Key words Instrumentation: spectrographs, Techniques: spectroscopic, Stars: abundances

From stellar spectra, a variety of physical properties of stars can be derived. In particular, the chemical composition of stellar atmospheres can be inferred from absorption line analyses. These provide key information on large scales, such as the formation of our Galaxy, down to the small-scale nucleosynthesis processes that take place in stars and supernovae. By extending the observed wavelength range toward bluer wavelengths, we optimize such studies to also include critical absorption lines in metal-poor stars, and allow for studies of heavy elements ($Z \geq 38$) whose formation processes remain poorly constrained. In this context, spectrographs optimized for observing blue wavelength ranges are essential, since many absorption lines at redder wavelengths are too weak to be detected in metal-poor stars. This means that some elements cannot be studied in the visual–redder regions, and important scientific tracers and science cases are lost. The present era of large public surveys will target millions of stars. It is therefore important that the next generation of spectrographs are designed such that they cover a wide wavelength range and can observe a large number of stars simultaneously. Only then, we can gain the full information from stellar spectra, from both metal-poor to metal-rich ones, that will allow us to understand the aforementioned formation scenarios in greater detail. Here we describe the requirements driving the design of the forthcoming survey instrument 4MOST, a multi-object spectrograph commissioned for the ESO VISTA 4m-telescope. While 4MOST is also intended for studies of active galactic nuclei, baryonic acoustic oscillations, weak lensing, cosmological constants, supernovae and other transients, we focus here on high-density, wide-area survey of stars and the science that can be achieved with high-resolution stellar spectroscopy. Scientific and technical requirements that governed the design are described along with a thorough line blending analysis. For the high-resolution spectrograph, we find that a sampling of ≥ 2.5 (pixels per resolving element), spectral resolution of 18 000 or higher, and a wavelength range covering 393–436 nm, is the most well-balanced solution for the instrument. A spectrograph with these characteristics will enable accurate abundance analysis (± 0.1 dex) in the blue and allow us to confront the outlined scientific questions.

1 Introduction

Spectra obtained in the near-ultraviolet to blue wavelength range ($300 \lesssim \lambda \lesssim 450$ nm) can carry a wealth of information. In stars, a blue colour can in-

dicating that the star is hot, metal-poor, or a combination of both. Most metals ($Z \geq 3$) have their strongest absorption lines in this wavelength region. The heavy elements ($Z \geq 38$) have their strongest, and sometimes their only absorption lines accessible from ground-based observatories, blue-wards of 430 nm (Cowan et al. 2002; Sneden et al. 2003). This region is

* Corresponding author: e-mail: cjhansen@dark-cosmology.dk

typically very crowded causing many severe line blends. Therefore, this region is often avoided in spectral analyses, as they require detailed and accurate line lists to allow for a precise chemical abundance analysis from the atomic and molecular features. Furthermore, high-resolution spectra are also needed to better resolve and separate the individual absorption features of the blending components.

Currently, there are only few high-resolution (i.e., $R = \lambda/\Delta\lambda \gtrsim 20\,000$), blue-to-near-UV sensitive spectrographs on large ground-based telescopes (≥ 4 m), namely the High-Resolution Echelle Spectrograph (HIRES) at the 10-m Keck telescope, the High-Dispersion Spectrograph (HDS) at the Subaru 8.2-m telescope, and the Ultraviolet-to-Visual Echelle Spectrograph (UVES) at the 8.2-m Very Large Telescope (VLT), all of which operate down to the atmospheric cut-off at ~ 300 nm. The MMT Advanced Echelle Spectrograph (MAESTRO) at the MMT¹ covers the UV spectral range down to ~ 315 nm, and on the same telescope, the Multi-object Hectochelle down to 380 nm. Finally, there are the Magellan Inamori Kyocera Echelle (MIKE) instrument at the 6.5-m Magellan telescope with a wavelength limit of 335 nm, and the High Resolution Spectrograph (HRS) at the 11-m South African Large Telescope (SALT) for which the bluemost observable wavelength is ~ 350 nm.

However, in order to answer some of the important open questions in astrophysics related to the origin and formation of the Galaxy as well as the creation of heavy elements (see Sect. 3), it is imperative to design more blue-sensitive, high-resolution, multi-object spectrographs. In particular, in old, metal-poor stars as typically found in the Galactic halo, we need to study the blue wavelength ranges to detect some of the heavy elements, as their redder lines are often too weak to be detectable. To address these questions, we carry out detailed studies on when absorption lines are detectable and useful in the blue spectral range for an abundance analysis.

The 4-metre Multi Object Spectroscopic Telescope (4MOST) will be a new fibre-fed instrument meant to simultaneously provide high- and low-resolution spectra. It is planned to be mounted at the VISTA telescope (Visible and Infrared Survey Telescope for Astronomy) at ESO's Paranal Observatory. Currently, 4MOST is in its Preliminary Design phase (see de Jong et al. 2014, 2012, for a detailed overview). It will carry out follow-up and extended observations for Gaia in addition to the large ongoing Gaia-ESO Survey (GES; Gilmore et al. 2012). The high-resolution spectrograph design of 4MOST also includes a green and a red arm, which lead to a wide spectral coverage (from ~ 390 nm to ~ 676 nm, including significant gaps; Ruchti et al. 2015, *subm.*), which allows for studies of substructure

in all major components of the Milky Way (MW), namely the disks, bulge, and halo. In addition, the instrument will simultaneously obtain spectra at lower resolution ($R > 5000$), and will pursue both Galactic as well as extragalactic studies. Within the Galaxy, the large number of low- and high-resolution fibres will provide spectra of up to 2400 stars spread over a field of at least 4 degrees² field in one single pointing. Hence, 4MOST envisions to target up to 30 million objects in its first survey of five year duration.

Ruchti et al. (2015, *subm.*) describe how the redder wavelength ranges ($\lambda \geq 450$ nm) of the 4MOST high-resolution spectrograph were optimized to maximize a versatile scientific outcome. Here, we focus on the scientific requirements of the high-resolution blue arm that drives the design, how its wavelength coverage is optimized for chemical tagging, and we describe blending issues that apply to every kind of spectrum densely populated by spectral lines.

This paper is arranged as follows: Section 2 sketches a concept design and highlights potential construction issues. Section 3 outlines the scientific drivers, Sect. 4 describes the scientific requirements such as wavelength coverage, resolution, sampling, and blending issues. Finally, the conclusion and outlook can be found in Sect. 5.

2 Constructing the blue arm of 4MOST

Fig. 1 Layout of the 4MOST HRS blue channel: common collimator optics, separation into three channels by dichroics (here only the blue channel is shown), followed by the VPH grating, and finally the camera.

The conceptual optical design and layout of the 4MOST High-Resolution Spectrograph (HRS) is presented in this section. We emphasize that the details of

¹ also known as Multiple Mirror Telescope

Table 1 Conceptual design specifications of the 4MOST HRS.

Components/Parameters	Values
Wavelength range	393-436 nm (blue) 516-572 nm (green) 610-676 nm (red)
Spectral resolution	> 18 000 (goal: 20 000)
Fiber core diameter	85 μm
Fiber separation	170 μm
Fiber output focal ratio	F3
Spectrograph beam size	250 mm
Collimator	Reversed off-axis Schmidt telescope
Grating	VPHG: 3586 1/mm (blue) 2836 1/mm (green) 2343 1/mm (red)
Camera focal ratio	F1.8
Detector	6K x 6K, 15 μm /pixel
Sampling (spatial direction)	3.4 pixels
(dispersion direction)	2.5 – 3.4 pixels
Gap between fiber images	3.4 pixels
Number of fibres	\sim 840

the design is conceptual, and the information provided is only intended to guide the reader. The HRS will have three channels covering the wavelength range from 392.8 to 675.5 nm; we will focus here on the blue channel covering the wavelength range from 393 to 436 nm.

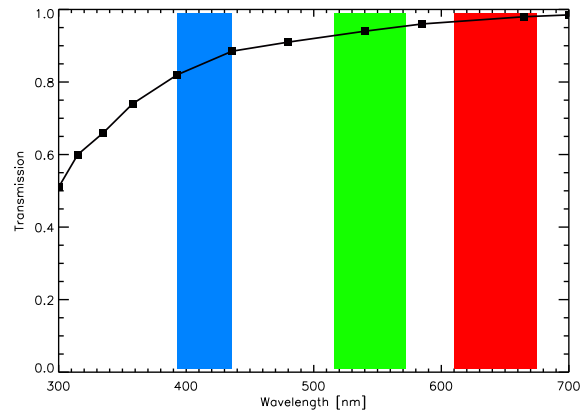

The main design parameters are given in Table 1 and the conceptual layout of the blue channel is shown in Fig. 1. Around 840 fibers can be injected in the HRS. After a common collimator optics, the light is split by dichroic filters into three separate channels to optimize the efficiency of the instrument. Volume-phased-holographic (VPH) gratings are foreseen to disperse the light in each channel. The camera optics for all channels is very similar, but not identical, and is also optimized for the wavelength range to be covered. As detector a CCD with 6k x 6k pixels is under evaluation. With this configuration, a minimum spectral resolving power of $R = 18\,000$ (goal: 20 000 – see also Sect. 4.1.1) is reached over the entire spectral range covered. The theoretical optical performance of the system is excellent. The mean value of the width that receives 80% of the energy is 0.7 pixel over all wavelengths and fields. The poorest value is obtained at the CCD edge and corresponds to 1.5 pixels. Thus, minimal degradation of the nominal resolution/spectral purity will occur.

In the blue wavelength range, the efficiency is a point that needs special attention. The total efficiency of the HRS blue channel, not including atmosphere and telescope, is given in Table 2. For a fiber-fed spectrograph such as 4MOST, the major limitation comes from the fiber throughput. Therefore, special measures are taken in the layout of the instrument at the telescope,

Table 2 Total efficiency of the blue channel not including effects from the atmosphere and telescope.

Component	Blue channel		
	393 nm	414 nm	436 nm
Fibers/Coupling	0.74	0.77	0.79
Collimator	0.95	0.95	0.95
Dichroic(s)	0.98	0.98	0.98
VPH grating	0.49	0.75	0.48
Camera	0.92	0.93	0.94
Detector	0.88	0.92	0.91
Total	0.27	0.46	0.30

such as to minimize the length of the fibers, which for 4MOST will be about 20 m. In Fig. 2, the internal transmission of a 4MOST fibre candidate for a length of 20 m is shown with the HRS wavelength ranges indicated. While the throughput is well above 90% for the green and red ranges, it drops to a mean value of about 85% in the blue range.

**Fig. 2** Expected throughput for a fibre candidate to be used in 4MOST with a length of 20 m. The curve shown is only internal transmission, no coupling losses are included. The boxes indicate the wavelength ranges for blue the ($\lambda \sim 400$ nm), green ($\lambda \geq 500$ nm), and red ($\lambda \geq 600$ nm) channel, respectively.

A typical, indicative detector quantum efficiency is shown in Fig. 3. There are several very efficient coatings for the detector, giving a high efficiency over the full HRS wavelength range: a coating candidate is illustrated in Fig. 3, which in the blue yields an efficiency close to 90%. For the VPH grating, the theoretical efficiency was calculated and a contingency factor of 0.9 applied, yielding a conservative estimate. The throughputs of the common collimator, dichroics and camera are summarized in Table 2. A peak efficiency of 46% is expected, with 27%/30% at the ends of the blue wavelength range.

Fig. 3 Indicative detector efficiency for 4MOST HRS on the basis of a typical $6\text{ k} \times 6\text{ k}$ chip and a candidate coating. The boxes indicate the wavelength ranges (as in Fig. 2) for the blue, green, and red channel, respectively.

3 Science drivers for the blue region

The Milky Way (MW) provides a unique study case for the formation of barred spiral galaxies. Detailed information on the formation history can only be accurately extracted from stars in our Galaxy, constraining models of spiral galaxy formation. The understanding of the involved physical processes can then be generalized to other galaxies that are too distant to be studied with the same accuracy.

Of particular importance in such studies are the chemical abundances of individual stars. For example, the α -elements (such as O, Mg, Si, Ca, and Ti) provide information on whether or not the star was likely formed in situ or brought into the Galaxy after a merger event with dwarf galaxy-like objects (e.g., Koch 2009; Nissen & Schuster 2010; Searle & Zinn 1978; Venn et al. 2004). The general low star formation efficiencies in the low-mass dwarf galaxies and the ensuing paucity of the α -producing Type II Supernovae (SNe) at the time the Fe-producing SNe Ia start to contribute leads to a low α /Fe-ratio (e.g., Adén et al. 2011; Koch et al. 2008; Shetrone et al. 2003), in contrast to the rapid enrichment the halo experienced creating higher $[\alpha/\text{Fe}]$ abundances (e.g., Nissen & Schuster 2010; Ruchti et al. 2014).

At low metallicity ($\lesssim -2$ dex) the low-luminosity dwarf galaxies (e.g., Gilmore et al. 2013; Koch & Rich 2014) share the same enhancement in α -elements as is seen in Galactic halo stars (e.g., Cayrel et al. 2004). However, this is not the case at higher metallicities, where the stars in the dwarf galaxies tend to show lower α -abundances compared to the Galactic stars. Furthermore, understanding the assembly history of our Galaxy also benefits from mapping the dynamics of important Galactic substructures through stellar

kinematical analyses. Thus tracing, e.g., stellar streams from disrupted satellites in phase space, ancient disruption events that are still coherent in velocity space can be efficiently recovered. In turn, these accurate kinematic tracers, such as streams and stellar velocities, are a requirement to constrain the mass distribution of the Milky Way and the shape of its dark matter halo (e.g., Koposov et al. 2010; Williams et al. 2011).

Altogether, this will also enable a characterization of the progenitor systems such as their mass, luminosity, star formation rate, and chemical enrichment histories. In particular old, metal-poor stars will provide a better understanding of the early formation and chemical evolution of the Galaxy. This outlines the importance of accurate dynamics and abundance studies, for which high-resolution spectrographs are needed (see also Lindegren & Feltzing 2013). Hence, high-resolution stellar spectra yielding radial velocities and elemental abundances will characterize a variety of features from the nuclear formation processes that created the elements to shed light on large-scale galaxy formation scenarios.

The stellar halo is the largest (yet least massive) component in the MW. There is growing evidence from kinematical and chemical abundance studies that it consists of two distinct subcomponents, an inner and an outer halo (Carollo et al. 2007; Nissen & Schuster 2010), although these results are still being debated (Schönrich et al. 2011). These two components are separated in their kinematics and elemental abundances, in particular iron abundances, from which a metallicity distribution function (MDF) can be calculated². Studies have shown that the outer halo is characterised by metal-poor stars ($< [\text{Fe}/\text{H}] > \sim -2.2$) on retrograde orbits, indicating that these stars were accreted from other galaxies, while the inner halo stars ($< [\text{Fe}/\text{H}] > \sim -1.6$) show prograde orbits, implying that they formed in situ (Carollo et al. 2007). A deeper, large survey of stars in both the inner and outer halos is needed to improve our current, incomplete understanding of hierarchical galaxy formation, and metal-poor stars play a crucial role for understanding this. 4MOST will consist of low- ($R \sim 5000$ with a goal of 7500) and high-resolution ($R \sim 18\,000$; goal 20\,000) spectrographs that are optimal for finding metal-poor stars with $B > 17.5$ mag, and acquiring high-resolution spectra of promising metal-poor candidates down to $B = 16$ mag.

In general, the halo is thought to be the Galactic component containing the oldest stars, and they are metal-poor. Recently, also metal-poor stars in the direction of the bulge have been found (Howes et al. 2014), and its old age has been demonstrated in Clarkson et al. (2008). The spectra of these metal-

² This MDF agrees with the one obtained from low-resolution metallicity indicators such as the Ca triplet or the Ca HK lines.

poor stars show very few detectable metal lines (Christlieb et al. 2004; Hansen et al. 2014b), and some of the strongest lines, still detectable in metal-poor stars, are found in the blue spectral region. In order to extract the maximum possible information from these metal-poor halo stars, a blue wavelength range is essential.

This is particularly true for the absorption lines of the heavy elements, as most of these lines are found below ~ 430 nm (Cowan et al. 2002; Sneden et al. 2003). They provide important tracers of elements created by the neutron-capture processes. There are two main channels for creating neutron-capture elements; the rapid and slow neutron-capture process. The exact physics and sites of these processes are poorly constrained, and this emphasises the need for abundances of heavy elements from blue high-resolution spectra, to map these processes observationally (see, e.g., Hansen et al. 2014a,b, 2012; Hansen & Primas 2011; Sneden et al. 2008).

Additionally, the blue range contains numerous elements useful for chemical abundance analyses of stars with $[\text{Fe}/\text{H}] \leq -1$, but this range can also be used for chemical analyses of more metal-rich stars. The blue spectral range hosts not only transitions of neutron-capture elements, but also lines from elements belonging to each of the following groups: α , odd- Z , (in)complete Si-burning, and Fe-peak elements, making this a crucial wavelength region for chemical tagging. Furthermore, the blue range $\lambda < 450$ nm contains the $A^2\Delta - X^2\Pi$ G-band of CH, which can be used to detect carbon-enhanced metal-poor (CEMP) stars³, and to determine their carbon abundances. Combined with the s -process elements (e.g., Sr, Y, Zr, Ba, La) and r -process elements (e.g., Eu, Nd), the blue spectra thus serve to classify CEMP stars into $-s$, $-r$, $-rs$, and $-no$ subgroups through their heavy element abundances (e.g., Bisterzo et al. 2012; Masseron et al. 2010). This is important, as many (20–40% or more; Beers & Christlieb 2005; Lee et al. 2013; Lucatello et al. 2006; Placco et al. 2014) of the extremely and ultra metal-poor stars are enhanced in carbon, and almost all the ultra Fe-poor stars are enhanced in carbon (Bonifacio et al. 2015; Christlieb et al. 2004; Frebel et al. 2007; Hansen et al. 2014c; Keller et al. 2014; Norris et al. 2007). Understanding how these stars form is key to understanding how the early halo was enhanced in metals, and this in turn will place constraints on the physics of the formation of the first few generations of stars in the Universe.

All of the above underlines the need for spectrographs sensitive at blue wavelengths ($\lambda \lesssim 450$ nm),

³ Metal-poor stars with $[\text{C}/\text{Fe}] > 0.7$ according to (Aoki et al. 2007).

and 4MOST would only be the eighth spectrometre⁴ sensitive in the blue.

4MOST also envisions a low-resolution mode ($R = 5000\text{--}7500$) to cover a broad range of Galactic science goals. Many of these differ from the high-resolution science cases, so we will only briefly comment on the science facilitated by the blue region of the low-resolution setting.

Even though the blue region can be used for chemical tagging of more metal-rich disk stars, this region is suboptimal owing to the extreme line blending in the blue region in metal-rich stars (see Sect. 4.3.1 - 4.3.2 for details on line blending). Therefore, chemical abundance analyses of metal-rich Population I stars are generally conducted at redder wavelengths. Moreover, radial velocities can also be determined from blue spectra of metal-rich disk stars, but again due to the large number of heavily blended and unresolvable lines, leading to more uncertain measurements, the redder regions of the low-resolution mode of 4MOST, such as the region around the near-infrared Ca triplet lines, are preferred for this purpose.

An important driver for the blue, low-resolution spectrograph is the detection and first characterization of hyper metal-poor stars⁵ in the MW halo. Here, the blue region of choice (goal) comprises 390–543 nm, to include the Ca H and K lines (at $\lambda = 397$ nm and 393 nm, respectively) as the strongest lines that remain detectable at these low metallicities. The Ba II 455.4 nm line is an important tracer of neutron-capture processes, in particular of the earliest nucleosynthesis in the Universe, as it remains measurable down to extremely low metallicity in most stars at the low resolution planned for 4MOST. This line will help us subclassify the CEMP stars and, in turn, place constraints on their formation scenario. The red wavelength cut of this region is set by the Mg b triplet and the molecular CN-bands. Depending on the effective temperature and carbon-enhancement, also the G-band of CH (431 nm) remains detectable; it can be used for inferring C abundances to a precision of up to ± 0.2 dex. Note that the Ca H and K lines can also serve as a measure of stellar activity in young stars.

⁴ Only UVES is accessible to the entire astronomy community, while all other high-resolution spectrographs listed above are restricted-user access instruments. This would make 4MOST the second instrument with a blue arm that will be globally available.

⁵ Following the definitions in Beers & Christlieb (2005) these stars have $[\text{Fe}/\text{H}] < -4$.

4 Scientific requirements to the blue instrument

4.1 Sampling and resolution

The spectral resolving power, $R = \lambda/\Delta\lambda$, and sampling s (pixels per resolving element) are amongst the most important quantities that drive the design of a spectrograph, and the science that can be achieved. In order to determine optimal values, taking into account technical as well as financial boundary conditions, we followed an approach similar to that outlined in Caffau et al. (2013). In the following we will only give a brief summary of our procedure, while our detailed tests will be presented in a forthcoming paper.

4.1.1 Synthetic lines and parameter space

First, we synthesized a Gaussian line profile, centered at λ_0 , of given equivalent width (EW) and Full Width at Half Maximum (FWHM) at initially very high sampling over a continuum level of unity. The FWHM is chosen to be the resolution element (RE) of the spectrograph, so that the resolving power of the simulated spectrum can then be expressed as $R = \lambda_0 / \text{RE} = \lambda_0 / \text{FWHM}$ [nm]. Next, the sampling of the simulated spectrum is degraded to a varying number of pixels per RE, and Poisson noise is injected to mimic different signal-to-noise ratios (S/N). The goal is to find a minimum set of requirements, that will still allow us to derive abundances with an uncertainty of ± 0.1 dex or better. This corresponds to a relative EW uncertainty of 0.22–0.25⁶.

For testing purposes, we ran 10 000 Monte Carlo realizations with a fixed S/N of the 256 different combinations of each of the parameters in steps of: EW = (1.25, 2.5, 5, 10) pm; R = (15 000 – 23 000); s = (1 – 4) pixels/RE; and S/N = (50, 60, 75, and 100 per pixel, or 154, 185, 231, 308 per \AA ⁷). This test was performed to explore the parameter space, and following find a set of useful parameters to explore in more detail. In each of the Monte Carlo trials, the position of the resampled pixels was rigidly shifted by a random (linear) amount of up to ± 0.5 times a resampled pixel with respect to the default value. This is to ensure that the position of the line center is different each time with respect to the positions of the resampled pixel, so as to avoid biases due to constant line-pixel offsets.

4.1.2 Line measurement, optimal resolution and sampling

The resampled and noise injected lines were evaluated by fitting a Gaussian line profile within $\pm 3 \times \text{RE}$ around the nominal line center. The continuum level, in turn, was estimated in two windows of $5 \times \text{RE}$ s width and located at $\pm 4 \times \text{RE}$ from the line center.

The first tests showed that a sampling of 1 pixel/RE is simply too low to retrieve abundances within the required accuracy, and we find that the sampling needs to be between the lower limit of 2 (Nyquist sampling) and 3 pixel/RE.

After exploring the parameter space, a more detailed test was carried out on the constrained set of promising parameters using finer steps compared to the aforementioned first test. Figure 4 shows our results (using the restricted sampling of $s = 2$ and 3 pixel/RE) in terms of the relative EW measurement uncertainty, $\sigma_{\text{EW}}/\text{EW}$, as a function of the tested resolution. A line of 25 m \AA was chosen to mimic a weak line such as the 670.6 nm Li line.

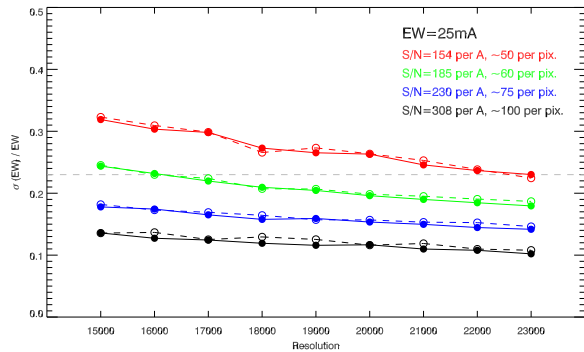

Fig. 4 Relative EW uncertainty vs. resolution for different rates of S/N ratio, and a sampling of 2 and 3 pixel/RE for the filled and open circles, respectively. An indicative relative EW uncertainty is plotted as a dashed, grey line.

Imposing our requirement that lines need to be measured to a precision of ± 0.1 dex elemental abundance to perform meaningful science for Galactic archaeology, and that the S/N should be obtainable within a reasonable exposure time (e.g., $S/N=170$ per \AA or 55 per pixel), a trade off must be made. In conjunction with the preliminary instrument design, we chose the value of 2.5 pixel/RE as a compromise⁸. This leads to our final specifications, namely:

⁸ We set a goal of 3 pixel/RE instead of the Nyquist-optimal of 2 pixel/RE to maintain resilience against CCD cosmetics defects that may fall over a measured line. Dispersion variations along the spectral range can make sampling locally worse, so here we assume 2.5 pixel/RE as a compromise.

⁶ for weak lines and less for strong or partly saturated lines.

⁷ we used $S/N_{\text{pixel}} \propto S/N_A \sqrt{\frac{\lambda}{R \cdot s}}$ and we calculated the S/N per \AA for this specific example with a fixed value of $s = 2.1$, $R = 19\,000$, and $\lambda = 4200\text{\AA}$.

- $R > 18\,000$ everywhere in the covered wavelength range;
- a sampling of at least 2.5 pixel/RE (goal: 3.0 pixels/RE).

The adopted (goal) abundance uncertainty of 0.1 dex is a value that, provided we have accurate atomic physics input, is well documented. It arises as a typical uncertainty owing to the influence from the stellar parameter uncertainty. This has been tested in great detail for 18 elements (see Table 6 and 7 in Cayrel et al. 2004). In Sect. 4.3.2 we will investigate how this uncertainty affects the usefulness of blends.

4.2 Selecting and optimizing the blue wavelength range

In order to fulfil the science requirements for the 4MOST high-resolution survey focussing on the halo, elements from each major group (α -, odd-Z, iron-peak, and neutron-capture elements) should be included in the covered wavelength range. Such elements can be efficiently measured from absorption lines in the blue range of metal-poor halo stars, whereas in more metal-rich stars from the disks and bulge, a redder wavelength region is preferred owing to fewer line blends (Ruchti et al. 2015, *subm.*). As part of the 4MOST requirements, we want to be able to derive accurate abundances (0.1 dex uncertainty) from several elements belonging to each group. Here we test the 390–460 nm (goal) region and require that each absorption line reaches 0.9 in residual flux, to be detectable even in noisy spectra.

Synthetic spectra were created with the MOOG synthetic spectrum code (Sneden 1973, version 2010), in conjunction with the MARCS stellar atmosphere models (Gustafsson et al. 2008) matching the stellar parameters listed below. A line list downloaded from the VALD database (Kupka et al. 2000) was used for this purpose. Several transitions in the line list were checked and updated with the atomic data given in NIST, and Cowan et al. (2002), Sneden et al. (2003), and McWilliam et al. (1995). The two first mentioned studies focus on heavy elements, while McWilliam et al. (1995) provides lists of both light and heavy elements and shows the detectability of numerous elements observed in various stars at a resolution matching that of the 4MOST HRS. The goal is to obtain a set of useful, detectable absorption lines of: Mg, Al, Si, Ca, Mn, Fe, Co, Ni, Sr, Y, Zr, Ba, and Eu. To probe the detectability, we inspected synthetic spectra in which all abundances are scaled to Solar (i.e., [element/Fe] = 0.0). We target lines that are as clean as possible, reaching the aforementioned 0.9 in residual flux, and we avoid saturated lines, to ensure that the lines are suited for chemical abundance analyses. This means that we need at least a S/N of about 30 (per pixel) to ensure 3σ detec-

Fig. 5 Detectable lines in the blue wavelength range in dwarfs (5500 K/4.0/-1,-2,-3/2.0 km s⁻¹ - dashed, black line) and giants (4500 K/2.0/-1,-2,-3/2.0 km s⁻¹ - solid, red line). Only a few Fe lines have been shown for simplicity. The yellow region indicates lines that could be lost, if the star has a strong G-band.

tions. In Fig. 5, we show the detectability in a typical dwarf and giant star as a function of metallicity, where the stellar parameters ($T_{\text{eff}}/\log g/[\text{Fe}/\text{H}]/V_t = 5500/4.0/-1, -2, -3/2.0\text{km s}^{-1}$, and $4500/2.0/-1, -2, -3/2.0\text{km s}^{-1}$, respectively) have been tested. These stellar parameters are consistent with the study of Caffau et al. (2013).

Furthermore, also the radial velocity needs to be known to better than $1 - 2\text{km s}^{-1}$, a value that was set to be able to accurately trace kinematic substructures such as streams from disrupted satellites in phase space. In this way, ancient disruption events that are still coherent in velocity space can be efficiently recovered. Finally, as we will see in Sect. 4.3.2 an accurate radial velocity is also important to recover abundances for blended lines.

For finding the optimal wavelength range, a trade off between an as large as possible number of included lines on one hand, and fibre efficiency and the costs of the blue arm of the instrument on the other hand, has to be considered. Taking these constraints into account, we arrived at the wavelength region 393–436 nm (after scanning the entire goal region: 390–460 nm). This range ensures that at least one element of each element group is detectable, and can be measured in either dwarfs, giants, or both, at the required 4MOST resolving power of $R > 18000$.

A few elements (Ni, and Ba) cannot be measured at this resolution in this range⁹, and we need to use lines from the green and red wavelength ranges (Ruchti et al. 2015, subm.). However, in addition to the elements listed above, the blue range also offers a large number of other elements such as C (CH), Sc, Ti, Cr, La, Nd, Ce (illustrated in Fig. 5).

With a considerable number of both lighter and heavy elements well represented in the blue wavelength range, we can use the 4MOST spectra to accurately map the fossil gas in old stars. Our optimized range will also provide a considerable number of Fe and Ti I and II lines (minimum 7 and 5, respectively, covering excitation potentials of $\sim 1 - 3\text{eV}$), needed for determining effective temperatures via excitation equilibrium, and surface gravities via ionisation equilibrium. Only the cleanest Ti and Fe lines are shown in Fig. 5 for the sake of clarity. This means that the blue region can, on its own, provide sufficient information needed for a full spectrum analysis. This is especially the case in metal-poor stars at $[\text{Fe}/\text{H}] \lesssim -1$, and the total number of clean lines will increase when including the green and red wavelength ranges, as envisioned for 4MOST.

The HRS blue wavelength range was also set such that key elements like Al, Y, Sr, and CH (plus continuum redward of the band head), which are located at the edges of the wavelength range, would remain inside

Table 3 List of lines (elements, Z) tested for detectability in dwarfs/giants at $[\text{Fe}/\text{H}] = -1, -2, -3$. The ‘worst’ losses are indicated with ‘*’. Columns three and four fall outside the covered wavelength range.

⁹ That is, unless the star is enhanced in either of the elements or if the range is extended to $\sim 460\text{nm}$ (goal region).

the observed range even for high radial velocity stars which are common in the Milky Way halo. A wavelength piece of $\sim 20 \text{ \AA}$ is required in the beginning and end of the wavelength range before/after the first/last line of interest. This allows for loosing $5\text{--}10 \text{ \AA}$ in the beginning of the spectrum to noise and even in stars with radial velocities of $\gtrsim 1000 \text{ km s}^{-1}$, we will still be able to get clean detections of Al in their stellar spectra.

The lines checked in the blue range can be found in Table 3. Several of the weak lines may be detectable or useful if the star is enhanced in the element, or if the S/N ratio is larger than 30–50 per pixel. Not all the weak lines have been listed, as the line list contains more than 4000 lines, most of which are too weak to be detected in several of the tested stellar spectra at this resolution and S/N ratio.

4.3 Blending issues

The blue part of the spectrum is a very crowded region, and as such, most absorption lines blend into each other. To investigate how strongly blended two lines can be, and still be useful for abundance determination, we start by investigating the idealized problem of fitting two lines with Gaussian profiles, $G(\lambda) \sim a \cdot \exp\left(-\frac{1}{2} \left(\frac{\lambda - \lambda_0}{w}\right)^2\right)$. The goal is to obtain a relation between the line separation and the EW uncertainty resulting from the mutual blending. Following, we test this theory using synthetic spectra mimicking those from the future 4MOST HRS.

4.3.1 A simple model of a two line blend

In this and the following subsection, we consider two weak lines (a, b) with Gaussian line profiles, and we assume that there are no other blending lines interfering with our tests. Furthermore, we assume that the stellar parameters, atomic data, and radial velocity are perfectly constrained, so that the line centres are at the rest wavelength. We want to find the minimum line separation needed to fully recover the abundances of two blended lines.

We consider two lines in a normalized spectrum characterized by two profile functions $A \geq 0$ and $B \geq 0$, scaled by amplitudes a and b , respectively. We assume that the spectrum is sampled at m points, and that the noise in each pixel is independently normally distributed with inverse S/N ratio n . We represent the lines in “depression format”, i.e. fitting the flux difference to the continuum. The data model F of the spectrum is in this case

$$F(\lambda) = aA(\lambda) + bB(\lambda) \quad (1)$$

where λ is the wavelength. We want to determine the amplitudes (a , b) scaling the line profiles of the observed data to be fitted f_i . Later, we specifically assume Gaussian profile functions (A , B) of given widths

(w_a , w_b) at wavelength positions (λ_a , λ_b). We determine a and b by maximum likelihood (hereafter ML) estimation. The problem is linear in a and b and we obtain as condition for a at the maximum of the (log) likelihood L

$$\frac{\partial L}{\partial a} = \sum_{i=1}^m \left(\frac{f_i - F_i}{n^2} \right) A_i = 0, \quad (2)$$

with the analogous relation for b .

We determine the uncertainties of a and b in the standard way from the inverse of the Fisher information matrix of the problem and obtain

$$\sigma_a^2 \geq 2 \cdot n^2 \frac{\sum_i B_i^2}{\sum_{i,j} (A_i B_j - B_i A_j)^2}, \quad (3)$$

and

$$\sigma_b^2 \geq 2 \cdot n^2 \frac{\sum_i A_i^2}{\sum_{i,j} (A_i B_j - B_i A_j)^2}. \quad (4)$$

As expected, the standard deviations scale inversely proportional to the S/N . Strictly speaking, relations 3 and 4 give only lower (the Cramér-Rao) bounds of the variances of a and b . However, ML estimators are efficient and usually get close to the Cramér-Rao bound, so that we consider the lower bounds as actual uncertainties.

We are interested in how the S/N ratio influences the accuracy to which the individual amplitudes a and b can be measured to ultimately obtain an estimate of the associated uncertainties in the derived elemental abundances. The problem of determining the EW of a blended line can be separated into determining the isolated clean line’s uncertainty stemming from noise, and finding a geometrical factor describing the blending configuration. When fitting a *single line in isolation* our simple model gives an uncertainty of the amplitude a' (assuming a profile function A)

$$\sigma_{a'}^2 \geq n^2 \frac{1}{\sum_i A_i^2}. \quad (5)$$

To have simple analytic expressions at hand, we now approximate the sums in the variances by integrals assuming Gaussian line profiles of a given, unique width ($w_a = w_b \equiv w$). For that, we have to assume a sufficiently fine sampling of the line profile, similarly to what was done in the derivation of Cayrel’s formula (Cayrel 1988). We obtain for the uncertainties σ_a^2 and $\sigma_{a'}^2$ the relation

$$\begin{aligned} \sigma_a^2 &\approx \sigma_{a'}^2 \left(1 - e^{-\frac{1}{2} \left[\frac{\lambda_a - \lambda_b}{w} \right]^2} \right)^{-1} \\ &\approx \sigma_{a'}^2 \left(1 - e^{-2.77 \times \left[\frac{\lambda_a - \lambda_b}{\text{FWHM}} \right]^2} \right)^{-1}. \end{aligned} \quad (6)$$

Interestingly, equation (6) states that the detrimental effect of blending is independent of the strength of the blending line as long as it remains on the linear part of the curve of growth. This is in agreement with the

findings in Cayrel et al. (2004), where the σ_{EW} is independent of EW. A penalty is already incurred when trying to fit two lines when there is in fact only one.

For our Gaussian line profiles, the equivalent width, EW , is given by $EW = \sqrt{2\pi}aw$, so that error propagation gives $\sigma_{EW}^2 = 2\pi w^2\sigma_a^2$. This means that equation (6) can also be interpreted as a relation between the uncertainties of the EW of a blended line to the corresponding value in isolation.

We checked our result by Monte-Carlo (MC) simulation using two weak lines of the same strength with $a = b = 0.1$. Figure 6 illustrates the result of 1000 noise realizations. The MC test confirms that the σ_{EW} is independent of EW (and therefore of line strength) for weak lines. For the MC run we chose a rather coarse (step size $\Delta\lambda = \text{FWHM}/2$) sampling, to show that the sampling is not particularly important for the validity of the analytical result – as long as it is not overly coarse. We note that the way we set-up the MC run leads to correlated noise among the various S/N cases. This explains that shifts relative to the analytical result appear the same for all S/N. All events for a particular S/N are independent. To double σ_{EW} in comparison to the case in isolation one needs a blending line as close as

$$\begin{aligned} \Delta\lambda_{\text{double}} &= \sqrt{2\ln(4/3)}w \approx 0.759 \cdot w \\ &\approx 0.322 \cdot \text{FWHM} \end{aligned} \quad (7)$$

At this separation two Gaussians appear essentially like a single one. If we instead look at the separation needed in order to derive abundances with an accuracy of 0.1 dex or better, the necessary separation is $\sim 0.6 \times \text{FWHM}$. This value should be compared to the tests conducted and described in the next section.

It might appear surprising that blended components can be separated to a distance of $\approx 3/5 \times \text{FWHM}$ according to the simple model presented in this section. However, the key property which makes this possible is the a-priori knowledge of the width of an isolated line. Close blends can be identified by a certain degree of additional broadening beyond what is expected for an isolated line. Conversely, the separation becomes more difficult when the intrinsic line width is not, or only approximately, known.

In the next section we test this in practice, but we also change perspective and address the question of what happens if uncertainties in the wavelength calibration or measured radial velocity lead to changes of the position of a blend with respect to the expected position based on the laboratory rest wavelengths of the blending components.

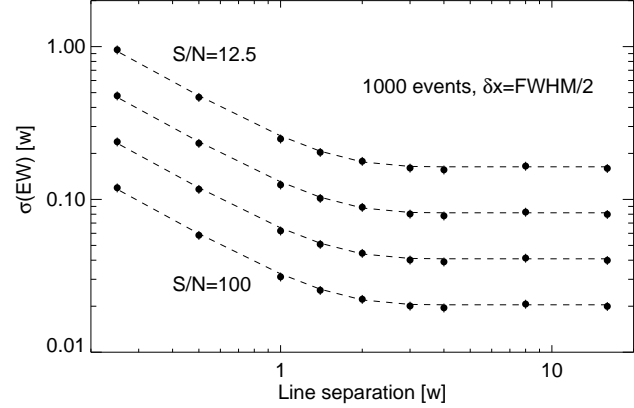

Fig. 6 Uncertainty σ_{EW} of one component in a blend of two Gaussian components as a function of their separation (both given in units of w). The analytical result according Eqs. (6) is depicted by the dashed lines, results of a Monte-Carlo simulation by solid dots. $\pm 3\sigma$ error bars (so small that they are barely visible) indicate the uncertainty of the Monte-Carlo result. Four cases with S/N=12.5, 25, 50, and 100 per pixel are shown from top to bottom.

4.3.2 Probing the line-to-line separation needed for an accurate chemical analysis of blended lines

Following the same assumptions as outlined in the previous subsection we test the needed line-to-line separation to recover the stellar abundances in practice. For this purpose we use synthetic spectra (mock data) that mimic those to be observed by 4MOST in the HRS setting. The two lines are weak, yet not so weak that they mistakenly could be taken as noise. The only free parameters are the two abundances, which we try to recover from spectra synthesized with different line-to-line separations (in units of FWHM) of the two blending lines. The lines are treated in isolation and analysed without any ‘a priori’ (input) information from other lines of the same species.

To test how close two blended lines can be, and remain useful for an abundance analysis, allowing for uncertainties of 0.1 dex, we start by selecting a region where this can be tested in the cleanest possible way.

In the bluest part of the blue range, this will be hard to test, since many blends will arise simultaneously, especially for the more metal-rich stars. Therefore, we choose a line that was clean in all the tests made for setting the wavelength region (see Sect. 4.2). The Cr I line at 427.48 nm provides a good test case, as it is clean in both dwarfs and giants from $[\text{Fe}/\text{H}] = -3$ to -1 dex. We then insert a line (here we chose Al as an example of a blend) in the core of the Cr line and in small steps move the centre of the Al line away from the centre of the Cr line. We generate synthetic spectra with separations in

steps of $0.1 \times \text{FWHM}^{10}$. The atomic data, adopted from a nearby Fe I line, was slightly altered to make this ‘Al’ line as strong¹¹ as the Cr line and visible at all three metallicities ($-3, -2, -1$) in both dwarfs and giants. To generalise this test to other elements that only show one blended line within the covered spectral range, we do not use abundance information from lines of the same species at other wavelengths. There are several other useful Cr and Al lines in the covered spectral range, but this is not the case for some of the other (heavier) elements. In this way we have two blending lines for which we have no a priori abundance information from other clean lines.

The test was carried out using noise-free spectra generated with the spectrum synthesis code used in Sect. 4.2, where the lines were broadened to the aforementioned instrumental resolution. Only the abundances of the two blending lines were kept as free parameters and the central wavelengths of these lines are assumed to be known. This allows us to simultaneously fit both lines and see if the abundances can be recovered with uncertainties better than ± 0.1 dex.

Fig. 7 Reduced χ^2 for the automated simultaneous fit to the isolated, blended lines of Al and Cr with a $0.3 \times \text{FWHM}$ separation. Their abundances are shown on the x- and y-axis, respectively. Contours are smoothed with a kernel of 0.1 dex width, and the ‘+’ marks the best solution (0.2,0.0) vs the true value ‘dot’ (0.2,0.1).

We set up a suite of 10 synthetic spectra with $[\text{Cr}/\text{Fe}] = 0.1$ and $[\text{Al}/\text{Fe}] = 0.2$ dex and with different line-to-line separation. These spectra were blindly anal-

ysed in three different ways by several co-authors. First we conduct an MC test on a randomly selected spectrum of a metal-poor dwarf star ($T_{\text{eff}}/\log g/[\text{Fe}/\text{H}]/Vt$: $5500\text{K}/4.0\text{dex}/-2.0\text{dex}/2\text{km s}^{-1}$).

1) We create a grid of synthetic spectra with Al and Cr abundances varying in steps of 0.1 dex (the adopted allowed uncertainty) and derive the abundances using χ^2 minimization. For this purpose we adopt a nominal uncertainty of 3% for the χ^2 -fitting i.e., the uncertainty on the data to be fitted, which roughly corresponds to an overall 0.1 dex abundance uncertainty. At a separation of $0.3 \times \text{FWHM}$ we recover the Al abundance ($[\text{Al}/\text{Fe}] = 0.2$ dex) exactly, while we obtain a Cr abundance lower than the input, at $[\text{Cr}/\text{Fe}] = 0.0$ dex, which is at the limit of the allowed uncertainty. This case is shown in Fig. 7 for which we find a reduced χ^2 of 0.93.

2) A manual test was made on the same spectra by blindly analysing them in MOOG and treating them as real observed spectra for the same dwarf star ($5500\text{K}/4.0\text{dex}/-2.0\text{dex}/2\text{km s}^{-1}$). At a separation of $0 \times \text{FWHM}$ the input Cr and Al abundances could not be recovered, but we find several possible solutions. At a separation of $0.5 \times \text{FWHM}$ or more, the input abundances can be recovered exactly. This agrees within $\pm 0.1 \text{FWHM}$ with the value of 0.6 found in the previous theory section (4.3.1). At $1 \times \text{FWHM}$ the separation of the lines is visible, and the abundances can be derived as if the lines were not blended.

In one test spectrum we introduced an extra line¹² with an abundance of 0.1 dex into the blend as an unknown blend. This increased the derived Cr abundance by 0.1 dex.

Finally, if we assume the abundance of one of the two blending lines to be known (e.g., Cr), based on measurements from other clean Cr lines, the abundance of the Al line can be perfectly recovered regardless of FWHM separation even when the centres of the two blending lines coincide.

The observed 4MOST spectra will not necessarily be shifted perfectly to rest wavelength, but the radial velocity might be off by $\sim 1\text{ km s}^{-1}$. According to another scientific requirement, the radial velocity must be accurate to within $\pm 1 - 2\text{ km s}^{-1}$. In metal-rich giants most of the lines will be very strong or even saturated, which means that the line profiles will no longer maintain a Gaussian shape¹³. Combining all these factors and furthermore adding the radial velocity as a free parameter will aggravate the abundance recovery from a blend containing a saturated and a weaker line. Thus, by considering a short wavelength range consisting mainly of non-Gaussian shaped strong lines, could lead to problems where an uncertain radial velocity no longer causes a simple systematic offset.

¹⁰ i.e., finer steps were used, compared to the step size in previous section, to probe the separation needed.

¹¹ i.e., reach the same residual intensity

¹² 0.15 \AA from the Cr line

¹³ This can also affect the accuracy of the radial velocity shift, since saturated lines tend to yield more uncertain shifts.

3) Therefore a different test was carried out on a ‘worst case scenario’, namely a more metal-rich giant ($4500\text{K}/2.0/-1.0/2\text{km s}^{-1}$) with numerous blends in the blue region. We used 0.1 dex lower abundances¹⁴ for this test. The saturation plus offset radial velocity can hide the weaker line and return an abundance that is off by up to 0.3–0.4 dex (see Fig. 8). To obtain the correct abundance a larger separation ($> 1\times\text{FWHM}$) is needed. The shift of the line centre (mock data offset by 0, 0.5, and 1 km s^{-1} see Fig. 8) is barely visible in the broad line with an almost flat core of the saturated line. Only under careful (χ^2) inspection this will be detected. In an automated code this could result in a false minimum, that would overestimate the abundance of the weaker line by up to 0.3–0.4 dex, while the stronger line could be reproduced within $\sim \pm 0.2$ dex.

Fig. 8 Mock data (observations – black diamonds) with different radial velocity shifts (i.e., offset by 0, 0.5, 1 km s^{-1} from top to bottom) compared to syntheses with different $[\text{Cr}/\text{Fe}]$ and $[\text{Al}/\text{Fe}]$ abundances. All spectra have been broadened to the 4MOST resolution. Residuals (observations - syntheses) show the quality of the fit. At an offset of 0.5 km s^{-1} the syntheses are equally good/bad. In order to derive abundances that are exact within ± 0.1 dex the radial velocity shift needs to be exact (0 km s^{-1}) or the separation of the blending lines needs to be larger than $1\times\text{FWHM}$.

¹⁴ i.e., $[\text{Cr}/\text{Fe}]=0.0$ and $[\text{Al}/\text{Fe}]=0.1$ dex

The last test (3) illustrates future limitations in the automated pipeline abundance analyses of ‘worst case scenarios’ which is needed for a survey like 4MOST. Not surprisingly, the more metal-rich giants are the hardest cases from which to recover the abundances for each of the lines. The lines are extremely strong (saturated or even damped) in metal-rich giants, making the abundance recovery even harder. This is why the blue range with all its blends can generally not be used for more metal-rich disk and bulge stars. This does not mean that this range does not contain any useful lines. Section 4.2 shows that there are several clean lines in metal-rich giants for which we can derive abundances within the adopted uncertainty (± 0.1 dex). Special attention needs to be paid to very metal-rich giants to ensure that the radial velocity shift is accurate since this could degrade the abundances derived from strong blended lines.

Such an extreme case would be very unlikely at a metallicity lower than $[\text{Fe}/\text{H}] < -1$, where there are fewer (saturated) lines, and if the lines are not studied in isolation, a ‘wrong’ radial velocity ($\pm 1\text{ km s}^{-1}$) should reveal itself by offsetting the surrounding lines.

This shows that as long as we deal with two weak, blended lines, these can be used for precise abundance measurements (± 0.1 dex) in the 4MOST HRS spectra, provided the line centres are separated by $\sim 0.5\times\text{FWHM}$ if all other parameters and input (e.g., atomic data, stellar parameters, and radial velocity) are well constrained. If we know the abundance for one of the blending elements from other clean lines, we can recover the abundance of the other component perfectly even if the two lines overlap. On the other hand, if the radial velocity is uncertain and the line is saturated or contains unknown blends, we will need a larger separation ($> 1\times\text{FWHM}$) to recover the abundances from the blending lines.

5 Conclusions and outlook

The future survey instrument 4MOST will provide data that are crucial for making advances in cosmology, active galactic nuclei, and the formation of galaxies. For the latter, the Milky Way will be used as a model organism.

4MOST will allow for studies on large scales to understand galaxy formation as well as on small scales by tracing the origin of heavy elements. Both of these are among the open questions in astrophysics to date, and they cannot be answered to the same extent using green and red spectral studies only. In particular, the important science case of metal-poor stars cannot be studied and answered using only redder spectra.

With the current design plan, the instrument will be able to simultaneously observe up to 2400 objects

in one pointing, using fibers feeding high- and low-resolution spectrographs. To be able to measure the abundances of at least the 20 elements that are most important for constraining the chemical evolution of the Galaxy, the blue arm of the 4MOST high-resolution spectrograph must provide a resolving power of $R \sim 18\,000\text{--}20\,000$, and a sampling of 2.5–3 pixels per resolution element.

The blue spectral range is very crowded and therefore many lines blend. Here we have shown that according to theory, the line centres of two weak, blending lines need to be separated by $\sim 0.6 \times \text{FWHM}$ to make an abundance recovery within ± 0.1 dex uncertainty. Our subsequent tests on synthetic spectra showed that the separation needs to be $\gtrsim 0.5 \times \text{FWHM}$ in order to recover accurate abundances (within ± 0.1 dex) from both components (unless we a priori know the abundance of one of the elements). The precision of the radial velocity determination plays an important role in how accurately we can recover the abundances from two blended strong lines.

To date only three high-resolution instruments are capable of observing all the way down to the atmospheric cut-off while most others stop $\sim 50\text{--}100$ nm redward of this. However, the 300–400 nm region is important when observing halo stars no matter if the science cases focus on constraining nuclear formation processes of elements with $Z \geq 38$ or searching for the origin of carbon enhanced metal-poor stars, which could be some of the first stars formed after the Population III stars. However, to unravel the origin of stars, nuclear processes, or large scale formation scenarios of the Milky Way, a large sample of stars is needed at $[\text{Fe}/\text{H}] < -3$. The efficiency of the fibres needs to improve to cover a wider wavelength range at higher resolution in the blue to make best use of these blue-most wavelength regions. Alternatively, a stronger initiative in the community focusing on blue-to-near-UV science is needed, and even more time needs to be allocated to high-resolution slit spectroscopy covering a deeper follow-up of these blue wavelength ranges.
