The Influence of Urban Street Characteristics on Pedestrian Heat Comfort Levels in Philadelphia

Abstract

This article describes relationships between selected physical characteristics of urban streets and pedestrian-level heat. It also identifies conditions that are particularly vulnerable to the summer heat. Field measurements of ambient temperatures 1 m above the ground were collected over sidewalks, green spaces, and parking lots in high density commercial and residential areas. Panel autoregression (PAR) analysis was then used to assess significant contributors, and prediction equations were developed. These explained over 90% of the total observed variation. The prediction equations were then used with a geographic information system (GIS) to create a cartographic map of hot and cool areas for a particular study site. The results indicate that planting trees can reduce ground ambient temperatures. Moreover, a cartographic map is effective tool for identifying heat vulnerable areas. This study offers a more comprehensive spatial scale analysis and most explicit prediction map than other studies to date.

TABLE OF CONTENTS

CONTEXT

PREFACE

The study presented in this paper was conducted as part of a research project examining the causes and effects of "urban heat islands" in Philadelphia. Conducted by faculty at the University of Pennsylvania and the Philadelphia Department of Public Health, the goal of that project was to explore causal relationships between observed levels of heat-induced morbidity and characteristics of the city's physical and social environment associated with the urban heat island effect.

This paper is encompasses one part of that project. It examines how physical characteristics of urban settings influence microclimate. To characterize this influence at a fine scale, differences among microclimates are expressed in terms of a physiological index that also represents human comfort. This assessment of human comfort is presented as a manuscript entitled "The Influence of Urban Street Characteristics on Pedestrian Heat Comfort Levels in Philadelphia" that will be submitted to the *Journal of American Planning Association* (*JAPA*). The format of this manuscript follows the specific guideline to fulfill *JAPA* requirements.

Due to the space limitations imposed on this submission, it does not include detailed background information, descriptions, or explanations. Those are presented separately in a context section and several appendices.

Title:

The Influence of Urban Street Characteristics on Pedestrian Heat Comfort Levels in Philadelphia

Abstract:

This article describes relationships between selected physical characteristics of urban streets and pedestrian-level heat. It also identifies conditions that are particularly vulnerable to the summer heat. Field measurements of ambient temperatures 1 m above the ground were collected over sidewalks, green spaces, and parking lots in high density commercial and residential areas. Panel autoregression (PAR) analysis was then used to assess significant contributors, and prediction equations were developed. These explained over 90% of the total observed variation. The prediction equations were then used with a geographic information system (GIS) to create a cartographic map of hot and cool areas for a particular study site. The results indicate that planting trees can reduce ground ambient temperatures. Moreover, a cartographic map is effective tool for identifying heat vulnerable areas. This study offers a more comprehensive spatial scale analysis and most explicit prediction map than other studies to date.

Introduction

- Today's cities are drawing people in increasing numbers. Although urban areas occupy only about 4% of the Earth's land mass, they contain nearly half the world's population. Moreover, it is projected that more than 60% of that population will be living in urban areas by 2030 (United Nations (UN), 2004; World Resource Institute, 2000). It is also projected that the Earth's temperature will increase by 1.4 to 5.8 °C over the next century (Intergovernmental Panel on Climate Change (IPCC), 2001a). Since the potential risk of damage to a wide range of ecological and human systems is known to be associated with these projected climate changes, interest in the influence of weather on human health has grown considerably in recent years. The major impacts of climate change on human health are likely to occur via changes in the magnitude and frequency of extreme events that trigger natural disasters (IPCC, 2001b). As a result, the impact of a variable climate on human health and well-being has been the subject of numerous studies, with the majority of the work being performed by medical specialists and a small group of climatologists (Kalkstein, 1991).

- Global warming is predicted to increase the frequency, duration, and magnitude of heat waves (IPCC, 2001a, 2001b). In the recent years, heat-related mortality and morbidity in the United States has already indicated a high vulnerability of urban populations to extreme heat (McGeehin & Mirabelli, 2001; National Weather Service (NWS), 2004). Indeed, heat waves are now the largest cause of human fatalities among all meteorological hazards (such as floods, hurricanes, and tornadoes). As temperature of urban air increases with city growth, the urban heat island (UHI) effect is believed to be a key factor that aggravates more heat wave impacts on urban dwellers (IPCC, 2001a; Wilhelmi, Purvis, & Harriss, 2004).

- In the US, the impact of UHI on human health has been a concern since the 1750s (Meyer, 1991), and excessive heat-related deaths have been correlated with urban density (Buechley, Van Bruggen, & Truppi, 1972). Thus, global urbanization, the UHI effect, and a potential increase of heat waves raise a series of interrelated questions regarding health risks to sensitive urban populations (Landsberg, 1970a; McMichael, 2000). While episodic events causing heat-related fatalities always draw the greatest public notice, heat-related illnesses, are of equal concern equally endangering athletes, children, the elderly, and ill individuals (Barrow & Clark, 1998; Wexler, 2002). The best prevention for heat-related corollaries is to avoid the hot environment (Barrow & Clark, 1998; Jones et al., 1982; Kilbourne, Choi, & Jones, 1982; Wexler, 2002). Thus, it is necessary to identify such environment for those vulnerable populations and develop mitigation strategies to alleviate those casualties.

- Recent applications of geospatial technologies involinh other natural hazards suggests that efforts to mitigate and/or manage heat wave impacts can be improved through spatial and temporal modeling of UHI dynamics (Wilhelmi et al., 2004). The aim of this study is to identify causal relationships between observed levels of pedestrian comfort and characteristics of a city's physical environment. Its goal is to identify areas within a city that are vulnerable to summer heat associated with UHI. This was done by [1] collecting field data on ground-level air temperature at selected sites, [2] relating field measurements to the nearby weather station record, [3] assessing physical comfort using a physiological heat index (HI), [4] determining the influence of selected urban characteristics on UHI by using regression analysis, and [5] using these results to construct a GIS-based cartographic model that identifies relatively hotter and cooler areas at the scale of city blocks. The result of this study will enable planners to better identify critical areas for tree planting in the City of Philadelphia.

Urban Heat Islands (UHI)

•   An UHI is defined as a local urban area of high air temperature in relation to its surroundings. This phenomenon is unique to cities, and is now well documented (Arnfield, 2003; Oke, 1974, 1979, 1987).[1] Its magnitude is typically proportional to the size and/or density of the urban area involved (Oke, 1973). However, it is also affected by a variety of human activities including fuel combustion and metabolism of living beings (Fan & Sailor, 2005). The reduction of ventilation and air exchange inside urban areas also affects evaporation processes and heat exchange (Britter & Hanna, 2003; Oke, 1973).

•   The most dominant factor affecting UHI is the change in the solar radiation balance (Oke, 1987). This is caused by several components of the radiation budget. Albedo, measurement of a surface reflectivity, decreases as natural landscapes succumb to urban construction. Indeed, urban buildings are very good heat conductors; they store considerably more energy than bare soil, grass or tree leaves. As a consequence, they act as reservoirs of the radiation received heat during the day and slowly re-emit its heat during the late afternoon and night.

•   The displacement of vegetation and soils further enhances heat retention by limiting the effective natural cooling effects of evapotranspiration. This is the process by which intercepted radiation energy is utilized by plant, soils, and water bodies to convert water to water vapor. In urbanized areas, precipitation rapidly drains from impervious surfaces of roofs and streets so that when the rain ceases, only a thin film remains to be evaporated. In contrast, soil and areas covered by vegetation have a large storage capacity for water, which therefore evaporates more gradually and thus consumes substantial amounts of heat. The excess heat energy absorbed by urban constructions is large enough to raise the average temperature of the urban area by several degrees relative to the surrounding nonurban areas (Oke, 1987) .

- The form and size of UHI varies over time and space. Though it occurs throughout both day and night, the night-time effect is much greater. At night, urban air temperatures are in fact often 5-11 ºC (9-19.8 ºF) greater than nearby rural areas (Chandler, 1976). This difference is greatest under a clear sky and calm wind conditions just after sunset. The UHI effect is generally attributed to the formation of an urban boundary layer that 'domes' up over the city, induced by the local slowing of the air flow (Britter & Hanna, 2003; Oke, 1987). It involves three atmospheric layers: an urban surface layer (USL) at ground level, an urban canopy layer (UCL), roughly from ground to roof level, and an urban boundary layer (UBL) from roof up and beyond. Each layer displays different characteristics depending on spatial and temporal variations controlled by various assemblages of energy exchange processes (Arnfield, 2003).

Implications of High Temperature

- Heat-related fatalities associated with extreme heat wave events in the US indicate a continuing vulnerability of urban populations. Although heat-related mortality is one of the most underestimated causes of death in the US (Kalkstein, 1991), the National Weather Service (NWS) has estimated that a total of 2,590 people in the US lost their lives due to extreme heat between 1986 and 2003 (NWS, 2004). Exposure to extreme heat waves, which are defined as 3 or more consecutive days of temperatures over 32.2 ºC (90 ºF), can have a number of negative health effects due to vital fluid and mineral loss in the body. Indeed, the effect of heat waves can be been seen in increased mortality as early as the day after such high temperature occurs (CDC, 1995). During the severe event, when body temperature rises over 40.6 ºC (105 ºF), heat-related illness and death are likely to increase (NWS, 2004). This was evident in early June 1994, when several US cities experienced a severe heat wave that took 1,021 lives (Wilhelmi et al., 2004).[2]

- A high number of deaths are primarily associated with high daytime and nighttime temperatures that last for 48 hours (Kalkstein, 1995). The geographic locations of the cities also play an important role. Recent estimates indicate that, in very large cities like Shanghai and New York, several thousand additional heat-related deaths can be expected annually by the middle of the 21st century. The impact will be greatest in mid-latitude cities, where heat events are less frequent but extreme when they occur (Kalkstein, 1995).[3]

- The factors that most affect rates of heat-related mortality are the duration and timing of a heat wave and the geographical location of the vulnerable population (Clarke & Bach, 1971; Nieuwolt, 1966). One reason for this phenomenon is that people living in warmer regions are likely to acclimate to high temperature more easily than those who live in cooler regions. Another is the difference of building design. In high and mid-latitude regions, buildings are designed to protect against cold more so than heat. According to the 25 years of analyzed mortality data, most of excess summer mortality in the US has occurred in northern cities (Kalkstein, 1995). There was little or no mortality response to high apparent temperatures in southern cities, regardless of the severity of the extreme heat event (Kalkstein, 1995). Susceptibility also appears to be greater early in the summer season, primarily because the human body has not yet acclimated to the inclement climate (Wilhelmi et al., 2004).

Heat Warning Systems

- With future global climate change, the impact of extreme heat on human health is expected to be exacerbated, and heat-related illnesses and deaths associated with it are expected to be a significant health concern in human settlements (IPCC, 2001a, 2001b). Accordingly,

there has been an increasing interest in the development of heat warning systems that could enable authorities to issue public health advisories when hazardous heat waves are imminent.

- The benefits of alerting heat-vulnerable populations in urbanized areas are already apparent from development and deployment of existing heat warning systems. In large cities around the world and several cities in the US including Philadelphia (Kalkstein, 2000). Philadelphia's system identifies potentially oppressive air masses that may elevate mortality in the summer (Kalkstein, Jamason, Greene, Libby, & Robinson, 1996). It employs a synoptic climatological approach by grouping days with homogeneous meteorological conditions (such as temperature, humidity, cloud coverage, wind speed, and other variables) and comparing past heat wave episodes that caused high mortality rates. A similar system was also developed by Guest *et al.* (1999). Moreover, Chan *et al.* (2001) developed a mechanistic framework based on environmental conditions and behavioral responses linked to a physiological model in order to achieve more accurate mortality rates.

- Even though these systems are currently operating and have the ability to reduce risks associated with heat, it remains to generate information that will lead to better understanding of heat impacts and to produce spatially explicit mitigation strategies (Chan et al., 2001; Patz et al., 2000; Wilhelmi et al., 2004). Indeed, existing heat warning systems clearly point to the need for a better understanding of the finer-scale geospatial conditions that affect heat-vulnerable populations.

Various Observation Techniques

- Previous studies of UHI have used three methods to observe air temperature in urban settings: placing instruments at selected locations (Clarke & Bach, 1971; Nieuwolt, 1966),

mounting instruments on vehicles that traverse the study site (Preston-Whyte, 1970; Sundborg, 1950), and the use of remote sensing (Adams, 1999; Aniello, Morgan, Busbey, & Newland, 1995; Hafner & Kidder, 1999; Iino & Hoyano, 1996; Voogt & Oke, 2003; Wilhelmi et al., 2004). Although each technique captures the trend, they all have certain disadvantages.

• The disadvantage of placing instruments at set location is that the parameters obtained from observation instruments are relatively unreliable if measurement errors are greater than ± 0.5 ºC (Sundborg, 1950). These samples are also spatially limited. Measurements made from instruments on moving vehicles, the second method, can provide insight into average conditions but do not provide simultaneous data collection from separate points (Sundborg, 1950) though it appears that beginning and end traverse observations seldom differ significantly (Preston-Whyte, 1970). Advanced remote sensing technology can quantify UHI, but roofs, treetops, roads and open horizontal areas are oversampled, while vertical surfaces (such as building walls) and areas below tree crowns tend to be ignored (Arnfield, 2003; Stone & Rodgers, 2001; Wilhelmi et al., 2004). Furthermore, most remote sensing information is at a coarse spatial resolution.

• Because the goal of this study is to evaluate the influence of physical features on local ambient temperatures, measurements were made using a set of portable air-temperature and moisture probes. The accuracy of utilized instruments was determined in a preliminary testing to overcome the limitation of instrumental error (data not shown).

Urban Characteristics

• Stresses are imposed on the body by meteorological conditions including temperature, moisture content of the air, wind speed, and radiant heat (Clarke & Bach, 1971; Wexler, 2002; Wilhelmi et al., 2004). These conditions are also affected by the materials and morphology of

urban environments, where heat storage is greater than in undeveloped or agricultural sites (Grimmond & Oke, 1999). Indeed, Landsberg (1970b) found that the warmest air occurred over the pavement in front of a high-rise apartment, in a parking lot in the center of the city, the parking lot in a garden apartment development, and a protected small square surrounded by a store and small shops and/or parking lots. Conversely, a tree-shaded playground in the city showed insignificant temperature rise compared to the surrounding rural area.

- These differences can be explained by the differences in the shape and materials of the urban surface. The climate of city streets is typically examined by considering the properties of symmetrical 'canyons' characterized by its width and length, building height, and orientation (Grimmond, Cleugh, & Oke, 1991; Grimmond & Oke, 1999; Kondo & Yamazawa, 1986; Oke, Kalanda, & Steyn, 1980/1981; Yersel & Goble, 1986). Façade materials also contribute to the phenomenon by increasing solar radiation absorption during the daytime (Oke, 1987). Consequently, previous studies have categorized urban microclimatic environments by vegetation (trees, grass, etc.), impervious surface (concrete, asphalt, etc.) and the three dimensional surface area of the buildings, subdivided into the area of roofs and walls (Grimmond & Oke, 1999; Grimmond & Souch, 1994).

Methodology

- The methodology employed in this study encompassed five major tasks of study area, physiological index and human comfort, field HI measurements, weather station HI records, urban characteristics, and prediction map.

- *Study Area*: In order to capture a variety of urban site characteristics, two adjacent zip code areas were chosen in Philadelphia, PA: 19103 (West Center City) and 19104 (University City) (Figure 1). The former is a business districts, and the latter is a mixed residential-institutional neighborhood. In general, University City has more pervious surfaces and planted trees, while West Center City contains more high-rise buildings (Figure 2).

- *Physiological Index and Human Comfort*: The heat index (HI) is one of the most familiar physiological indices used to quantify the impact of heat on human beings (Rothfusz, 1990). This has been utilized by NWS and the popular media to reveal how hot the human body feels when temperature and humidity are combined. This relation is

$$HI = -42.379 + 2.049015323T + 10.14333127R - 0.22475541TR - 6.83783*10^{-3}T^2$$

$$- 5.481717*10^{-2}R^2 + 1.22874*10^{-3}T^2R + 8.5282*10^{-4} - 1.99*10^{-6}T^2R$$

where T = ambient temperature (ºF) and R = relative humidity (%).

This equation is based on the parameters from Steadman (1979) that uses more conventional independent variables. The equation is only valid for temperatures 80 ºF or higher, and relative humidities of 40% or greater. Those conditions were always met in this study.

- *Field HI Measurements*: Field measurements were carried out between mid-June and early September of 2005. HOBO H8 Pro RH/Temp loggers (H08-032-08, Onset Computer Corp.) were used to record temperature (ºF) and relative humidity (%). After preliminary testing[4], instruments were mounted on a wooden box covered with white tape to reduce direct solar

energy absorption. Each instrument was placed horizontally 1m above the ground surface on a wooden tripod. To be freely exposed to the environment, these instruments were placed at least 2 m away from nearby buildings, obstructions, and artificially-generated heat sources such as air-conditioning exhaust. Instruments were programmed to record at 10-minute intervals. These measurements were then averaged on an hourly basis. Since the storage heat flux is typically greatest at noon, and the most intense UHI effects occur several hours after sunset, field HI measurements were conducted at 13:00 (daytime) and 22:00 (nighttime). These measurements were conducted for two consecutive days at the each location to eliminate measurement errors. The observed temperature and relative humidity were then used to compute HI as described above and the results in Fahrenheit were converted into Celsius.

- *Weather Station HI Records*: HI announcements by the popular media are based on records of weather stations that are located in open spaces and on roof-tops, and thus do not capture the pedestrian level conditions within the urban settings. In order to predict the spatial distribution of pedestrian level HI, above-canopy HI recorded at a nearby roof-top weather station was incorporated. The weather station is one of a network of more than dozen stations in the City of Philadelphia. It is equipped with a standard AirWatch system that is operated and maintained by the Automated Weather Source's AirWatch system (http://achieve.weatherbug.com/) and the Department of Earth and Environmental Science of the University of Pennsylvania. The station is situated 2.75 m (9 feet) above the top of a four story building near the center of the study area. The station measured temperature and relative humidity every 5 minutes. These measures were averaged on an hourly basis and then used to calculate the average hourly above-canopy HI that corresponded to the ground level measurements.

- *Urban Characteristics*: Following previous studies, the amount of shade (tree coverage), street width (including sidewalks), distance to nearest building, and building height (number of stories) were used to determine the urban street characteristics. The percent of shade above each sample point was measured by an AccuPAR (model LP-80, Decagon Devices, Inc.). The AccuPAR measures intercepted photosynthetically-active radiation under any type of canopy. These measurements indicate the amount of shade within a horizontal circle of 2 m in diameter directly over the field measuring instrument. Measurements were also made in full sunlight and used to calculate the shade covering upon the measuring instrument. This includes shade from tree coverage and buildings. The numbers of building stories adjacent to the sampling areas were counted visually during the field measurement. Two other indices, street width (feet) and distance to building (feet) were determined by the use of GIS data obtained from Pennsylvania Spatial Data Access (PASDA: http://www.pasda.psu.edu/).

- *Prediction Map*: Data on the residential building stories was acquired from the Cartographic Modeling Laboratory (CML: http://cml.upenn.edu/) at University of Pennsylvania. The information on high rise building stories data was provided from the Mayor's office of Philadelphia City. Utilizing the linear regression equation derived from the OLS model, cartographic models were created by way of map algebra (Tomlin, 1990) using the ArcGIS geographic information system (ESRI). Note that shade generated by buildings and/or other obstructions was not included in this map. Building roofs were also excluded thus indicated as white color. These maps were constructed at a raster resolution of 10×10 feet.

Analysis

- *Verifying Underlying Assumptions for Regression Analysis*: Four basic underlying assumptions were checked under the ordinary least squares (OLS) statistical model in JMP-IN (SAS Institute, Inc.). These four basic conditions are: [1] relationship between independent and dependent variables by Pearson product-moment correlation matrix, [2] higher order of colinearity by the variance influence factor (VIF), [3] normality of residuals by normal quantile plot, and [4] linearity assumption by regressing residuals on explanatory variables.

- *Stepwise Regression Analysis*: Variables that are ineffective under OLS model is unlikely to be effective under autoregressive model. This was also carried out in JMP-IN and omission of variables that indicated over the significant level of 0.25 was done under OLS statistical model.

- *Panel Autoregression (PAR) Analysis*: Field HI measurements were carried out for two consecutive days at the same location and under different urban environments. Accordingly, it is likely that spatial and temporal autocorrelation could occur. Spatial autocorrelation was present, but its influence was not evident and results were similar relative to the OLS statistical model. Thus, temporal autocorrelation was only considered in the analysis. To take into account for this, PAR model was created on a basis of autoregressive model (Bailey & Gatrell, 1995). The model is $y = X\beta + u$, $u = \rho Wu + \varepsilon$, $\varepsilon \sim N(0, \sigma^2 I)$ where W is a temporal weight matrix that directs second day field HI measurement to depend on the first day measurement, u is the prediction errors, ρ is an autoregressive parameter, and I is the Moran's I. The analysis was conducted in MATLAB (The Math Works, Inc.).

- *Goodness-of-fit Measurement*: Relative to R^2 in OLS statistical model, four alternative indices (Pseudo R^2, squared correlation, log likelihood value, and Akaike's Information Criterion (AIC)) were used (Anselin, 1988). These calculations were also conducted in MATLAB.

Results

- All independent variables (weather station HI records = SHI, amount of shade = Sh, street width = SW, distance to building = DB, and building stories = BS) had linear relations to the dependent variable (field HI measurement = FHI). The strength of the correlations changed depending on the surface materials and time (Table 1B). Indeed, for the daytime measurements over the impervious surfaces, Sh, SW, and BS were negatively correlated while SHI and DB had positive correlations. Over pervious surfaces during the daytime, only SHI had a positive correlation. Similarly, for the nighttime measurements over the impervious surface, all explanatory variables entailed positive correlation. Nevertheless, over pervious surfaces during the nighttime, SHI and BS exhibited positive correlation while SW and DB revealed negative correlation. Here, strong correlation was only apparent between FHI and SHI, over 0.88, and others were relatively weakly correlated.

- Although models that include all explanatory variables can be effective in prediction, stepwise regression analyses under OLS model were conducted to reveal the most important variables (data not shown). From this, SHI, Sh, and BS were significant for both surface materials at daytime. Nevertheless, all variables were correlated with both types of surface materials at nighttime. As variables that are ineffective under OLS model are unlikely to be effective under autoregressive model, only the variables derived from stepwise regression analyses were incorporated into the autoregression analysis. Although there were skewed distributions of some variables, there were no reasons to reject the underlying assumption for regression analysis (data not shown).

- Since same field HI measurements were conducted for two consecutive days at the same location, temporal autocorrelation was determined to be present. The violation of independence

result the estimates obtained from the OLS estimator to be biased and lead to indicate some

coefficients to be significant, when in fact they are not. Accordingly, PAR analysis was utilized

to capture the true occurrence of the event (Table 2A). Similar to the correlation of variables,

parameter estimates revealed that the effect of independent variables changed over different

surface materials and time, except for SHI that was strongly significant in all cases. Certainly, at

daytime regardless of surface material, both Sh and BS indicated strong significant effect. On the

other hand, at nighttime over the impervious surface, SW and DB entailed significant level and

BS to be weakly significant. Nonetheless, over the pervious surface, both DB and BS exhibited

strong coefficient, but SW revealed no significant effect. The final models explained over 90%

of the total variation (Table 2B). In both timeframes, impervious surfaces indicated slightly poor

goodness-of-fit measurements.[5]

- The models prediction precision was evaluated using OLS model (Table 3A) by way of

calculating 95% prediction intervals (PI) on conditional means (Table 3B). Similar to the PAR

models' goodness-of-fit measurements, adjusted R^2 for impervious surface indicated slightly

lower value in both time periods. Additionally, it indicated that over 90% of the total variations

were explained. Based on these significant models, 95% PI did not exceed $\pm$ 2.62 ºC ($\pm$ 9.45 ºF)

and $\pm$ 2.08 ºC ($\pm$ 7.51 ºF) at daytime and nighttime, respectively (Table 3B). The high

performance of the model can also be determined by the root mean square error (RMSE) that

they were less than 1.5. Again, pervious surface materials had lower RMSE than impervious

surface where they were even less than 1.0.

- These results indicate that the prediction models are sufficient to identify the pedestrian

level HI once SHI is recorded. Thus, prediction models in Table 3A were applied in ArcGIS for

creating an explicit cartographic prediction map for the study site (Figure 3). This was simulated

under the SHI of 32 and 28 ℃ (89.6 and 82.4 ℉) for daytime and nighttime, respectively (Figure

3 A and C). The cool and hot areas within this study site were the lower and upper 10% bounds

of the predictions (Figure 3 B and D).[6] Comparing these maps to those of tree coverage (Figure

2D) indicates that the cool and hot areas corresponds to the amount of trees that are covering the

area. Obviously, tree-shaded areas are much cooler than those without trees.

- During the daytime, non-shaded impervious surfaces with low BS are as much as 3.91 ℃

(7.04 ℉) higher HI than SHI. Conversely, shaded pervious surface that are related with high BS

at same time were as much as 0.75 ℃ (1.35 ℉) lower HI than SHI. Grouping the nighttime

under- and overestimated areas indicated that impervious surface that are associated with wide

streets, adjacent to buildings and few building stories can have a HI as 3.74 ℃ (6.73 ℉) higher

HI than SHI. On the contrary, pervious surfaces that are situated with narrow streets, far from

nearby building, and low building stories indicated as much as 0.63 ℃ (1.13 ℉) lower HI than

SHI. Cool areas are essentially large tree planted green spaces and hot areas are in opposition

large open parking lots. The maximum HI difference of cool and hot areas are approximately

4.66 ℃ (8.39 ℉) and 4.37 ℃ (7.86 ℉) at daytime and nighttime, respectively.

Discussion

- This study demonstrated that the physical characteristics of urban streets and parking lots can have a large influence on the local HI. Moreover, these influences can cause the HI to vary over 4 ºC between nearby areas within a city. The techniques used in this study are useful in identifying locally hot areas within a city and can be used to focus education and assistance during heat waves. Indeed, the prediction derived here explicitly indicates where mitigation strategies should be implemented.

- Pedestrian-level HI, and thus level of discomfort and stress is dependent upon the thermal radiation and thermal properties of the site. This study indicates that hotter areas during the day and night are typically non-shaded impervious areas exposed to the direct sun. Cooler areas are typically on pervious ground and are well shaded by trees or building. This study also suggests that the thermal bulk properties (including heat capacity and thermal conductivity) and the radiative properties (albedo and emissivity) of buildings and streets are the main factors responsible for differences in heat in urban environments.

- The study also demonstrates that Sh, SW and DB can influence nighttime HI. Since non-shaded areas absorb more heat for longer periods of time, especially in the case of impervious surfaces, the heat emitted by such areas is significant after sunset. Certainly, streets and building façades on treeless blocks are likely to absorb more heat than shaded ones. Therefore, heat emitted from those surfaces increases pedestrian discomfort.

- These results also suggest that more trees should be planted at areas of open parking lots and along wide streets with heavy traffic (both pedestrian and vehicles). This is especially true in areas that do not receive artificial shade from surrounding tall structures. In the processes of tree

planting, appropriate orientation should also be considered. It is ideal to cover roofs and south-, east-, and west-facing walls.

- Alleviating the impact of heat during the summer by way of planting trees in a community is often suggested as one of UHI mitigation strategies (Rosenfeld et al., 1995). Large open parks in particular are known to reduce ambient air temperature within the urban setting at microclimate (Jauregui, 1990/91). Along with heat reduction, the presence of urban trees and/or forests is known to provide numerous additional benefits. Among these are a more pleasant, healthy, and comfortable environments to live, work and play in, savings in the costs of providing a wide range of urban services, substantial improvements in individual and community well-being, increase in real estate values, reduced energy use during the summer, and improved air quality (Akbari, Pomerantz, & Taha, 2001; Dwyer, McPherson, Schroeder, & Rowntree, 1992; Rosenfeld, Akbari, Romm, & Pomerantz, 1998; Wachter, 2004; Wagrowski & Hites, 1997).

- Taking these benefits into account, efforts to cool communities via tree plantings (Semrau, 1992) and proactive local activities - such as those of the Philadelphia Horticulture Society and University City Green (both in Philadelphia area) - are encouraged. However, many tree species are reported to emit highly photochemically reactive hydrocarbons that may potentially adversely affect air quality (Benjamin, Sudol, Bloch, & Winter, 1996). Hence, appropriate species selection and orientation of trees are highly recommended.

- If a program of tree plantings were to be put into place, urban pedestrian heat discomfort would be alleviated during the heat events and throughout the summer. This might then reduce the incidence and severity of heat-related illnesses among vulnerable populations. Considering these benefits, city planners and authorities should advocate plantings in the hotter areas.

Footnotes

- 1. The identification of UHI was first documented by Luke Howard's pioneering examination of London's climate (1818). It is typically presented as a temperature difference between the air within the urban settlement and that measured in a rural area immediately outside the settlement (ΔT_{u-r}). This ΔT_{u-r} is used to detect the UHI intensity where maximum degree is depicted at the urban core (Oke, 1987).

- 2. Temperature was initially thought to be the single predictive meteorological variable for increasing mortality during the heat wave (Clarke & Bach, 1971; Wexler, 2002). It is now known that various meteorological variables contribute to the cause. These additional variables include relative humidity, wind speed, and fluxes in both short- and long-wave radiation (Buechley et al., 1972). Heat-related incidents are a greater problem in cities than in suburban or rural areas due to the combined effect of high temperature and high humidity. Indeed, it is already evident from the July 1966 that hot spell impacted several metropolitan regions of the US where higher mortality ratios were found in the center of cities than in surrounding suburban/rural areas where positive correlation between higher temperature and population density are evident during the heat wave (Wilhelmi et al., 2004).

- 3. These are areas which exhibit the greatest number of heat-related deaths, and include large cities in eastern and Midwestern North America, western Europe, northern India, and China (CDC, 1984, 1994). In the US, increased mortality due to heat waves has been linked to high and mid-latitude regions such as New York City and Philadelphia (Wilhelmi et al., 2004). During the episode, 118 deaths (11.56% of total death toll) were determined to be associated with the heat wave in Philadelphia, PA, where the condition was with high temperatures of 33.9-38.3 ℃ (93-101 ℉) and high humidity of 36-58% (CDC, 1994).

- 4. These instruments were first tested in various conditions such as in a refrigerator and an incubator. These tests showed that the standard deviations between instruments were less than 0.3 ℃ and less than 1.9 % for temperature and relative humidity, respectively (data not shown). They were then placed over two different surface materials, impervious and pervious. Impervious surfaces include asphalt, concrete, and brick. Pervious surface were limited to grass growing areas and excluded bare soil. The reason impervious surfaces include three materials is that during the preliminary testing temperature above concrete and brick were not significantly different (data not shown). Differences between asphalt and concrete/brick can be explained by the variables of street width and distance to buildings.

- 5. The reason that impervious surfaces have a lower goodness-of-fit measurements and larger errors can be understood from previous studies. Indeed, surface roughness elements cause complex flows around them thus three-dimensional effects are strongly dependent on the characteristics of the elements including their shape, plan density, flexibility, etc. (Oke, 1987). Voogt and Oke (2003) also support this notion that overall urban surface structure have impacts of structural features such as: roof geometry, variable building height and vegetation geometry. Therefore, impervious surfaces are regarded to have rougher property than pervious surfaces.

- 6. In the nighttime prediction map, inaccuracy due to the over- and underestimation became evident. Indeed, from the data sampled analysis (Table 1), the range of HI prediction was determined to be 27.37-31.74 ℃ (81.27-89.13 ℉). Therefore, areas that are beyond this range are extrapolated regions. The maximum SW and DB within the study site were 440 and 848, respectively. As a result, impervious surfaces that are related to wider SW beyond the collected range can be overestimated. Likewise, pervious surface that are associated with DB beyond the collected range can be underestimated.

Background Information

<u>Necessity of the Warning System</u>

In recent years, heat-related mortality and morbidity records in the United States have indicated a high vulnerability of urban populations to extreme heat. This is, in fact, the major cause of fatalities among natural disasters (NWS, 2004). Appendix 1-1 summarizes the fatalities and injuries associated with a variety of hazards that occurred in the United States between 1995 and 2003. As climate change is expected to raise humidity and nighttime minimum temperature (more than daytime highs), heat-related illnesses and deaths associated with heat events are anticipated to be a significant health concern in human settlements (IPCC, 2001a; 2001b). Accordingly, there has been a growing impetus to develop warning systems that would allow authorities to issue advisories to the public when hazardous heat waves are imminent.

Such systems are already evident in Rome, Shangahi, Toronto, and several American cities including Philadelphia (Kalkstein, 2000). The Philadelphia Hot Weather-Health Watch/Warning System (PWWS) identifies potential-oppressive air masses that may elevate heat mortality in the summer (Kalkstein *et al.*, 1996). It employs a synoptic climatological approach that operates by grouping days with homogeneous meteorological conditions (such as temperature, humidity, cloud coverage, wind speed, and other variables) and comparing these to the past heat waves that caused high mortality rates. A similar system was also developed in Australia, where correlations between temporal synoptic indices and past heat-related mortality data were utilized to identify dangerous air masses (Guest *et al.*, 1999). Chan *et al.* (2001) also developed a mechanistic framework based on environmental conditions and behavioral responses linked to a physiological model in order to achieve more accurate mortality predictions.

Although these systems are capable of predicting upcoming heat events and thus reducing mortality rates, Wihelmi *et al.* (2004) argue that there is inadequate understanding of the geospatial nature of vulnerable populations and their surroundings, which limits the ability to design and develop effective strategies for reducing human health threats. Likewise, Chan *et al.* (2001) state that finer distinctions among physiological conditions are warranted when more data become available, including varying degrees of compromised health and varying levels of heat acclimatization. Although these warning systems are currently in operation, it has been suggested that further interdisciplinary research is needed: to develop and integrate improved weather forecasting capabilities for extreme heat events, to generate more sophisticated vulnerability assessments, and to produce innovations in warning and response systems (Patz *et al.*, 2000). Considering these implications, the generation of information that will lead to better understanding of these impacts and to produce more effective mitigation strategies are crucial.

In order to meet these needs, finer scales of temporal, geographic, and demographic resolution are needed. Furthermore, such studies must incorporate physiological factors, including core body temperature and adverse health impacts. Since heat-related illnesses are mostly treatable and preventable (CDC, 1995; 1994; Barrow and Clark, 1998), an bility to anticipate conditions that warrant prompt treatment would likely reduce the mortality rate associated with extreme heat. Accordingly, it is anticipated that modeling relationships among physical characteristics of the urban environment, social characteristics of that environment, and observed levels of fatalities associated with the urban heat will produce the foundation for an explicit system of UHI analysis and prediction.

Taking into to account the necessity of further development and deployment of heat reduction strategies aimed at heat vulnerable population, a collaborative research project was established involving various peers across the Penn campus and from Philadelphia Department of Public Health. The initiative was designed to examine the causes and effects of UHI in Philadelphia where causal relationships between observed levels of heat-induced morbidity and characteristics of this city's physical and social environment that are associated with UHI effects can be established. This research project was designed to synthesize five major principals: [1] compiling data on urban heat [2] modeling urban heat [3] assessing data on heat-related morality, [4] relating morbidity to urban environment, and [5] recommending heat reduction strategies.

The main objective of this study is to compile a collection of data, create a spatially-explicit model of urban heat, and to develop a set of heat mitigation strategies. These are the first, second, and part of fifth research principal. Therefore, further studies (third, fourth, and additional fifth principals) were not discussed here. However, prospective principals could be conducted by assessing of data on heat-related fatalities and them to the urban environment.

Data on heat-related fatalities could be done by identifying and evaluating information from available sources of current data on heat-related records in Philadelphia. As source or combination of sources would yield reliability, comprehensive and geographically-detailed information should be applied. Four primary sources includes 911 calls (available at the census tract level and containing demographic information such as age and gender of the ill patients), emergency room records indicating heat-related illness as the chief complaint (providing demographic information such as age and gender at the zip code level from the Temple University Hospital, the Presbyterian Medical Center, the Hospital of the University of

Pennsylvania, the Methodist Hospital, and the Episcopal Hospital), hospital discharge and admission billing data (containing detailed information on diagnosis at the zip code level), and Philadelphia Health Center data (available at level of individual street addresses). Additional sources of morbidity data may be sought as well, and barriers to obtaining address-level 911, emergency room, and hospital discharge data should also be assessed.

For relating morbidity data to the urban environment, exploring at finest scale achievable should be considered. Then, utilization of spatial analysis techniques is recommended for assessment. Since previous studies have suggested social factors and physical conditions can exacerbate the cause of heat-related fatalities, this process should aim to reveal the correlation of those factors to actual records. The intent could be to look for a relationship between heat-related morbidity (as dependent variable) and selected characteristics of the both the social and physical characteristics (as independent variables). The selection of social and/or physical characteristics should reflect those previous studies (such as from Appendix 1-2 to 1-6). Spatial autoregression and spatial lag models are suggested to be used for assessment that will take into account a spatial autocorrelation. Ultimately, the results should be able to generate a map depicting the relative risk for heat morbidity throughout the City of Philadelphia.

After these were conducted, examination on existing UHI mitigation strategies and determination on remediation measures in reducing heat-related mortality (for example, addressed by the current heat/health warning system of the NOAA/National Weather Service and the Philadelphia Department of Public Health.) should be considered. If those were not feasibly implemented by the City of Philadelphia, an essential task should be to make location-specific recommendations on their use in appropriate urban settings. It should advocate policies that would encourage community intervention in the built environment.

<u>Heat- illnesses and Vulnerable Populations</u>

Common heat-related illnesses include (in order to severity) heat edema, heat cramp, heat syncope, heat exhaustion, and heat stroke (Barrow and Clark, 1998). These illnesses are likely to be deadly if not adequately treated or prevented. All are believed to be triggered by pre-existing illness, certain medical conditions (Wexler, 2002), and environmental conditions (Wexler, 2002; Barrow and Clark, 1998). A vulnerable population is generally defined as a group of individuals based on epidemiological and statistical analyses (Chan *et al.*, 2001; Wilhelmi *et al.*, 2004).

According to these criteria, the main causal factors are characteristics of the environment, social and behavioral attributes, and biological and medical conditions (Kilbourne *et al.*, 1982). In addition, females, children (particularly infants), elderly individuals (over the age of 65), persons under certain drugs treatments (e.g., neuroleptics, anticholinergics, and tranquilizers), and individuals with excessive alcohol consumption have been determined to be at a higher risk for heat-related illness and mortality (CDC, 1994; 1995). Appendices 1-2 to 1-4 summarize the those potential risk factors (Kilbourne *et al.*, 1982; CDC, 1984; Barrow and Clark, 1998).

The body's ability to regulate temperature decreases for those who are elderly and/or obese, have heart disease, are under certain medications, and/or live in areas of poor air circulation. Under these conditions, people actually lose some of their ability to thermoregulate their bodies through radiation and evaporative heat loss when exposed to high temperatures and elevated humidity (Wilhelmi *et al.*, 2004). Additionally, they often do not have the ability to leave a hot residence for cooler alternatives. Living conditions and social networks also contribute to the overall vulnerability to extreme heat (McGeehin and Mirabelli, 2001). Significantly higher deaths occurred among people living in nursing homes without air conditioning during the heat events in New York City in 1972 and 1973 (Wilhelmi *et al.*, 2004).

Moreover, the elderly, the poor, and African Americans were found to be highly vulnerable groups during the extreme heat episode of July 1980 in St. Louis and Kansas City, MO (Jones *et al.*, 1982).

The elderly were the most vulnerable age group during the extensive heat waves in New York City during June of 1984 (CDC, 1984). A study of the Chicago heat wave in July of 1995 revealed that the elderly and infirmed are more likely to be at risk as they may be confined to a bed, unable to care for themselves, living alone, and/or incapable of leaving home each day (Wilhelmi *et al.*, 2004). This risk decreases if they have a social network of friends or family in the neighborhood, air conditioning, and/or access to transportation (Wilhelmi *et al.*, 2004). The poor are another vulnerable group, as they often do not own an air conditioner, lack means of transportation to cooler location, and/or often live in highly dense neighborhoods (Wilhelmi *et al.*, 2004).

During extended heat waves, deficient nocturnal cooling can have a particularly devastating impact on morbidity and mortality, especially in urban high-rise buildings. Urban settings often include high-rise apartment buildings, and people residing in the top floors of such buildings are at a greater risk as well (Barrow and Clark, 1998). Homes located in high crime rate areas are also more vulnerable because people are often afraid to leave their windows open at night thereby obstructing indoor air circulation (Wilhelmi *et al.*, 2004). With the changing demographics in the US, there has been increased attention to natural hazards and to the vulnerability of racial and ethnic communities (Wilhelmi *et al.*, 2004). A lower preparedness level, language barriers, and socio-economic factors such as income, housing issues, and availability of quality health care, may also contribute to increased vulnerability of racial and ethnic communities (Wilhelmi *et al.*, 2004).

Substitute Descriptions

Observation

For the purpose obtaining temperature and humidity data, HOBO H8 Pro RH/Temp loggers (Appendix 2A; H08-032-08, Onset Computer Corp.) were mounted on a wooden box (Appendix 2B), which was covered with white tape to protect from the precipitation and to reduce direct solar radiation. They were place horizontally (Appendix 2C) above 1m from the ground surface on a wooden tripod (Appendix 2D) for the field observations.

This logger has a feature for temperature measurement range of -30 to 50 ºC (-22 to 122 ºF) by accuracy of $\pm$ 0.2 at 21 ºC (0.33 at 70 ºF) and relative humidity measurement range of 0 to 100% by accuracy of $\pm$ 3% ($\pm$ 4% in condensing environment). During the preliminary testing, the accuracy was tested in three stable conditions: incubator, refrigerating room, and closed office space. In all cases, they indicated sufficient precision (data not shown) that are thought to eliminate a concern toward error generated by instruments during the observations. Consequently, these instruments were used to record two meteorological parameters in the field measurements.

Physiological Index

Conduction, convection, radiation, and evaporation are four processes involved in removing excess heat from human body (Barrow and Clark, 1998). Conduction occurs when the body comes in contact with something cold, allowing heat to be transferred to the cooler object. Convection takes place when air passes over the body, lifting heat away, as occurs on a windy day or through the use of fans. Radiation is the infrared dissipation by which the body leases heat into the environment. Evaporation, the primary thermoregulatory mechanism, is the process where a sweat from the skin plays a major role in heat dissipation. However, these systems can

be overwhelmed during periods of heat load and when the metabolic heat load exceeds the body's capability for heat dissipation. As ambient temperature and humidity increase, heat dissipation is less efficient. Elevated humidity also decreases the evaporation of sweat. Also, high ambient temperatures can cause heat gain through radiation.

Heat-related fatalities are induced by multiple environmental factors such as temperature, humidity, sun exposure, and wind (Barrow and Clark, 1998). Previous study has examined that when the core body temperature is higher than 104ºF (40ºC), heat-related illnesses and deaths occurs (Jones *et al.*, 1982; Kilbourne *et al.*, 1982; CDC, 1995; 1994; Barrow and Clark, 1998; Wexler, 2002). Although core body temperature is known to be increased through work-related activities and athletic performance that increase metabolic rate, elevated ambient temperature also play a role in this process. In fact, the basic mechanism that leads to heat-related illness is the body's inability to dissipate heat produced by metabolic activity, often as a result of increased ambient temperature (Barrow and Clark, 1998).

As ambient temperature and humidity increase, heat dissipation is less efficient, and elevated humidity decreases the evaporation of sweat. Also, high ambient temperatures can cause heat gain through radiation (Barrow and Clark, 1998). Therefore, reasonable physiological index that can be utilized in this study is the estimation of the core body temperature. However, limitation of individual deviations from the average response, physiological, emotional, and/or anthropometric characteristics raises difficulties for calculating the core temperature (Givoni and Goldman, 1972). Thus, heat index (HI) was chosen as physiological indicator in this paper.

HI is a combination of several factors and is used to evaluate heat stress on the human body. It is considered as index of how hot the actual body feels when temperature and humidity are combined. The HI values are derived from a collection of empirical equations that comprise a

model. Rothfusz (1990) developed the HI equation by calculating the parameters from Steadman (1979), which uses more conventional independent variables. Each of those parameters is given by assumed magnitudes, in parentheses, in order to simplify the model (Appendix 1-7). This equation is utilized by NWS to more effectively alert the general public and appropriate authorities to the hazardous and prolonged excessive heat episodes (NWS, 2005).

Note that HI equation is based upon shady and light wind condition. Exposure to direct sunlight can increase the HI values by up to 15 ℉. Also, strong winds, particularly with very hot and dry air can be extremely hazardous. Additionally, The there is an error of $\pm$ 1.3 ℉ as it is obtained by multiple regression analysis. The equation is only valid for temperatures higher than 80 ℉ and relative humidities greater than 40%. Kalkstein (1995) suggest that HI is not sufficient to be utilized for accurate indicator. Moreover, it is possible that identification of core body temperature (Givoni and Goldman, 1972) would be a better estimation. Considering these, it is likely that HI may not be an optimal indicator that should be considered.

Despite the fact that HI have certain limitations, it can be derived from two observable meteorological parameters and effectively represent the variations of the study area. Hence, above limitations were ignored and it was utilized to designate pedestrian level comfort.

Urban Characteristics

In order to characterize the study area, simpler but adequate environmental indices to Grimmond and Souch (1994; Appenddix 1-5) and Grimmond & Oke (1999; Appendix 1-6) were implemented to determine the environmental conditions. Since observations were done at very local scale, four indices were believed to capture the general urban condition. Here, however, the direction of the street (north-south and east-west) employed by Kondo and Yamazawa (1986)

was not implemented due to the complexity that may rise. Orientation of streets may effect the ventilation and length to sun exposure, but this was ignored due to the fact that observation period was relatively short and difference within the observation periods were likely to be insignificant for consideration.

Regression Analysis

After compiling field measurements, they were aggregated into hourly base measurements (Appendix 3) and regression analyses were conducted. Results of analyses are shown in Appendix 4. It consist of 6 procedures: (A) Distribution of Variables, (B) Pearson Product Moment Correlation Matrix, (C) Stepwise Regression, (D) OLS Regression, (E) Distribution of Residuals derived from OLS Regression, and (F) Regressing Residuals on Explanatory Variables were conducted separately for different surface type and time periods.

In multiple regression analysis, a linear model should satisfy the condition of errors to have no correlation, expectation of residual to be zero, and each explanatory variable to have equal variances. Therefore, colinearity of independent variables should be avoided. Additionally, normality of residual and linearity assumption should be fulfilled. Accordingly, these basic three underlying assumptions were confirmed under OLS statistical model in JMP-IN.

After three basic procedures (A through C), firstly, by way of the variance influence factor (denoted as VIF), colinearity of variables were determined under OLS regression analysis (D). VIF is one of the measurements that are used to detect the impact of colinearity among the explanatory variables in a regression model on the precision of estimation. If any of VIF value is significantly different from others, it indicates the existence of colinearity. Considering this, however, all results suggested no existence of colinearity among the variables.

Multiple regression analysis also assumes that the residuals are normally distributed. Thus, this was verified by normal quantile plots. Normal quantile plot is a sctterplot of the percentiles of the data versus the percentiles of a population in fact having the normal distribution. If the data comes from a normal population, the resulting point should fall closely along the straight line. Accordingly, there were no reasons to reject the normality of the residuals under the OLS regression for each dataset.

Lastly, multiple regression analysis also requires the variances to be the same for all explanatory variables, linearity assumption. So, this condition was determined by bivariate scatterplot where residuals were plotted against each explanatory variable. If all variables in the sequence or vector have the same finite variance, it is expected to have no increasing or decreasing condition, zero. As a result, there were no evidences to violate the condition in all cases. Consequently, skewed distributions of variables were left untransformed and further analysis was conducted from the original values.

Panel Autoregression (PAR) Analysis

The linear model of autocorrelation is understood to be $u_i = \sum_{j \neq i} \rho W_{ij} u_j + \varepsilon_i$. W is the weight matrix, $\sum_{j \neq i} W_{ij} u_j$ summarizes the spatial influence of other residuals on u_i, and ε_i is the internal effect at i being identically and independently distributed ($\varepsilon_i \sim N(0, \sigma^2)$, $i = 1, \ldots, n$). Here, $\sum_j W_{ij} u_j$ is a simple weighted average of the u_j's reflecting the dependency on u_i. The scale of these influence is reintroduced by parameter, ρ, which is assumed to be common to all residuals that satisfies the condition of $|\rho| < 1$. Thus, autocorrelation model could then be written as $u_i = \rho \sum_j W_{ij} u_j + \varepsilon_i$, $i = 1, \ldots, n$.

Only temporal autocorrelation was considered in this study as spatial autocorrelation had no influence and results were similar relative to the OLS statistical model. (data not shown). In order to take into account for the temporal autocorrelation, panel autoregressive (PAR) model was created on a basis of spatial autoregressive (SAR) model (Bailey and Gatrell, 1995). The autoregressive model provides a foundation for general autocorrelation analysis. A linear model of this is expressed by: $y_i = \beta_0 + \sum_{i=1}^{k} \beta_i x_{ij} + u_j$, $j = 1,\ldots,n$ of data ($y_j, x_{1j},\ldots,x_{kj}$) for units, $j = 1,\ldots,n$. Spatial effects is to postulated that the residuals ($u_i : j = 1,\ldots,n$) follow a spatial autoregressive model: $u_j = \rho \sum_{h=1}^{n} W_{jh} u_h + \varepsilon_h$, $\varepsilon_h \sim N(0,\sigma^2)$. Therefore, SAR model is given by: $y = X\beta + u$, $u = \rho W u + \varepsilon$, $\varepsilon \sim N(0,\sigma^2 I)$ where W is the spatial weight matrix, ρ is the spatial dependency parameter (residual dependency), and I is the Moran's I.

In the PAR model, W is the temporal weight matrix that directs second day field HI measurement to depend on the first day measurement. The weight matrix takes the condition of

$$u_t \begin{cases} \varepsilon_i & , \quad t = 1 \\ \rho u_{t-1} + \varepsilon_i & , \quad t = 2 \end{cases}$$ and $|\rho| < 1$ where t denotes the observation day. Thus, it is expressed as:

$$\rho W u = \rho \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} u_{t_1} \\ u_{t_2} \end{pmatrix} = \rho \begin{pmatrix} u_{t_1} & 0 \\ 0 & u_{t_1} \end{pmatrix} \text{ where } u_t = \begin{bmatrix} u_{t,1,1} & \cdots & u_{t,1,k} \\ \vdots & \ddots & \vdots \\ u_{t,n,1} & \cdots & u_{t,n,k} \end{bmatrix}, k \text{ is number of parameter}$$

estimates, and n is the number of sample points. As seen in Appendix 3 (observing the column "Date/Time"), datasets were arranged in such a way that first day field measurements were organized at the upper table followed by the second day field measurements. The PAR analysis with its procedure commands and OLS regression analysis conducted in MATLAB are shown in Appendix 5.

In this model, unknown parameters are essentially β, ρ, and σ^2. Therefore, maximum likelihood estimation (MLE) was used to estimate these unknown parameters capturing the influences of the underlying probability distribution of a given dataset. The idea behind MLE is to determine the parameters that maximize the likelihood (probability) of the sample data. This leads to the notion that the likelihood of a set of data is the probability of obtaining that particular set of data, given the chosen probability distribution model.

Goodness-of-fit Measurements

The indication of R^2 (or adjusted R^2 depending on the model) is best known for measuring the goodness of fit of the model where errors are assumed to be identically and independently distributed, $\varepsilon \sim N(0, \sigma^2 I)$. As this condition is violated under the presence of spatial autocorrelation, four alternative measurements (Pseudo R^2, squared correlation, Log likelihood value, and Akaike's Information Criterion [AIC]) were applied to reveal more meaningful indication and comparable to the R^2 measurement in OLS regression.

Observe first that both PAR model could be reduced into $y_\rho = X_\rho \beta + \varepsilon$ where it satisfies all conditions of the linear model, $\varepsilon \sim N(0, \sigma^2 I)$. Accordingly, first of all, since MLE procedure provides a consistent estimate ($\hat{\rho}$) of ρ, under $y_{\hat{\rho}} = X_{\hat{\rho}} \beta + \varepsilon$ analogous measurement to R^2 could be obtained by $\hat{R}^2 = \dfrac{\hat{y}' B_{\hat{\rho}}' D B_{\hat{\rho}} \hat{y}}{y' B_{\hat{\rho}}' D B_{\hat{\rho}} y}$. Here, $D = (I - \dfrac{1}{n} 11')$ denotes the deviation vector, and predicted value is given by $B_{\hat{\rho}} \hat{y} = B_{\hat{\rho}} (X' B_{\hat{\rho}}' B_{\hat{\rho}} X)^{-1} X' B_{\hat{\rho}}' B_{\hat{\rho}} y$ where $B_{\hat{\rho}} = I - \rho W$. This alternative measurement is called the Pseudo R^2, which is an interpretation similar to the R^2 where its maximum is 1. Similar to the adjusted R^2, adjusted

Pseudo R^2 modifies both the numerator and the denominator by their respective degrees of freedom that is more meaningful for the case in multiple regression analysis. Secondly, the squared correlation is the method for measuring how closely related the variances are. The expression focus on the degree, parameter θ (maximum likelihood), relationship between y and $\hat{y}$, by $R^2 = corr(y, \hat{y})^2$ where $corr(y, \hat{y}) = \cos[\theta(D_y, D_{\hat{y}})] = \dfrac{y'\hat{y}}{\|y\| \cdot \|\hat{y}\|}$. For both Pseudo R^2 and squared correlation, higher value to 1 suggests better fit of the model. Thirdly, Log likelihood is a function of the parameter θ with actual observed data that is derived from MLE, $L(\hat{\theta})$. This calculates the ratio of the maximum value of the likelihood function under the constraint of the null hypothesis ($\rho = 0$) to the maximum with constraining the value by (-2)* Log($\cdot$) where smaller value suggests a better model. And finally, AIC also utilizes $L(\hat{\theta})$ to compute $2(L(\hat{\theta}) + k)$. Again the model that yields lower value of AIC is considered to be better.

Appendix 1-2. Risk Factors to Heat Illnesses (CDC, 1984; Kilbourne, Choi, & Jones, 1982).

Environmental	Social and Behavioral	Biological and Medical	
No home air conditioning	Race (black)	Heat disease	Arthritis
Less home fan use	Gender (female)	Lung disease	Hypertension
Less windows open	Low educational attainment	Liver disease	Cancer
Less trees and shrubbery	Not warned about heat danger	Kidney disease	Diabetes
Low ceiling height	Unemployed	Thyroid disease	Depression
High number of living units	Living alone	Able to care for self	Use of drugs
High home floor	Less contact with others	Smoking	
Facade of brick, stone, or concrete	High activity during heat	Obesity	
Surface of concrete or asphalt	Wearing thick clothing	Alcohol consumption	
High buildings within 300ft	Less time in cool places	Alcoholism	
Home near to buildings	No extra cool baths or showers	Characteristic activity level	
	No extra liquids	Mental illness	
	No use of heat wave shelter	Previous heatstroke	

Appendix 1-3.Vulnerable Conditions to the Risk of Heat Illness (Barro & Clark, 1998).

Physical Conditions	**Increased Body Mass**
Fever	More heat generated for same level of activity
Dehydration	Less efficient heat dissipation
Medication	Fewer heat-activated sweat glands in skin overlying adipose tissue
Prolonged exertion	Decreased cardiac output per unit of body weight
Chronic Illnesses	**Younger age**
Cardiac conditions	Decreased ability to sweat
Cystic fibrosis	Decreased cardiac output at a given metabolic rate
Uncontrolled diabetes	Greater core temperature required to initiate sweating
Uncontrolled hypertension	Slower acclimatization
Eating disorders	More heat produced for the same level of activity
Malignant hyperthermia	**Additional Factor**
Peripheral vascular disease	Lack of access to air conditionings
Extensive skin disease or damage, or both	Residing in upper floors in tall building
Autonomic nervous system disorders	Sleep deprivation (decreases skin blood flow and rate of sweating)
Psychiatric conditions	Use of equipment or heavy clothing (football player's pads, etc.)
Hyperthyroidism	Previous heat stroke
Older Age	Recent move from a temperate to hot climate
Decreased vasodilatory response	Urban setting
Decreased thirst response	
Decreased fitness level	
Decreased maximum heat rate, resulting in decreased maximum cardiac output	
Decreased mobility resulting in increased difficulty of easily obtaining fluids	

Appendix 1-4. Medical Conditions to the Risk of Heat Illnesses (Barro & Clark, 1998).

Alpha agonists	Heroin
Amphetamines	Inhaled anesthetics
Anticholinergic medications	Laxatives
Antihistamines	Lysergic acid diethylamide
Anti-parkinsonian agents	Monoamine oxidase inhibitors
Beta-adrenergic blockers	Phencyclidine hydrochloride
Calcium channel blockers	Phenothiazines
Cocaine	Sympathomimetic medications
Diuretics	Thyroid agonists
Ethanol	Tricyclic antidepressants

Appendix 1-5. Attributes Determined for Each Land-Use Category (Grimmond & Souch, 1994).

Densities	Percent areal cover			
Buildings	Buildings	Trees/shrubs	Water	Sand
Trees	Garages	Parking lot	Dirt	Scruff
Roads	Grass	Main road	Pavement (non-parking lot)	

Appendix 1-6. General Land-Use Categories (Grimmond & Souch, 1994).

General Land-Use		Categories and Description
Residential	A	Housing density and shape (whether attached or not).
	B	Moderated density housing, small houses with trees
	C	Moderate density housing, size of houses and yards (trees/extensive landscaping)
	D	Large houses, small grass yards with some trees and shrubs
	E	Large houses, large yards, yards landscaped with shrubs and trees
	EA	Mixture of "A" and "E" type housing
	F	Houses equally spaced, large grass yards, few trees (with housing density)
	MH	Mobile homes
Apartments	AA	5-6 stories, U-shaped (arrangement of parking around the building)
	AB	Square shaped buildings
	AL	L-shaped buildings, 7 stories tall, no trees
	AL1	Rectangular shaped buildings
	AR1	Duplexes
	AR2	Mixture of "AR1" and "A" type houses
	AR3	Highly mixed
	BB	Low-level apartments (2 stories), rectangular shape, and height and size
Commercial	CB	Large commercial buildings - less than 6 stories
or Industrial	CC	Very tall commercial buildings - at least 15 stories
	CS	Small commercial buildings
	I	Industrial - either large low level buildings or many small buildings
Institutional	HS	High school: Large building, few trees, medium size parking lot
	S	Elementary/Junior High school: Much smaller building than HS
	U	University: Large buildings, parking lot, vegetated grounds
Transportation	MRI	Major roads (e.g. interstates)
	RR	Rail road tracks or side-yards
Vacant/Wild	DI	"Dirt"
Vegetated	VG	Golf course
	VGR	100% grass
	VM	50% grass/ 50% tree and shrub
	VPC	Cemetery
	VT	Trees and shrubs
Impervious	CN	Concrete
surfaces	IP	Parking lot (impervious)
	IS	Tennis court
Water	WL	Lake
	WR	River

Appendix 1-7. Assumed Parameters of Magnitudes for HI Equation (Rothfusz, 1990).

Vapor pressure. Ambient vapor pressure of the atmosphere. [1.6 kPa]

Dimensions of a human. Determines the skin's surface area. [5'7'' tall, 147 pounds]

Effective radiation area of skin. A ratio that depends upon skin surface area. [0.8]

Significant diameter of a human. Based on the body's volume and density. [15.3cm]

Clothing cover. Long trouser and short-sleeved shirt is assumed. [84% coverage]

Core temperature. Internal body temperature. [98.6 F]

Core vapor pressure. Depends upon body's core temperature and salinity. [5.65 kPa]

Surface temperature and vapor pressures of skin and clothing. Affects heat transfer from the skin's surface either by radiation or convection. These values are determined by an iterative process.

Activity. Determines metabolic output. [180 W m-2 of skin area for the model person walking outdoors at a speed of 3.1 mph]

Effective wind speed. Vector sum of the body's movement and an average wind speed. Angle between vectors influences convection from skin surface (below). [5 kts]

Clothing resistance to heat transfer. The magnitude of this value is based on the assumption that the clothing is 20% fiber and 80% air.

Clothing resistance to moisture transfer. Since clothing is mostly air, pure vapor diffusion is used.

Radiation from the surface of the skin. A radioactive heat-transfer coefficient determined from previous studies.

Convection from the surface of the skin. A convection coefficient also determined from previous studies. Influenced by kinematic viscosity of air and angle of wind.

Sweating rate. Assumes that sweat is uniform and not dripping from the body.

Ventilation rate. The amount of heat lost via exhaling.

Skin resistance to heat transfer. A function of activity, skin temperature, among others. [2-12%, depending upon humidity]

Skin resistance to moisture transfer. A function of the vapor-pressure difference across the skin (and, therefore, relative humidity). It decreases with increasing activity.

Surface resistance to heat transfer. As radiation and convection from the skin increases, this value decreases.

Surface resistance to moisture transfer. Similar to heat transfer resistance but also depends upon conditions in the boundary layer just above skin's surface.

Appendix 2. HOBO H8 Pro RH/Temp loggers Images

(A)

(B)

(C)

(D)
(A) H08-032-08., Onset Computer Corp., (B) the HOBO instrument mounted on a wooden box covered with white tape, (C) horizontal image of (B), and (D) the HOBO instrument placed above 1m from the surface on a wooden tripod.

Appendix 3-1. Dataset of Impervious Surface at Daytime (13:00).
