9       **Abstract:**

10       Community-based renewable energy could play a key role in the transition to a low carbon  
11       society. This paper argues that given the right environmental and societal conditions,  
12       communities in the UK could source a high percentage of their electricity supply from a  
13       mixture of localised renewable electricity technologies. Here we use exploratory scenarios  
14       to assess demand and renewable electricity supply-side options at the community-scale for  
15       a location in Cumbria, UK. Three scenarios are presented, using narratives of how local  
16       demand and renewable electricity supply could be constructed under either existing or  
17       modified environmental and societal conditions. The three scenarios explored were  
18       ‘Current State of Play’, ‘Low Carbon Adjusted Society’ and ‘Reluctant Scenario’.

19       **Keywords:** Energy scenarios, energy & environment, community-based renewable  
20       electricity, climate.

21       **1. Introduction**

22       Approaches that will increase the supply of renewable energy and reduce demand are  
23       needed in response to the UK’s goal of reducing carbon emissions by 2050 (Climate Change

24 Act, 2008) and in response to the European Union's (EU) renewable energy target of 20%  
25 by 2020 (DECC, 2009). The UK has a lower target of 15% renewable energy by 2020,  
26 however is making slow progress having achieved 7% in 2014 (DUKES, 2015, Renewable  
27 Energy Strategy, 2009). Furthermore, the UK aims to generate 30-40% of its electricity from  
28 renewable sources but to date has only achieved ~18% (DUKES, 2015). Significant changes  
29 will need to be made in the UK's approach to energy if these targets are to be met.

30 Although a centralised large-scale approach to energy currently dominates, there is  
31 emerging interest in distributed small-scale renewable energy, particularly where  
32 communities are involved in the ownership or management of local developments. Interest  
33 has been fuelled by the perceived benefits that locally-led developments can play in  
34 increasing local acceptance of renewable technologies and in altering energy behaviours by  
35 providing real-time information to inform energy use decisions (Heiskanen et al., 2010, CSE,  
36 2007, Warren and McFadyen, 2010). The concept of generating and using locally-owned  
37 energy is gaining popularity with residents in the UK, with the number of energy schemes  
38 labelled as 'community-based' rising to over 1000 in 2012 (Hargreaves et al., 2012). This is  
39 partly due to concerns over increasing fuel prices, with consumers wanting to become  
40 more independent from large energy providers and having more control over where their  
41 energy comes from (Butler et al., 2012, Watson et al., 2008, Gormally et al., 2013). The UK  
42 coalition government declared support for community-based activities, releasing its first  
43 'Community Energy Strategy' recognising the 'advantages that community-based action  
44 offers energy and climate change policy' (DECC, 2014, p.3)

45 Given the perceived relevance community energy could have in promoting low carbon  
46 technologies and reducing local demand, this paper examines the technical, societal and  
47 environmental aspects of local schemes by exploring the potential contributions of  
48 renewable supply and demand-side options for a case study community, using a set of

49 exploratory scenarios. This paper argues that given the right societal and environmental  
50 conditions, communities in the UK could become significant producers of electricity. As  
51 shown on The Isle of Eigg (Yadoo et al., 2011), it is possible for a small community to  
52 generate almost all electricity needs through community-based renewables when this is  
53 the only option available. Supply-side options used on Eigg involve combining a mix of  
54 renewable resources which have different seasonal and weather dependencies. By  
55 combining a mix of hydro-power, wind-power and solar photovoltaics (PV), together with  
56 24 hour battery storage and back-up diesel generators, they have managed to overcome  
57 some of the issues associated with the variability of renewable generation. This is coupled  
58 with demand-side measures including a household cap of 5KW (all households are provided  
59 with OWL energy meters) and by asking residents to voluntarily reduce demand in times of  
60 low renewable electricity generation. Here we consider whether this concept of balancing  
61 supply and demand locally through utilising local renewable resources translates to on-grid  
62 rural communities on the UK mainland.

63 This paper presents the final phase of an interdisciplinary, mixed methods research project  
64 that has examined community-based renewable energy in Cumbria, UK. The first phase  
65 combined quantitative methods (spatial analysis and calculated energy outputs) with  
66 secondary data in order to assess annual renewable resource potential at the regional scale  
67 and identify areas with sufficient local resources to support a portfolio of renewable energy  
68 technologies (Gormally et al., 2012). The second phase involved using quantitative and  
69 qualitative methods to assess residents' attitudes to renewable energy, in three Cumbrian  
70 communities. Themes included attitudes towards localised ownership of renewable energy,  
71 involvement in local energy schemes and preference towards different renewable  
72 technologies (Gormally et al., 2013). The communities were chosen using the results of the  
73 spatial analysis conducted in the initial phase, which identified them as having high

74 resource potential for a portfolio of renewable technologies. Subsequently, one of the  
75 three communities was chosen as the focus for developing community-level energy  
76 scenarios in this final phase of the overall study.

77 In this paper we use one type of energy scenario to explore possible 'renewable futures' for  
78 our chosen case study community. Scenarios are a means of exploring alternative futures  
79 and Kowalski et al., (2009) describe three main types that are often used - forecasting  
80 scenarios (those which are a continuation of the past), normative scenarios (those which  
81 aim for milestones and assume a certain future can be created) and exploratory scenarios  
82 (those which explore a possible space for the future but do not aim to predict it). Here we  
83 use exploratory scenarios to examine electricity demand and supply at the community  
84 scale. Therefore, we do not aim to predict the future for this community, we simple aim to  
85 explore plausible and potential futures based on different assumptions of technologies,  
86 acceptance and climate.

87 The scenario options described in this paper are modified by both local demand and  
88 renewable supply-side conditions. Reviewing renewable supply-side options involves  
89 exploring the existing potential (current meteorological conditions) and future potential  
90 (possible future meteorological conditions) by exploring the effects of climate and extreme  
91 weather events. The impact of extreme weather events is important in terms of ensuring  
92 security of supply, especially as extreme events in the UK are predicted to become more  
93 severe and more frequent in the coming decades (Meehl, 2007, Fowler and Ekström, 2009).  
94 Indeed, this has raised interest among the energy-related research community with studies  
95 addressing the energy outputs and economic impact of such changes on hydro-power and  
96 wind-power (Harrison and Whittington, 2002, Greene et al., 2010). The UK has seen a shift  
97 in some meteorological conditions, for example, rainfall patterns are found to be changing  
98 with winter rainfall events becoming more intense and more frequent in upland areas such

99 as Cumbria (Ferranti et al., 2009, Malby et al., 2007, Burt and Ferranti, 2012, Osborn et al.,  
100 2000). This could have implications for renewable technologies in the future (for instance,  
101 energy outputs from hydro-power). It is important to note that the aim of this paper is not  
102 to model future climate for this community. That is beyond the scope of this research and  
103 outside of the remit of the ‘exploratory’ scenario approach taken here. To help explore  
104 possible impacts of climate or changing weather patterns on renewable supply-side  
105 options, we take a simplified approach by using ‘extremes’ identified in the local 30-year  
106 meteorological record (for more details see section 2.1.2).

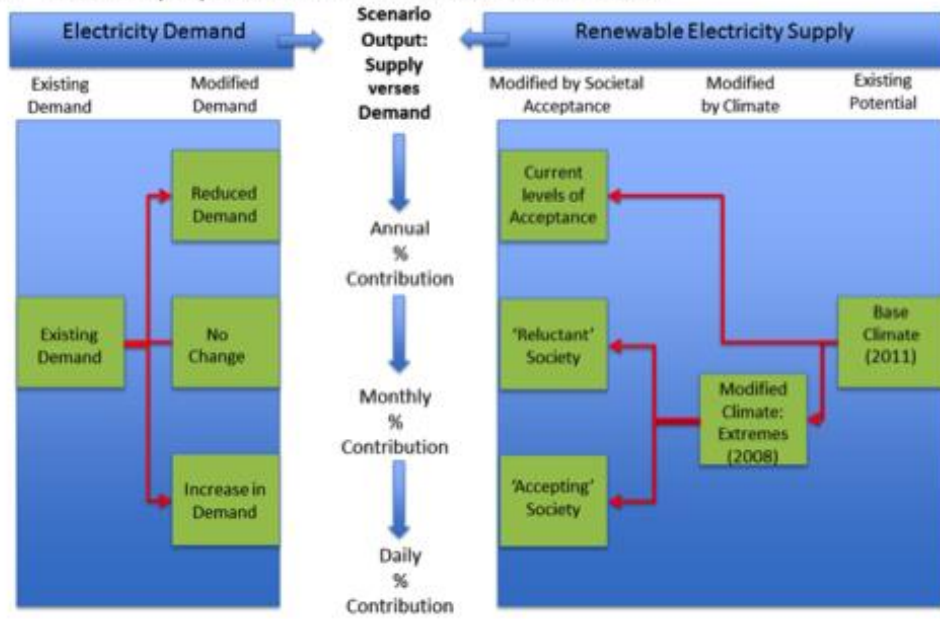

107 Supply-side options are additionally modified by societal acceptance which is used to  
108 define both the renewable technology options used and the scale of the chosen  
109 technology. Demand-side options use current estimates of local residential electricity  
110 demand and future estimates which explore both reduced (high awareness) and increased  
111 (low awareness) levels of residential demand. For an example of all pathway options used  
112 to construct the scenarios described in this paper, see Figure 1.

## 113 **2. Methodology & Results**

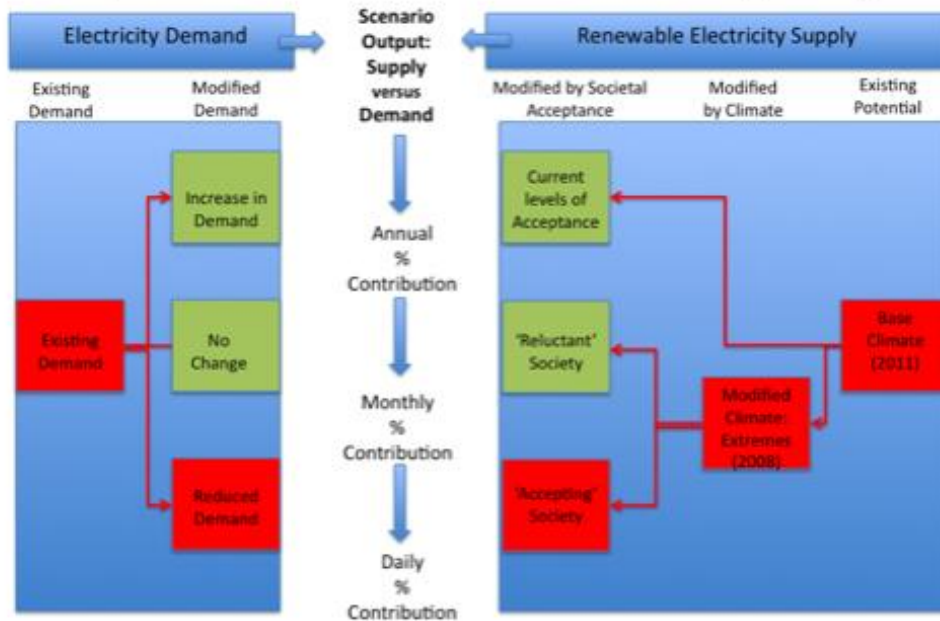

114 The following methodology was used to develop exploratory energy scenarios for one  
115 community in Cumbria, UK. We firstly describe the case study community followed by the  
116 methods and data used to determine local levels of electricity demand and renewable  
117 energy supply. Three exploratory scenarios are then constructed. These are ‘Current State  
118 of Play’, ‘Low Carbon Adjusted Society’ and ‘Reluctant Society’. All three scenarios  
119 represent different narratives of how local demand and renewable energy supply could be  
120 constructed under either existing or modified environmental and societal conditions. Each  
121 scenario considers the demand and supply balance on temporal scales ranging from annual  
122 to monthly and daily. To contextualise the results, each scenario considers whether the

123 community could generate sufficient renewable electricity to satisfy three different levels  
124 of local demand. Firstly, greater than 30% of the community's electricity needs; secondly  
125 90-100% of the community's electricity needs and thirdly, in excess (>100%) of the  
126 community's electricity needs. The 30% contribution was chosen in line with the UK's  
127 overall target of >30% renewable electricity by the year 2020 (Renewable Energy Strategy,  
128 2009), the 90-100% contribution was chosen due to its suggested feasibility given the  
129 evidence from The Isle of Eigg (Yadoo et al., 2011), and the >100% contribution was chosen  
130 to establish whether given the right conditions of environmental, societal and technology  
131 mix, the community could become a net exporter of electricity to the grid.

### A – Pathway options for scenario construction

### B – Example scenario construction for 'Low Carbon' pathway

132

133 Figure 1. (A) Shows the different pathway options for scenario construction through  
 134 considering modifications of demand (ie. existing demand and increase or decrease in  
 135 demand), which then aligns with the chosen scenario options for renewable supply  
 136 electricity supply (ie. Impact of climate and societal acceptance). The scenario output  
 137 considers the contribution of the renewable electricity mix to annual, monthly and daily

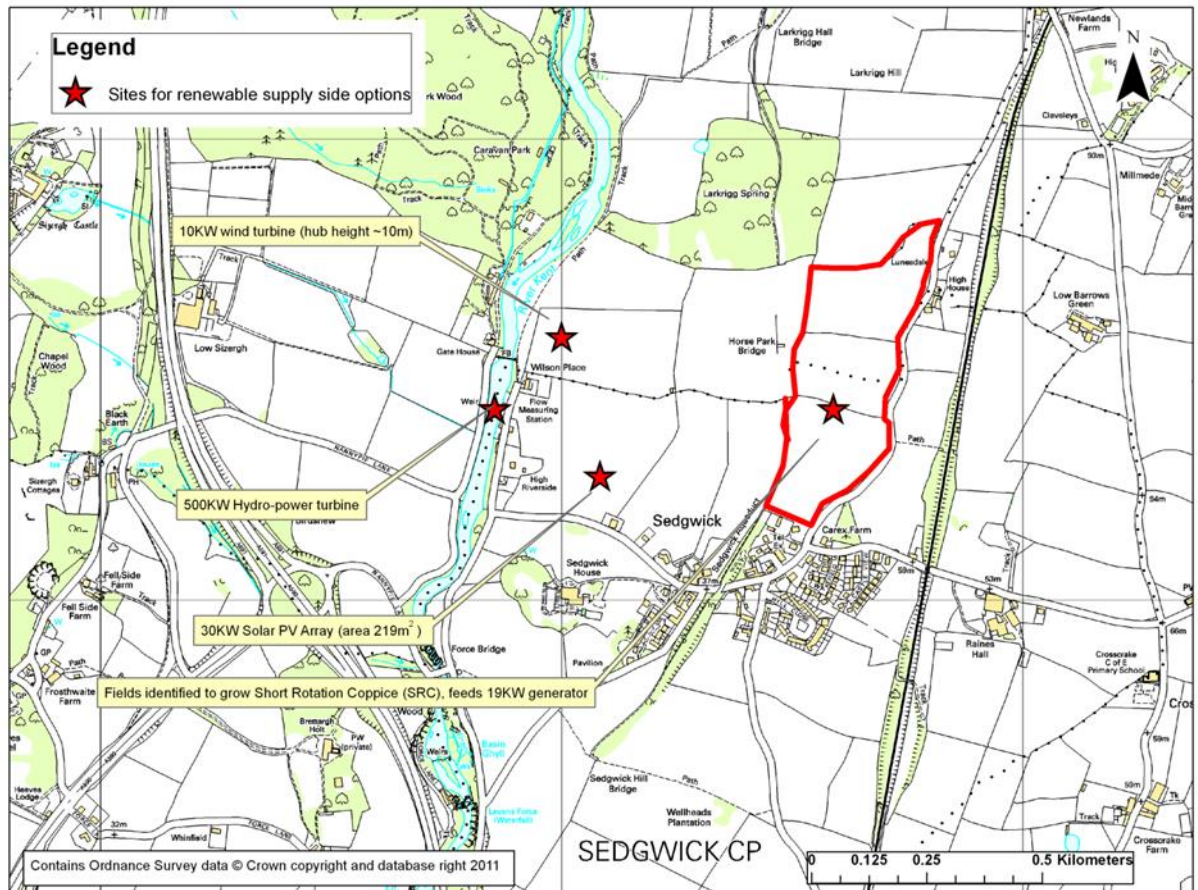

138 demand patterns. Figure 1 (B) provides an example pathway for the scenario ‘Low Carbon  
139 Society’ option, with reduced demand, ‘accepting’ society and modified climate (increased  
140 rainfall).

141

## 142 *2.1 Case Study Community*

143 The village of Sedgwick (Figure 2) was chosen as the case study community to develop the  
144 energy scenarios and explore possible ‘renewable futures’ at the community level. It is  
145 located in the South Lakeland District of Cumbria in the North-west of England and is  
146 situated between the boundaries of the Lake District National Park and the Yorkshire Dales  
147 National Park. It has a population of 378 inhabitants (source: 2001 census; key statistics)  
148 and achieved a high response rate (61%) to the household questionnaire survey on  
149 community energy carried out in an earlier phase of this research (Gormally et al., 2013).  
150 Results of this survey indicated a high level of support for locally-led initiatives. The  
151 regional scale mapping of resource potential carried out in Gormally et al., (2012) also  
152 suggests that this community and its immediate surroundings could potentially support a  
153 number of renewable electricity developments. For example, hydro-power, wind-power,  
154 solar PV and land for bioenergy crops, specifically Miscanthus or Short Rotation Coppice  
155 (SRC).

156

157 Figure 2. The village of Sedgwick in Cumbria showing proposed locations of renewable  
 158 supply-side technologies including, wind-power, solar PV array, hydro-power and land  
 159 identified for bioenergy (SRC) crops.

160 *2.1.1 Electricity Demand*

161 Existing levels of local electricity demand were derived on an annual basis. This was  
 162 achieved using domestic electricity consumption data taken from the Digest of UK Energy  
 163 Statistics produced by the Department for Energy and Climate Change (DUKES, 2010)  
 164 available at Lower Level Super Output Area (LLSOA). LLSOA consist of approximately four  
 165 Output Areas which are used to define the UK Census. LLSOA's take into account  
 166 population size (mean population 1500), mutual proximity and social homogeneity (ONS,  
 167 2011). This electricity data has been used due to its availability over LLSOA scales, however

168 it is acknowledged that it doesn't provide information on other factors that could  
169 contribute to electricity consumption such as building type, income, occupation and  
170 weather dependencies (for examples of studies considering these aspects see Azevedo et  
171 al., 2015 and Azevedo et al., 2016).

172 These data revealed that the community had an annual domestic electricity consumption  
173 of 4725 KWh per household. To determine the mean annual electricity consumption for the  
174 community, this value was multiplied by the number of households in the village (204  
175 households) taken from the 2001 UK census of population (most recent available at the  
176 time of the research). Although this approach leads to an estimate of community electricity  
177 consumption rather than demand, it gives an indication of how much renewable capacity  
178 would be need to be developed to match generation with demand on an annual basis.

179 Existing levels of community electricity consumption were also derived on a monthly and  
180 daily (including hourly) basis. Seasonal adjustments (eg. For months DJF, MAM, JJA, SON)  
181 were then applied based on seasonal patterns of UK household electricity use  
182 (Sustainability First, 2012). Daily profiles were based on UK household electricity  
183 consumption data taken from the Energy Saving Trust (2012) which were compared to the  
184 localised outputs from above and adjustments (including daily and seasonal) were made  
185 accordingly. These figures were then multiplied by the number of households in the case  
186 study community.

187 Having derived current levels of household demand (consumption) two future  
188 modifications were considered; one in which local demand was reduced through high  
189 levels of energy awareness, and one in which local demand was increased through lack of  
190 energy awareness. These demand-side modifications are based on scenarios used by DECC  
191 (2012). Modifications resulting in reduced levels of local demand were based on 'policy on'

192 pathways resulting in high levels of residential abatement. This results in a reduction of  
193 residential electricity consumption of ~42%, which was then applied to existing levels of  
194 local electricity demand, described above. Modifications resulting in increased levels of  
195 local demand were based on the 'policy off' pathway (also called business as usual) used by  
196 DECC (2012), which implies no significant policies have been implemented to reduce  
197 carbon and energy usage. This results in an increase of ~16% of residential electricity  
198 consumption. This modification was then applied to existing levels of local electricity  
199 demand, described above.

### 200           2.1.2 *Renewable Energy Supply*

201 The village of Sedgwick has already been identified as having significant resource potential  
202 to develop run-of-river hydro-power, wind-power, bioenergy (SRC or Miscanthus) and solar  
203 PV (Gormally et al., 2012). Therefore these four technologies were considered as  
204 renewable energy supply-side options. To determine energy outputs from supply-side  
205 options, base environmental data were used from the year 2011, for example, river flow,  
206 wind speed and solar radiation data. Renewable energy supply-side options were also  
207 modified by meteorological extremes (referred to in this article as climate). In this study we  
208 focus on extremes of river flow (data taken from the flow gauge on the River Kent at  
209 Sedgwick), a decision justified by evidence showing notable changes in rainfall in Cumbria  
210 and an increased frequency of extreme events (Ferranti et al., 2009, Burt and Ferranti,  
211 2012). The inter-annual variability of wind speed was also examined using data taken from  
212 a weather station at Hazelrigg, Lancaster, located 28 km south of Sedgwick. These data  
213 were obtained from the British Atmospheric Data Centre (MIDAS, 2013), and adopted for  
214 reasons including length of record (> 30 record)<sup>1</sup> reliability of readings and similar

---

<sup>1</sup> A climate period in meteorological terms is based on a 30 year time period (see UK Met Office for more details <http://www.metoffice.gov.uk/climate>)

215 landscape to the village of Sedgwick. For further particulars relating to environmental data,  
216 see Table 1.

217 On examining both the river flow and wind-speed records it became apparent that wind  
218 speed varied little on an annual basis (annual mean wind-speed  $5.05\text{m s}^{-1}$  from 1977-2009,  
219 SD:  $0.39\text{m s}^{-1}$ ), however, river flow showed much greater inter-annual variability (annual  
220 mean flow  $9.24\text{m}^3 \text{s}^{-1}$  from 1969-2010, SD:  $1.65\text{m}^3 \text{s}^{-1}$ ). Therefore, for scenario options that  
221 considered a modified climate, environmental data for the year 2008 were used, as this  
222 was the year in which the flow deviated most significantly from the long-term (30 year)  
223 annual and monthly means. Wind-speed data for 2008 was also used for a modified  
224 climate, to keep meteorological and hydrological parameters consistent and to avoid  
225 unnecessary 'mixing and matching' of data. In contrast, modelled solar radiation data was  
226 adopted (as used for base climate) since there was no difference when modelling radiation  
227 between years. No change was made to bioenergy yields as it was felt this was beyond the  
228 scope of this paper.

229 Point locations for run-of-river hydro-power were pre-determined from the Environment  
230 Agency's (2010) mapping study and therefore restricted to certain locations. The site  
231 selected for use in this study was located by the monitoring station on the River Kent at  
232 Sedgwick. This site had a potential generating capacity of between 100-500KW  
233 (Environment Agency, 2010). Due to the predicted increases in rainfall (and subsequently,  
234 river flow), the upper capacity of 500KW was used for the generator size. In order to find  
235 locations for wind turbines the DTI's 1km wind-speed data base was used to assess  
236 variations in annual wind speed across the study area. 15 min wind-speed data from  
237 Hazelrigg, either for the base climate (2011) or modified climate (2008), were then used for  
238 the chosen location for the wind turbine to calculate energy outputs. All scenarios used  
239 small-scale (10KW) wind turbines and therefore no vertical interpolation of wind-speed

240 was necessary. Wind-speed data were recorded at 10m above ground level (agl) and the  
241 suggested hub-height of a 10KW wind turbine is approximately 10m.

242 Solar irradiance was modelled using a GIS from a 50m digital terrain model (DTM)).  
243 Potential sites for the PV array were located by identifying areas of high solar irradiance  
244 within fields currently not used for agriculture (eg. non-arable land). Fields were selected  
245 by eye due to the small size of the study area, using Ordnance Survey (OS) Mastermap data  
246 (1:2500 scale) and the Centre for Ecology and Hydrology (CEH) Land Cover Map (2007). The  
247 Land Cover Map (LCM) is derived from satellite images and describes land cover for the UK,  
248 for instance urban areas, water bodies, natural and managed vegetated surfaces (CEH,  
249 2011).

250 For bioenergy, we assume that the community will source its own feedstock, and therefore,  
251 only consider land close to or within the community boundary. The bioenergy methodology  
252 first identified non-arable land (ie. areas of grassland but not semi-improved grassland  
253 which are important for ecological reasons) using LCM (2007). The slope of the terrain was  
254 then calculated from OS 1:10,000 scale Landform Profile data and areas with gradients <  
255 12% were considered as being most practical for growing crops such as SRC due to  
256 harvesting constraints ie. suitable for harvesting machinery to work (Tenerelli and Carver,  
257 2012). Areas of land that satisfied the land use and slope criteria and which fell in close  
258 proximity to a road (essential for coppicing machinery access) were selected (Defra, 2004).  
259 The total area of land available was then calculated and the number of available hectares  
260 determined. A yield potential of 12 odt (oven dried tonnes) ha<sup>-1</sup> yr<sup>-1</sup> was used to calculate  
261 potential annual electricity output as per the methodology in Gormally et al., (2012). Yield  
262 outputs were taken from Defra's (2007) study on Opportunities and Optimum Sitings for  
263 Energy Crops. A total of three fields covering approximately 13 hectares were selected,

264 giving a potential annual electricity output of 148.2 MWh yr<sup>-1</sup>. This would be suitable  
 265 feedstock for a 19KW generator.

266 Renewable energy supply-side options were also modified by societal acceptance. This  
 267 constrained both the technology choice and scale of technologies. Information gathered on  
 268 what the community would be willing to accept was taken from questionnaires and  
 269 interviews with residents (for more detailed information on outputs from this research see  
 270 Gormally et al., (2013)). The modification by societal acceptance will be detailed for each  
 271 scenario in section 3: ‘Scenario Selections and Results’.

272

273

Resource	Renewable Technology	Dataset	Source	Data Type	Time Period	Time Resolution

### 276 3. Scenario Selections and Results

277 Three exploratory scenarios were produced which narrate different possibilities of how the  
 278 case study community could balance local demand with different renewable energy supply-  
 279 side options. These considered pathways modified by societal and environmental  
 280 conditions. For all scenarios, demand and renewable supply contributions are shown  
 281 annually and monthly (not all the results can be shown here, however, highest and lowest

282 monthly contributions per scenario are highlighted in Table 2). Additionally, portfolio  
283 contributions were broken down into daily profiles. This was achieved specifically for a  
284 given winter week and summer week, to highlight seasonal weather dependencies. A single  
285 day from each week was chosen to show daily and hourly profiles, an example of which is  
286 shown for the 'Low Carbon Adjusted Society' scenario. Although this only provides an  
287 example, and there will inevitably be variability both between daily profiles and between  
288 different weeks, it demonstrates how demand could be compared to renewable supply  
289 options at finer temporal scales. The following will describe the scenario options and  
290 results. Figures 3 to 5 show annual, winter day and summer day profiles.

### 291 *3.1 Current State of Play*

292 This scenario assumed existing levels of local electricity demand and existing levels of  
293 renewable resource potential (base climate, 2011). Resource potential is then modified by  
294 societal acceptance, using results of local preferences to renewable technologies and  
295 scales. Details of the societal acceptance results can be found in Gormally et al., (2013). In  
296 this scenario we assume the portfolio of hydro-power (500KW), solar PV array (30KW) and  
297 small-scale wind (10KW). These options were chosen to provide a balance between  
298 providing some level of seasonally inter-changeable renewable generation (ie. as achieved  
299 on The Isle of Eigg) and residents' preference for specific renewable technologies. For  
300 instance, wind farms and bioenergy schemes appeared to hold least favour with residents  
301 in terms of perceived visual impacts, efficiency (wind farms) and land use issues  
302 (bioenergy). Consequently, only small-scale wind was included in this scenario and  
303 bioenergy was excluded.

304 Overall this mix contributed 11% annually to the community's electricity needs (Figure 3A).  
305 The highest monthly generation is achieved in December (at 14.9%). Although demand for

306 electricity is high in winter and the contribution from the PV array is negligible, demand is  
 307 offset by the high levels of electricity generation from the hydro-power turbine and wind  
 308 turbine. The lowest monthly generation is in March (at 7.5%) due to low performance from  
 309 all renewable sources.

310 This scenario was also explored for a typical winters day and summers day. On the winters  
 311 day, the generation from the chosen renewable mix generates double the community's  
 312 needs. Generation is dominated by hydro-power as a result of high winter river flows.  
 313 However, the same mix only contributes to 27% of the community's electricity needs on a  
 314 typical summers day. Although the solar PV array is now making a significant contribution,  
 315 low river flow and limited wind-power leave the community with a 73% electricity deficit.  
 316 Demand and supply-side pathways including an overview of annual, monthly and  
 317 winter/summer day examples, are illustrated in Table 2.

S1 - CURRENT STATE OF PLAY						
	> 30%	> 90%	> 100%	Average score (% contribution to local electricity needs)	High	Low
Annual	x	x	x	11%		
Monthly	x	x	x	11%	14.9 (Dec)	7.5% (March)
Winter day	yes	yes	yes	>100%	>100% (23:00 hrs)	>100% (08:00 hrs)
Summer day	x	x	x	27%	50.3% (03:00 hrs)	10.9% (20:00 hrs)
S2 - LOW CARBON ADJUSTED SOCIETY						
	> 30%	> 90%	> 100%	Average score (% contribution to local electricity needs)	High	Low

318

319 Table 2. Contribution to local electricity needs from the different renewable portfolio  
320 options for scenarios 1, 2 and 3.

### 321 *3.2 Low Carbon Adjusted Society*

322 This scenario considers the community's electricity supply and demand under favourable  
323 modifications. It assumes lower levels of demand and considers renewable energy supply  
324 under a modified climate (meteorological data from 'extreme' year 2008). The supply side  
325 is also modified by societal acceptance in that most renewable energy technologies are  
326 assumed to have become both economically and culturally acceptable. Therefore,  
327 bioenergy is additionally included in the renewable supply-side mix. Short rotation coppice  
328 (SRC) rather than Miscanthus is used because SRC had a higher yield potential across the

329

330 Figure 3. Annual plots for scenario A (Current State of Play), B (Low Carbon Adjusted) and C  
 331 (Reluctant Society), showing renewable electricity generation under modified conditions of  
 332 climate, demand and acceptance.

333

334 case study area (Defra, 2007). The portfolio of renewable energy technologies was  
335 subsequently hydro-power (500KW), solar PV array (30KW), small-scale wind (10KW) and  
336 SRC bioenergy (19KW CHP generator, assuming feedstock sourced from within the  
337 community).

338 On an annual basis this scenario contributed 46% to the community's annual electricity  
339 needs (Figure 3B). Other than the consistent monthly contribution from bioenergy, supply  
340 was once again dominated by hydro-power, however wind-power and solar PV also make a  
341 significant contribution. This is also complemented by the lower levels of predicted  
342 electricity consumption in this scenario.

343 August saw the highest levels of renewable electricity generation which accounted for  
344 73.6% of local electricity needs. February was the month which contributed the least to  
345 local electricity needs (35%). This scenario saw the winter and summer day profiles greatly  
346 exceed local electricity needs. For the winters day, supply was heavily dominated by hydro-  
347 power (Figure 4B). For the summers day it was a combination of higher summer river flows,  
348 the complementary mix of wind-power and solar PV and the lower levels of estimated  
349 electricity consumption (Figure 5B). It should be noted that although bioenergy was  
350 included in the renewables mix for this scenario (as seen on the annual contribution  
351 figures) it was excluded from the daily profiles. This is because it was difficult to determine  
352 how much feedstock would be used on an hourly basis. Considering the very high levels of  
353 renewable generation for the more 'immediate' renewable technologies such as wind,  
354 solar and hydro-power, it was felt that bioenergy would not be used on these days.

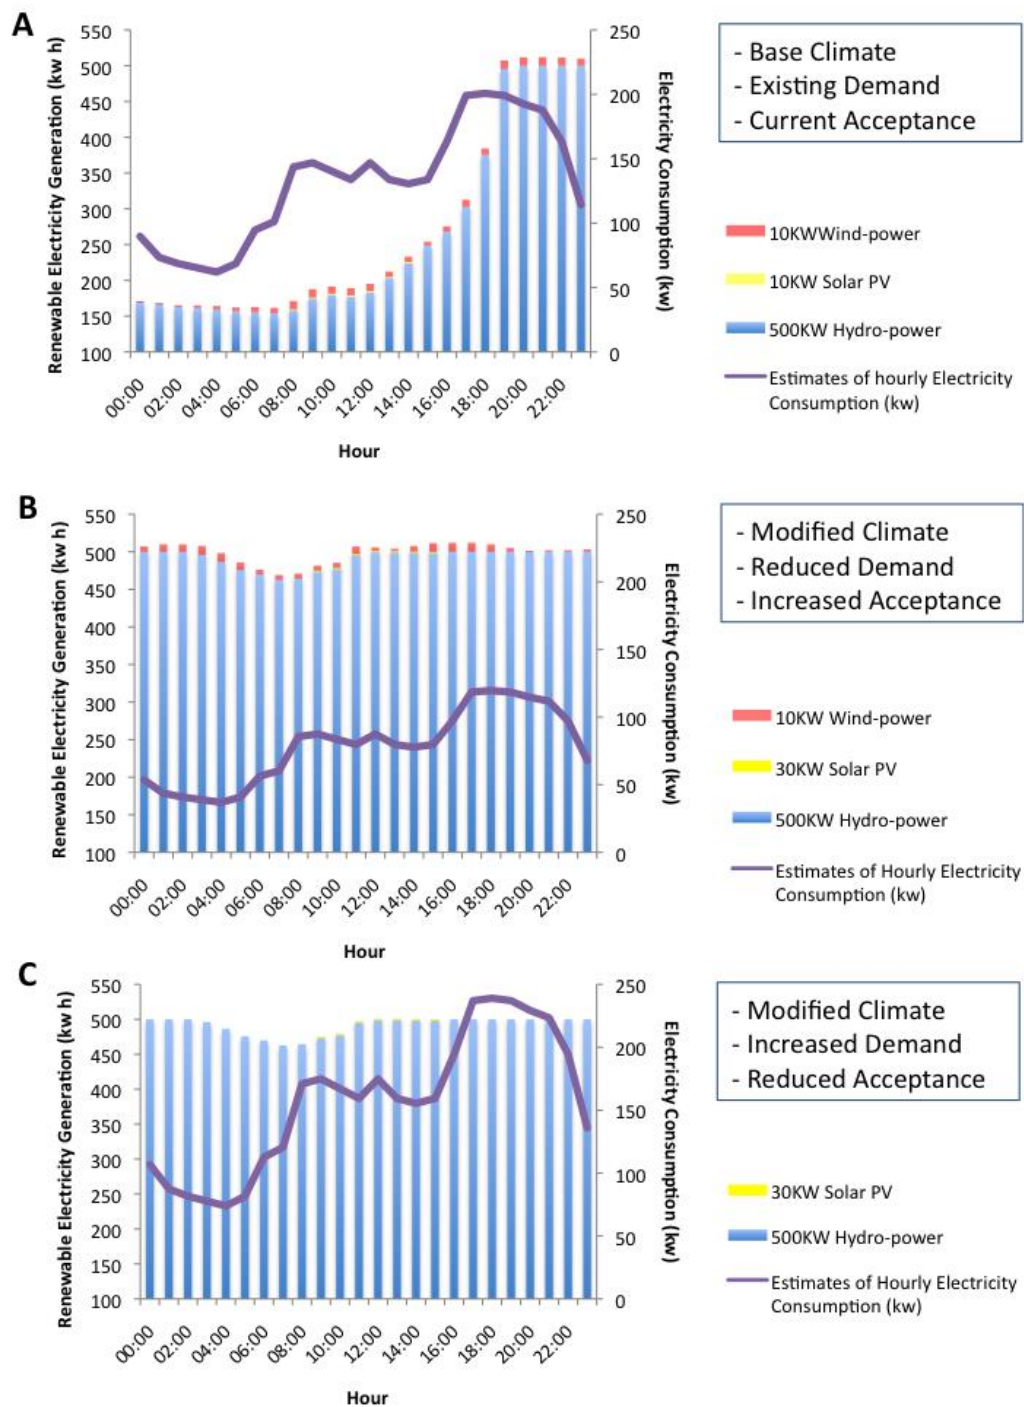

355

356

357            *3.3 Reluctant Society*

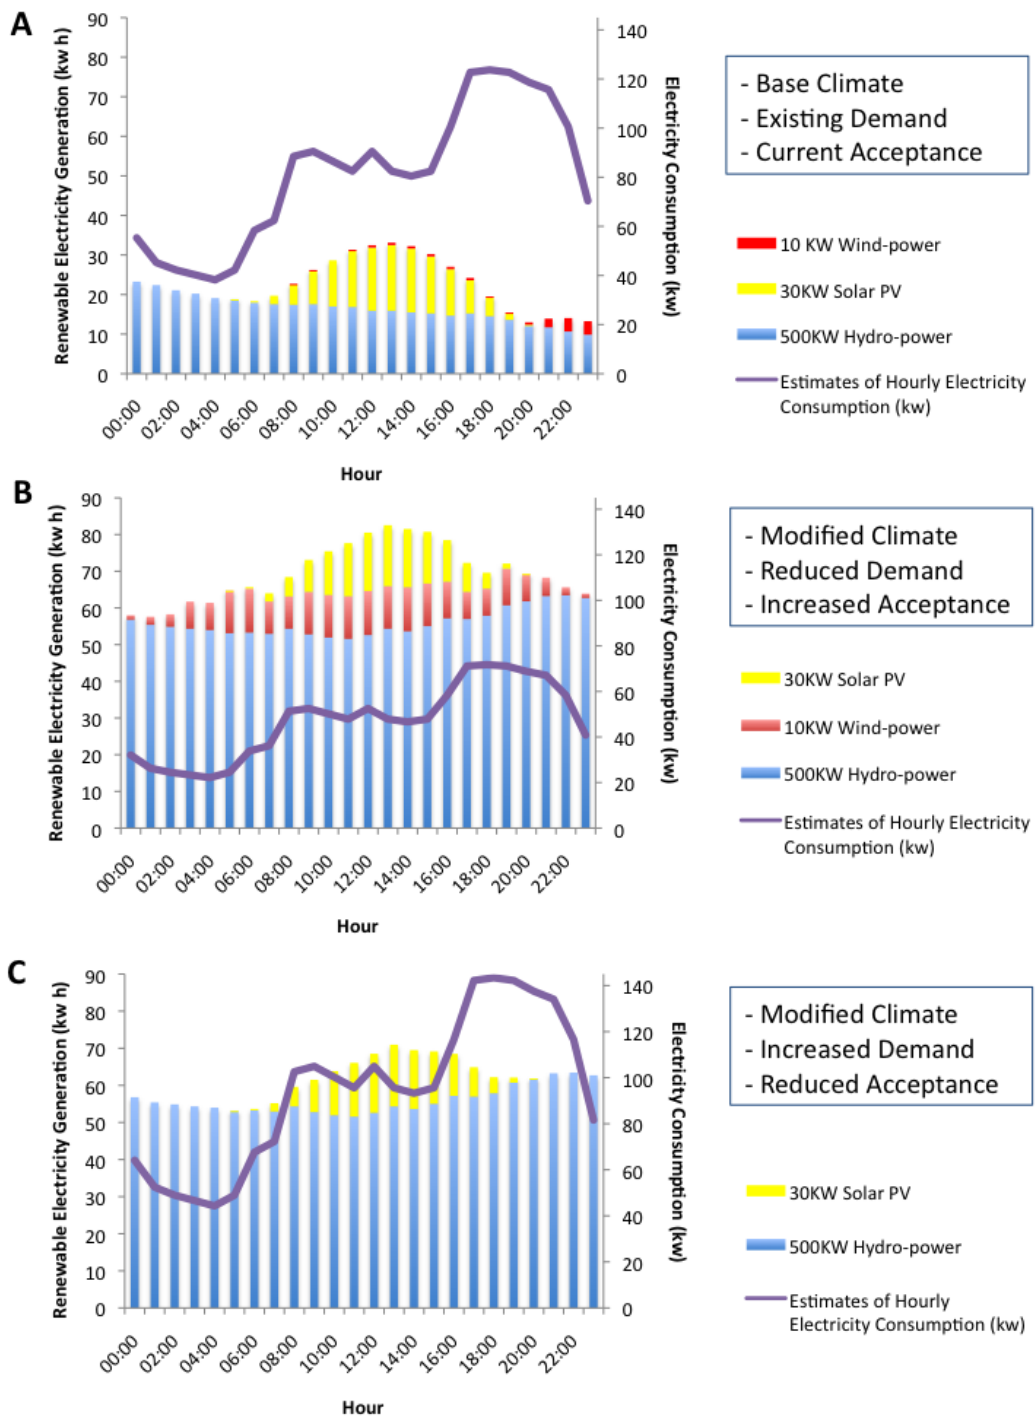

358    This scenario considers the community's renewable energy supply and demand under less  
359    favourable conditions. This scenario increases local demand and assumes a modified  
360    climate, under which societal acceptance to renewable energy technologies is considered  
361    low. The portfolio of renewable energy technologies chosen was subsequently hydro-  
362    power (500KW) and a solar PV array (30KW). Hydro-power was chosen because this was by  
363    some margin the most favourable renewable technology during the questionnaire and  
364    interview stage of phase 2 (Gormally et al., 2013). It was assumed that even in a scenario  
365    with societal reluctance towards incorporating renewable technologies, small to medium  
366    sized hydro-power would be considered acceptable. Solar PV was included in order to  
367    provide some level of seasonal mix and was considered to be the other most likely  
368    technology to be accepted under a reluctant future given its perception as a well  
369    developed technology in light of the growing numbers of households adopting solar PV  
370    occurring the in the UK (Cherrington et al., 2013).

371    Annually this mix contributed 8% to the community's electricity needs (Figure 3C). August  
372    saw the highest contribution (18.5%) and February the lowest (5.4%). This was again a  
373    balance between the output from the hydro-power and solar PV and the high estimated  
374    levels of local electricity consumption. The winters day profile saw an excess of renewable  
375    generation of more than 3 times local needs, dominated by the high winter flows and  
376    generation from the hydro-power (Figure 4C). The summer day profile saw a contribution  
377    of 66% to local needs (Figure 5C).

378

379 Figure 4. Winter day plots showing hourly renewable electricity generation compared to  
 380 consumption for scenarios A (Current State of Play), B (Low Carbon Society) and C  
 381 (Reluctant Society).

383 Figure 5. Summer day plots showing hourly renewable electricity generation compared to  
 384 consumption for scenarios A (Current State of Play), B (Low Carbon Society) and C  
 385 (Reluctant Society).

386

#### 387        **4. Discussion & Conclusions**

388        This paper set out to describe and explore the final phase of an interdisciplinary mixed-  
389        methods research project that has examined community-based renewable energy in  
390        Cumbria, UK. This final phase has produced exploratory energy scenarios for a specific  
391        community, Sedgwick in the South Lakeland area of Cumbria, which was identified as  
392        having significant resources to support a range of renewable technologies at the  
393        community-scale and was also found to have a high level of interest in the concept of local  
394        energy by residents (Gormally et al., 2012, Gormally et al., 2013). The exploratory scenarios  
395        considered how local demand could be matched with a portfolio of seasonal and weather  
396        dependent renewable supply-side options under existing conditions and modified futures.  
397        The results are contextualised by comparing results firstly to the UK's renewable electricity  
398        target (30-40% renewable electricity), then to the success on The Isle of Eigg (> 90%  
399        renewable electricity), and finally in relation to export of excess electricity to the national  
400        grid (> 100%).

401        In our regional-scale assessment of renewable resources we concluded that there were  
402        sufficient supply-side resources to provide a surplus of electricity to this community on an  
403        annual basis (based on existing levels of demand) (Gormally et al., 2012). Here, we find  
404        that when community preferences to renewable technologies and scales of development  
405        are incorporated at local scales, and when demand and supply are considered at different  
406        temporal scales, it is much harder to not only achieve a target of 90% or greater renewable  
407        electricity supply but also to achieve the national target of 30-40%, at the community-scale.  
408        Under the 'Current State of Play' scenario which considers existing levels of demand and  
409        incorporates local preferences to supply-side options, the downscaling of wind-power and  
410        the exclusion of bioenergy has a significant impact on the ability of the community to  
411        match demand with supply. It is only during the winters day profile that supply exceeds

412 demand and this is dominated by the significant level of river flow influencing hydro-power  
413 production. This is seen again in the Reluctant Society scenario, which excludes bioenergy  
414 and wind-power altogether but does consider the effects of a modified climate in terms of  
415 extreme river flows and a slight increase in local demand. The only positive effect from this  
416 scenario in terms of matching supply and demand is the increase in summer river flow  
417 influencing outputs from hydro-power in both winter and summer day profiles. The Low  
418 Carbon Adjusted Society scenario offers a more successful option by reducing levels of local  
419 demand, using a modified climate with extremes of river flow and incorporating bioenergy  
420 (SRC) into supply options. Under this scenario the community could source approximately  
421 half their electricity needs from the accepted portfolio of technologies, and become  
422 exporters to the grid on days of high generation, given the reduction in local demand.

423 At the beginning of this paper we set out to argue that under the right societal and  
424 environmental conditions, some on-grid communities in the UK could generate a significant  
425 proportion of their electricity needs by incorporating a portfolio of local renewable energy  
426 resources. The outcomes from previous work on annual resources in this area (Gormally et  
427 al., 2012), and the results from the scenarios reported here, would suggest that there is the  
428 *potential* for local resources to meet local demand. However, *realising* this potential in a  
429 way that is acceptable to the community is likely to be problematic. Of course, these  
430 scenarios only offer specific narratives of events determined by community attitudes and  
431 predictions of future climatic events. These narratives have imposed limitations on the  
432 scale of certain technologies eg. wind turbines, and have focussed on certain  
433 meteorological effects eg. river flow effecting hydro-power potential. Alternative scenario  
434 narratives could be developed, for instance, by increasing the size and/or scale of the  
435 generators or by incorporating the effects of changes in other meteorological resources

436 and their effects on renewable electricity generation. Equally, other scenarios of local  
437 demand could be used, for instance, demand patterns influenced by climate modifications.

438 However, what these scenarios do suggest is that unless on-grid communities have the  
439 pragmatic response to energy supply that off-grid communities have, they are currently  
440 unlikely to successfully integrate these types of renewable portfolios in a way which  
441 successfully matches demand with supply. Other measures would need to be incorporated,  
442 such as localised storage and/or some form of demand response measure. This currently  
443 poses difficulties for on-grid solutions with large-scale electricity storage expensive, and  
444 storage at the distributed level unconventionally aligned with existing infrastructures  
445 (Jardine and Ault, 2008, Grunewald et al., 2012). Local-level initiatives also offer up  
446 interesting questions surrounding management and regulation. Developments of this kind  
447 (variable output to the grid) and of this scale will also have implications for grid operators  
448 when trying to balance electricity flows around the national grid and in balancing supply  
449 with demand on a national scale (Wilson et al., 2010). Understanding the potential role  
450 that these types of on-grid community-based developments might have in the future is not  
451 only important when trying to envisage changes in future energy behaviours, but  
452 additionally when trying to connect these with the role of new energy infrastructures and  
453 the impact this will have nationally (and internationally) in configuring our future energy  
454 supply. Although on-grid community-based initiatives are on the increase in the UK as  
455 evidence by the new implementation of the Community Energy Strategy (DECC, 2014,  
456 Hargreaves, 2012), without the right co-ordination of economic, societal and  
457 environmental conditions, on-grid communities are unlikely to have enough incentive to  
458 become independent from the national grid. However, the concept of self-dependent  
459 electricity generating communities is interesting given the increased interest in locally

460 owned energy and the social reasoning behind that impetus, for example, disenchantment  
461 with current energy suppliers.

462 The approach described in this paper helps shed some light on the role of on-grid  
463 community-based renewable energy for a specific case study community in Cumbria, UK. It  
464 offers a way of assessing the contribution of renewable supply-side options to local  
465 electricity demand under different societal and environmental conditions and on a range of  
466 temporal scales. The methodology could also be adapted to incorporate the effects of  
467 climate extremes on local demand patterns in addition to supply. Future work could  
468 involve assessing the impact of localised energy storage and greater levels of demand-side  
469 management in balancing demand and supply at the local-level. Understanding these areas  
470 in greater detail would provide a better picture of the role on-grid community-based  
471 renewable energy could have in the UK and provide an evidence base on which to make  
472 future policy decisions in this area.

473 Cumbria holds many of the attributes associated with aspects of community energy that  
474 have been specifically addressed in this paper and previous work in this area, for example,  
475 diverse resources, range of community scales and evidence of climatic changes. (Gormally,  
476 et al., 2012 and Gormally et al., 2013). Other regions hold similar challenges in terms of  
477 understanding the role of community energy, but will hold different solutions. Other  
478 regions might have different resources to utilise, be experiencing regionally specific  
479 changes in climate and contain communities which hold different concepts of place. These  
480 differences would offer alternative options for communities to become 'energy  
481 independent' through utilising renewable portfolios. Future research could test out this  
482 hypothesis by replicating the methodological approach for alternative regions, both upland  
483 and lowland. This would provide a greater evidence base to help understand and inform  
484 the future role of community energy in the UK and its potential to become a significant part

485 of any future energy system. It could also be used to highlight relevant support that would  
486 need to be put in place if community-based renewables were chosen to be supported  
487 further in the future.

## 488 **5. Acknowledgements**

489 This research was funded as part of an interdisciplinary Ph.D. studentship from the UK  
490 Energy Research Centre and was supported by the UK Research Councils under the Natural  
491 Environment Research Council award NE/G007748/1. The authors would like to  
492 acknowledge the Environment Agency for the provision of hydro-power data, the British  
493 Atmospheric Data Centre (BADC) for weather data and those residents in Cumbria who  
494 generously gave up their time to participate in this study.
