods tend to be more physically active (Berke *et al.*, 2007; Frank *et al.*, 2010; King *et al.*, 2011; Marshall *et al.*, 2014; Van Holle *et al.*, 2014; Marquet and Miralles-Guasch, 2015). However, a study based on a national survey on Canadian adults reports that there is a positive association between neighbourhood greenness in a 500 m buffer around the home location and leisure-time PA (McMorris *et al.*, 2015). Research on the influence of greenness on PA in late middle-aged adults is however limited, and there is hitherto no research on how neighbourhood greenness impacts the time spent active in green areas. In general, specific research on late middle-aged adults is relatively uncommon (especially in Europe) and does often not include objective measures of PA (Berke *et al.*, 2007; Kaczynski *et al.*, 2008; Lovasi *et al.*, 2008; Shigematsu *et al.*, 2009; Frank *et al.*, 2010; McMorris *et al.*, 2015) or shows inconsistent results (Berke *et al.*, 2007; Lovasi *et al.*, 2008; Frank *et al.*, 2010; King *et al.*, 2011; Carlson *et al.*, 2012; Van Holle *et al.*, 2014). To our knowledge, research on the influence of personal characteristics and neighbourhood greenness on the association between greenness, location and PA in late middle-aged adults in Europe is unprecedented. We also feel that the use of detailed GPS and accelerometer data in this line of research can offer new insights. The main goal of this study is to reach an understanding where late middle-aged adults are mostly physically

active in terms of location and in relation to greenness. Secondly, the influence of several individual characteristics, such as gender, working status, body mass index (BMI) and diploma as well as neighbourhood greenness has been studied with respect to PA and its association with greenness and location.

## Materials and Methods

### Participants and procedures

We used data from 180 community-dwelling late middle-aged adults selected from a systematic random sample. Participants were all between 59 and 65 years old, working or retired, and living in Ghent, a medium-sized city (156.2 km<sup>2</sup>-250,000 inhabitants) (Stad Gent, 2014) in Belgium. In order to participate, individuals had to meet three criteria: i) understand and speak Dutch; ii) live independently; and iii) be able to walk a couple of hundred meters without severe physical restrictions. The home address for each participant was available. They were all visited at home and asked to wear a GPS device (Qstarz BT-Q1000X; Qstarz International, Taipei, Taiwan) and an accelerometer (Actigraph GT3X, GT3X+, or GT1M; ActiGraph, Fort Walton Beach, FL, USA), a valid and reliable tool for objectively measuring PA levels (Melanson and Freedson, 1995; Copeland and Esliger, 2009; Pruitt *et al.*, 2010). The instruments were worn at waist height for a week. The participants entered the required information on PA for different purposes (home, work, transport, recreation) in the international PA questionnaire (*i.e.*, the *long past seven days* version; IPAQ, 2014). They also provided information regarding several personal characteristics: gender, working status, height and weight (from which the BMI was calculated), and diploma.

### Data collection and analysis

#### Global positioning system and accelerometer data

GPS and accelerometer data were captured during the participants' waking hours. GPS data were collected at a 15-second time interval, between February 22<sup>nd</sup> 2013 and April 5<sup>th</sup> 2013 resulting in a raw dataset of 5,672,590 points. Additionally, participants were equipped with an accelerometer that showed the number of accelerations per 15 seconds. GPS and accelerometer data were linked using the personal activity and location measurement system (PALMS) (Demchak *et al.*, 2012; PALMS, 2015) enabling us to know the number of accelerometer counts for each GPS point, from which each participant's PA level was calculated based on the Freedson cut-off points (Freedson *et al.*, 1998) as shown in Table 1. Because distinction between car and bike movement (especially in the city centre where they have similar speeds) is difficult, the *vehicle* PA level was only studied in the first part of the manuscript. In the current study, we only took into account data points where people are either sedentary or active. Data points showing non-wearing time and erroneous ones were omitted from the dataset, resulting in 3,019,491 valid (wearing) data points (53.2% of the original dataset).

#### Location calculation

For each data point, the network distance to each participant's home address was calculated in ArcGIS 10.0<sup>TM</sup> using Network Analyst (ESRI, 2011). Based on this distance, the following movement classification was made: i) 0 to 50 m: at the home location; ii) 51-1000 m: in the neighbourhood; and iii) >1000 m: outside the neighbourhood.

We used a distance of 50 m for the home location including the yard, since too little movement can cause noise in the GPS data. A distance

of 1000 m coincides with a 10-15 minute walk and is internationally used as the neighbourhood boundary (Frank *et al.*, 2005; Oliver *et al.*, 2007; Bauman and Bull, 2007; Lovasi *et al.*, 2008; Boruff *et al.*, 2012).

### Greenness calculation

A 10-m resolution land use map containing 48 classes of the Flanders and Brussels region was used to calculate the greenness of each location using ArcGIS 10.0™ (Van Esch *et al.*, 2011). This map was developed by the Flemish Institute for Technological Research (*Vlaams Instituut voor Technologisch Onderzoek*, VITO), Mol, Belgium, and combines the CORINE land cover, detailed parcel data, a biological appreciation map and others. The following land use classes were considered as *green*: agriculture, grassland, forest, swamp, heath land and coastal dune as well as park, recreation and sport terrains. The other classes were considered as *non-green* land uses (*e.g.* residential, commercial, industrial, roads). While a further distinction could be made between *e.g.* natural/built green areas and commercial/residential non-green ones, in this exploratory study we made a dichotomist distinction to offer a first view on the association between greenness and PA.

### Average values per person

To analyse the association of greenness and location with PA per person and to study the influence of personal characteristics of this association, the point dataset was summarised to obtain average values per person. The following values were calculated using the administration and management tool pgAdmin™ (PostgreSQL Global Development Group: <https://www.postgresql.org/>): hours of PA levels [sedentary, vehicle, light physical activity (LPA), moderate-to-vigorous physical activity (MVPA)] per day, hours in green/non-green areas per day, hours at home/neighbourhood/further per day, hours of PA levels in green/non-green per day, hours of PA levels at home/neighbourhood/further per day. Only participants with at least 6 hours of valid accelerometer data per day and at least 4 valid days were included in the analyses. As a result, we maintained 138 (76.7%) participants of the initial 180, with respect to whom full further analyses were done.

### Neighbourhood greenness

The neighbourhood greenness was calculated in a network buffer (only using *walkable* roads) of 1000 m around each participant's home location using ArcGIS 10.0™ (ESRI, 2011), and expressed as the percentage green land use cells of all cells. Data on the road network (TeleAtlas MultiNet®: [http://www.tele-mart.com/teleatlas\\_multinet.php](http://www.tele-mart.com/teleatlas_multinet.php)) was used to define the *walkable* roads.

### Geographical and statistical analyses

Geographical and visual analyses were performed in QGIS 2.8™ (QGIS Development Team, 2015). Statistical analyses were done using SPSS Statistics 22™ (IBM Corp., 2013). The association between greenness, location and PA per GPS data point ( $n=3,019,491$ ) was tested for significance using an independent-samples t-test (after successfully testing the data for normality). The averaged data per person ( $n=138$ ) were examined by performing a linear regression analysis to study the associations of greenness and location with PA (again, after successfully testing the data for normality). To examine whether these associations are similar in different socio-demographic subgroup, stratified linear regression analyses were conducted.

## Results

This section first presents some general descriptive statistics about the population sample. The second part describes analyses of the 3,019,491 valid data points to detect where the late middle-aged adults ( $n=180$ ) are mostly active. The third part deals with the analyses based on the data per person ( $n=138$ ) and has to do with the association between greenness, the distance from home and PA level per person and includes an analysis of the influence of several personal characteristics and neighbourhood greenness.

### General descriptive statistics

General descriptive statistics of the 180 participants are presented in Table 2. The majority of the sample was non-smoking, had a higher education, was retired and had a partner. The mean age was 61.7 years and the mean BMI was 26.0. The sample contains slightly more women than men. From all valid data points ( $n=3,019,491$ ) it is clear that the participants were mainly sedentary (65.5%), followed by LPA (24.0%), vehicle (5.8%) and MVPA (4.7%). Table 3 shows the distribution of valid data points for both greenness and location. The data points referring to the participants' whereabouts mainly pointed at non-green land use classes (residential, commercial, or other industrial) compared to green land use classes (forest, recreation, park, grassland, agriculture). Additionally, it was found that late middle-aged adults spent most of their time at the home location rather than anywhere else.

### Where are late middle-aged adults mostly active?

#### Geographical and visual analyses

In Figure 1, data points from one specific green area as an example (the *Citadel* park) are visualised for all participants, indicating the PA level. One can see that in this green area MVPA (probably mainly walking) was done along the walking trails. At certain locations, we observed some LPA and sedentary behaviour as well, mainly near certain points of interest (in the Southwest a statue with benches, in the Northeast a pond with benches). This type of pattern was also observed at other green locations.

**Figure 1.** Visualisation of the collected global positioning system and accelerometer data in a green area (*Citadel Park* in Ghent, Belgium). The figure includes all participants and indicates the physical activity level for sedentary, light physical activity and moderate-to-vigorous physical activity per data point.

**Associations of greenness, location and physical activity per data point**

Figure 2 visualises the PA levels depending on the location and greenness of the data points, summed to 100% for greenness. We did not consider the home location (>50 m) here, since this is a mainly non-green area, where this analysis would be purposeless. In the neighbourhood, the participants were mainly sedentary and performed LPA. Outside the neighbourhood we observed less sedentary behaviour ( $P<0.05$ ) in favour of more time spent in the vehicle ( $P<0.001$ ) and more MVPA ( $P<0.001$ ). LPA was approximately the same in the neighbourhood and further, and mainly involved walking at a slow pace.

Taking greenness into account, sedentary time was found to be much higher in non-green areas than in green areas ( $P<0.01$ ). There is generally more vehicle use ( $P<0.01$ ) in green areas, because green areas are often located outside city centres and car use is higher there. LPA ( $P<0.05$ ) but more striking MPVA ( $P<0.001$ ) was significantly higher in green areas than in non-green areas.

**Individual greenness/location/physical activity association and the influence of personal characteristics and neighbourhood greenness**

**Descriptive statistics**

Table 4 shows some additional general descriptive statistics of the participants ( $n=138$ ), concerning greenness, location and PA. Each participant had an average of 12.0 hours of data per day (non-wearing time and sleeping excluded) for on average 6.6 days. Only 30 minutes per day was spent in green areas, 6.7 hours were spent at the home location, almost 2 hours in the neighbourhood and more than 3 hours further away (the histogram of the time spent further away shows a large peak between from 1 to 5 hours, and a smaller peak from 6 to 9 hours). Almost 8 hours were spent being sedentary, and approximately 2.8 hours per day were spent being active (LPA and MVPA).

The results indicate that 70% of the late middle-aged adults are sedentary for more than 7 hours per day and 35% does not reach the 21.4 minutes of MVPA per day (or 150 minutes per week) to benefit positive health effects.

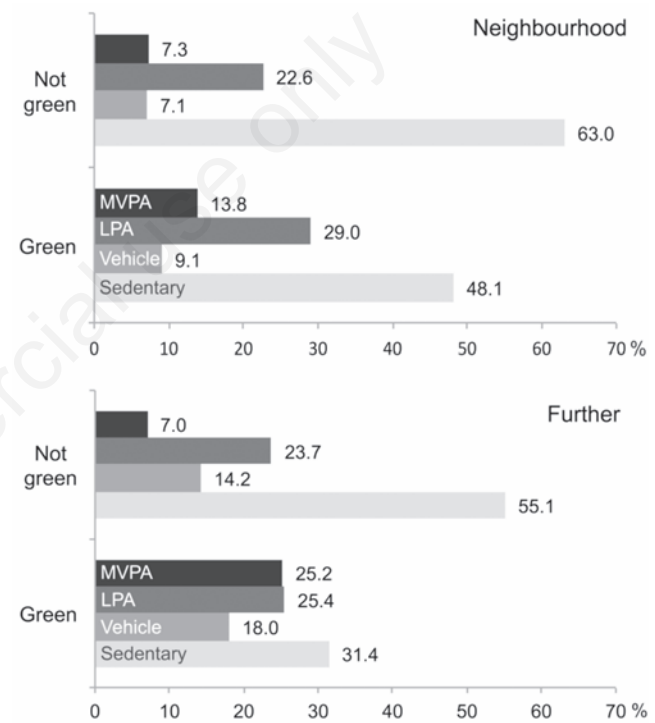

**Associations of greenness, location and physical activity per person**

We performed a linear regression analysis to study the association of greenness and location (*i.e.* being at home) with PA and found some significant results (Table 5). More time spent in non-green areas was associated with more hours of sedentary behaviour and LPA, while more time in green areas was associated with less sedentary behaviour and more hours of MVPA. More time spent at home was also associated with more sedentary behaviour and LPA.

**Influence of personal characteristics and neighbourhood greenness**

Table 6 shows whether the association of greenness and location with PA differs depending on various personal characteristics (gender, working status, BMI, and educational level).

The positive associations between time spent in non-green areas and time being sedentary or in LPA were comparable for the different subgroups. The association between time spent in non-green areas and time in MVPA was positive for males, *i.e.* more time spent in non-green areas was related to more MVPA, and negative for females, *i.e.* more time in non-green was related to less MVPA. The negative association between time spent in green areas and sedentary time was only significant for male, retired participants with a normal BMI and lower education. The positive association between time spent in green areas and

**Figure 2. Percentages of the type of physical activity of all valid points depending on greenness and location. Activity types refer to sedentary, vehicle, light physical activity and moderate-to-vigorous physical activity.**

**Table 1. Accelerometer counts based on estimated physical activities.**

Accelerometer data (counts per minute)	Type of defined physical activity	Activity
>60	Non-instrument wearing/sleeping	Non-defined; not measured
0-100	Sedentary	Reading, watching TV, eating, desk work
0-100 (speed >5 km/h)	Vehicle-related	In transport (car/tram etc.); biking
101-1951	LPA	Standing (e.g. ironing, washing up and other household tasks; low-speed walking)
1952-100,000	MVPA	Walking, running
>100,000	Error <sup>o</sup>	na

LPA, light physical activity; MVPA, moderate-to-vigorous physical activity; na, not available. <sup>o</sup>Removed from the dataset.

LPA was only significant for men, and the association between time spent in green areas and MVPA was the strongest for highly educated people and those living in a green neighbourhood. The positive association between time spent at home and sedentary behaviour was strongest for retired participants. The association between time spent at home and doing LPA is comparable in the different subgroups.

## Discussion

Previous research has shown that being active in green areas has a positive effect both on physical and mental health (Frumkin, 2001; St Leger, 2003; Thompson Coon *et al.*, 2011; Dewulf *et al.*, 2016). This study demonstrates that late middle-aged adults spend an average of 30 minutes per day in green areas, and when more time is spent there, people are more active compared to their behaviour in non-green areas. This suggests that availability of green areas lead to higher amounts of PA. The knowledge of the link between greenness and PA hotspots is important for policy makers wishing to stimulate PA. Nevertheless, there will always be a large proportion of PA occurring in non-green areas (*e.g.* in city centres). Being physically active in non-green areas does not necessarily imply a negative health impact, but small green features could be introduced to improve people's wellbeing. However, spending more time at home is associated with more sedentary behaviour, and with more time spent at home with increasing age (Kerr *et al.*, 2012). A vicious circle is established that could thus lead to more sedentary behaviour and related health risks (Clark *et al.*, 2014; Ortlieb *et al.*, 2014). Our results of the influence of various characteristics on the association between greenness, location and PA indicate that the association between the time spent in non-green and MVPA is positive for males and negative for females. This means that more time spent in non-green areas is related to more MVPA for males, while to less MVPA for females. The positive association between the time spent in green areas and MVPA is strongest for highly educated people and for those living in a green neighbourhood, indicating that living in a green neighbourhood leads to more PA when time is spent in green areas, which coincides with the findings by McMorris *et al.* (2015). In contrast to previous studies (Berke *et al.*, 2007; Frank *et al.*, 2010; King *et al.*, 2011; Marshall *et al.*, 2014; Van Holle *et al.*, 2014; Marquet and Miralles-Guasch 2015), on the other hand, living in a non-green neighbourhood was not found to be associated with more PA and less sedentary behaviour. The positive association between the time spent at home and sedentary behaviour was found to be the strongest for retired participants, indicating that once retired the time spent at home is often linked with sedentary behaviour. It would be interesting to study the association between greenness in the home neighbourhood and PA (and more specifically PA in green areas) further in different age groups. Our study has several strengths compared with similar studies. First, this research is the first to study the association between green-

ness, location and PA with respect to late middle-aged adults in Europe. Second, most studies are only based on self-reported PA values (Berke *et al.*, 2007; Lovasi *et al.*, 2008; Kaczynski *et al.*, 2008; Shigematsu *et al.*, 2009; Frank *et al.*, 2010), while we used accelerometer-based PA, which offers more objective values. This made it possible to attribute PA levels to each GPS data point, which cannot be done when using only self-reported data, where for example only binary data (participant walked or did not walk today) is extracted (Clark *et al.*, 2014). Third, the combined use with GPS data offers detailed insights in where active behaviour is done (Duncan *et al.*, 2009; Troped *et al.*, 2010; Oreskovic *et al.*, 2012; Kerr *et al.*, 2012). In contrast to previous studies, where only the home neighbourhood is considered, we additionally gathered information on the specific context of where PA is carried out. Although our approach had also limitations, they open up interesting avenues for future work. First and foremost, we already described the difficulty to detect bicycle use (Hansen *et al.*, 2012) when deriving PA levels from accelerometer data. We considered both bike and car use as *vehicle*, therefore losing some active data when people are biking. In future work, mode-detection algorithms could be used to detect transport modes. However, for the specific research results reported here, the loss of information must be deemed limited as only 5.8% of the entire dataset was considered *vehicle*-related. Second, in this cross-sectional study it was not possible to extract causal relationships. One must therefore be careful when interpreting the results, because it is not given that the greenness of the area is the cause of a higher PA activity. Future studies should focus on longitudinal research to detect whether or not changes are causal, and occasional or persistent. In this way, the

Total number of points=3,019,491.

effect of introducing green areas (using natural experiments) on PA levels can be studied (Bauman and Bull, 2007). Third, the data were collected in March, possibly influencing space-time activity patterns of some participants because of the weather (e.g. low temperatures, snow). Future research should incorporate weather characteristics (e.g. temperature, rain, wind speed) to account for this. Fourth, future studies on this topic should try to incorporate socio-economic status (e.g. income, education) indicators, to analyse its possible correlation with *walkability* and greenness and potential influence on the association of greenness, location and PA. Finally, we considered agriculture as a green area. Despite the fact that moving through these areas is associated with positive health effects, this can possibly affect our results since there can also be functional trips. For example people living in a rural neighbourhood are likely to spend more time in green areas because they automatically pass through green areas when moving. This could be reduced in future research by filtering the trips per goal. Related to this final limitation, a more detailed distinction could be made between natural (e.g. forest, coastal dune, grassland) and built

green areas (e.g. park, sport terrain), in future work considering the possibility that they could be differently related to PA.

### Conclusions

The combined use of GPS and accelerometer data can help to detect where people are sedentary or physically active. Knowing where older people are mainly physically active should encourage policy makers to increase activity in this age cohort. Despite the fact that the observed population spends little time in green areas, higher levels of PA are reached in green areas. As this is the first research studying the association between greenness, location and PA, and considering the influence of several characteristics on this relationship, our results are useful in updating the current knowledge on PA in late middle-aged adults. However, more research is needed to better understand where and why late middle-aged adults are physically active or sedentary.

**Table 4. Descriptive statistics of the study sample (n=138) concerning greenness, location, and physical activity.**

Greenness	
Non-green	11.6, (8.4-14.4)
Green	0.4, (0.0-1.7)
Location	
Home	6.7, (0.0-12.0)
Neighbourhood	1.8, (0.1-10.3)
Further	3.4, (0.6-9.4)
Physical activity	
Sedentary	7.9, (5.2-10.4)
Vehicle	0.6, (0.1-1.3)
LPA	2.3, (1.3-3.6)
MVPA	0.5, (0.1-1.3)

LPA, light physical activity; MVPA, moderate-to-vigorous physical activity. Values are expressed as mean (confidence interval=5-95%).

**Table 5. Results of linear regression analysis among greenness, location and physical activity.**

Independent variable	Dependent variable	$\beta^{\circ}$
Hours in non-green area	Hours of sedentary behaviour	0.80***
	Hours of LPA	0.47***
	Hours of MVPA	0.10
Hours in green area	Hours of sedentary behaviour	-0.16*
	Hours of LPA	0.02
	Hours of MVPA	0.17*
Hours at home	Hours of sedentary behaviour	0.33***
	Hours of LPA	0.37***
	Hours of MVPA	0.03

LPA, light physical activity; MVPA, moderate-to-vigorous physical activity. \*P<0.05; \*\*\*P<0.001.  $^{\circ}$ Standardized regression coefficient.

**Table 6. Results of the stratified linear regression analysis.**

Independent variable	Dependent variable <sup>o</sup>	Gender		Working status		BMI			Diploma		Neighbourhood greenness	
		$\beta_{male}$	$\beta_{female}$	$\beta_{retired}$	$\beta_{working}$	$\beta_{normal}$	$\beta_{high}$	$\beta_{low}$	$\beta_{high}$	$\beta_{not}$	$\beta_{green}$
