13
 14 **ABSTRACT**

15 1. The impacts of human activities on tropical forests are widespread and increasing. Hence,
 16 a good knowledge-base about ecological processes in undisturbed tropical forest is crucial
 17 to provide a baseline for evaluating anthropogenic change.

18 2. Our five-year study focused on understanding the background spatial and inter-annual
 19 variation in dung beetle communities at 12 sites of undisturbed lowland tropical rainforest in
 20 the Brazilian Amazon. We then assessed how this variation may affect ecological
 21 evaluations of anthropogenic influence by comparing community metrics with comparable
 22 dung beetle data collected from 15 sites of *Eucalyptus* plantation in the same region.

23 3. Of all measured environmental variables, soil texture best explained spatial variation in
 24 dung beetle communities in undisturbed forests. Furthermore, soil texture was important for
 25 community assembly as it was associated with dung beetle nesting behaviours. While the
 26 relative abundance of dung beetle functional groups was stable over time, there were
 27 important inter-annual temporal dynamics, with a five-fold variation in abundance and body

28 mass, and with species richness ranging from 52-74. These temporal oscillations were
29 probably caused by variation in dry season rainfall.

30 4. This inter-annual variation influenced the comparison between undisturbed forests and
31 plantations, which could lead to inconsistencies in evaluation of anthropogenic change. We
32 therefore highlight the importance of understanding natural variation in studies evaluating
33 the consequences of land-use change and other forest disturbances on forest biodiversity.

40

41 Running title: Dung beetle dynamics in undisturbed forests

42 INTRODUCTION

43 The negative influence of human beings in natural habitats has reached an
44 unprecedented level (Ceballos *et al.*, 2015; Lewis & Maslin, 2015). Tropical rainforests are
45 threatened by the advance of monoculture and pasture, and the exploitation of timber and
46 non-timber resources in the remaining forests. The effects of these changes on biodiversity
47 have been evaluated in a variety of taxa and summarised in pan-tropical and global meta-
48 analyses (Cullen *et al.*, 2000; Koh & Wilcove, 2008; Gibson *et al.*, 2011; Newbold *et al.*,
49 2015; Panday *et al.*, 2015).

50 Most studies have highlighted the negative impacts of large changes in vegetation
51 structure. However, the natural spatio-temporal fluctuations of many populations from
52 'control' or 'undisturbed' areas might lead to misinterpretations of the real effects of
53 anthropogenic changes (Magurran *et al.*, 2010). Conservation efforts could therefore benefit
54 greatly from detailed information on spatio-temporal distribution ('Prestonian shortfall') of
55 species and their sensitivity to habitat changes ('Hutchinsonian shortfall'; Hortal *et al.*, 2015).
56 Such information is especially important for organisms used as bioindicators of change, such
57 as dung beetles (Cardoso *et al.*, 2011; Davis *et al.*, 2001).

58 Dung beetles are often used as focal organisms to evaluate anthropogenic impacts
59 and habitat recovery from disturbance (e.g. Audino *et al.*, 2014; Braga *et al.*, 2013; Korasaki
60 *et al.*, 2013), with recent advances relating dung beetle sensitivity to disturbance to
61 functional traits such as species body mass or size, nesting behaviour, diet preference, and
62 activity period (Barragán *et al.*, 2011; Nichols *et al.*, 2013; Silva & Hernández, 2014).
63 However, dung beetles also show high spatial variation due to their association with soil
64 texture, which can cause changes in community composition over short distances (Hanski &
65 Cambefort, 1991), even though some species show relatively high dispersal ability (Almeida
66 *et al.*, 2011; Gardner *et al.*, 2008; Silva & Hernández, 2014, 2015). Furthermore,
67 establishing baseline conditions is complicated by temporal change, as many dung beetle
68 species show seasonality, and their abundances and distributions can vary inter-annually
69 (Andrade *et al.*, 2011).

70 To the best of our knowledge, there is no large-scale study that evaluates variation in
71 dung beetle communities over multiple years in undisturbed tropical forests. We therefore
72 assessed natural temporal and spatial variation in dung beetle communities over a five year
73 period, focussing on undisturbed lowland tropical rainforest in the Brazilian Amazonia to
74 explore the possible drivers and consequences of this variation. We tested the following
75 hypotheses: (1) dung beetle community parameters (abundance, richness, body mass,
76 composition, structure and abundance of functional groups - activity period, nesting
77 behaviour and diet preference) will display high local variation. We relate any observed
78 changes to local variation in soil texture (Osberg *et al.*, 1993; Sowig, 1995), canopy
79 openness (Andrade *et al.*, 2011), rainfall prior to the sampling period, and geographic
80 distance between sites; (2) inter-annual variation will be low for the community parameters
81 listed above, as the structure of undisturbed forest buffers against external changes in the
82 climate and offers a stable environment; and (3) natural temporal variation will influence the
83 dissimilarity between communities in undisturbed forests and a local prevalent
84 anthropogenic habitat, *Eucalyptus* plantations.

85

86 **MATERIAL AND METHODS**

87 *Study site*

88 The study was conducted within a cellulose company area of 1.7 Mha situated in the
89 Jari River basin on the border between the States of Pará and Amapá in north-eastern
90 Brazilian Amazonia (00°27'00" - 01°30'00" S, 51°40'00" - 53°20'00" W). The climate is
91 classified as tropical monsoon (Amw - Köppen classification), with an average annual rainfall
92 of 2115 mm (Coutinho & Pires, 1997), a marked wet season from January to June, and a
93 distinct dry season from September to November (Parry *et al.*, 2007). The mean annual
94 temperature is 26.9 °C (± 0.6 °C), and is constant throughout the year, with monthly maxima
95 and minima of 31.4 °C (± 1.1 °C) and 22.5 °C (± 0.2 °C), respectively (Climate-Data.org,
96 2016).

97 The original continuous pristine forest was managed for Brazil nuts and subsistence
98 livelihoods prior to 1967 (Coutinho & Pires, 1997). Since then, the area has been modified
99 and is now a matrix of native forest with large patches of *Eucalyptus* plantations (c. 130,000
100 ha), disrupted by wide primary forest corridors (c. 200 m wide). There are a few human
101 activities for subsistence within the native forest; mainly collection of Brazil nuts and other
102 non-timber forest products, and some hunting (Parry *et al.*, 2009).

103

104 *Dung beetle data*

105 We sampled the dung beetle community during the wet season (from January to
106 June) in each year from 2009 to 2013 at the same sampling points. We selected 12 sites of
107 undisturbed forest, separated by 0.2 to 56 Km (average distance c. 27 km) to evaluate the
108 shifts within this land cover, and 15 sites of *Eucalyptus* plantation, separated by 1.6 to 59.6
109 Km, to assess the influence of temporal variation on evaluation of human-induced impacts.
110 In each site we installed five pitfall traps in a 600 m linear array, with traps aligned 150 m
111 apart and 500 m from the forest/plantation edge. Pitfall traps consisted of plastic containers
112 (19 cm diameter and 11 cm deep), which were part-filled with water, salt and detergent, and
113 baited with 30 g of human and pig dung mixture, in the same proportion (Marsh *et al.*, 2013).
114 Each trap was protected from rain with a plastic lid suspended 20 cm above the surface. In
115 every year, collections took place over a period of 48 hours at each sampling site.

116 Dung beetle specimens were transported in 90% alcohol from the field to the
117 laboratory, then sorted, dried and stored in paper envelopes. Voucher specimens were
118 deposited at Coleção de Referência de Escarabéneos Neotropicais at the Universidade
119 Federal de Lavras (CREN – UFLA) in Minas Gerais State, Brazil. We identified the dung
120 beetles using a key to the genera and subgenera of the subfamily Scarabaeinae of the New
121 World (Vaz-De-Mello *et al.*, 2011), a field guide for dung beetles of the Jari River basin
122 (Louzada, J., *unpublished*), and the reference collection at CREN – UFLA..

123 We grouped the species into functional groups to describe groups of species that
124 share the same traits, forming groupings based on nesting behaviour, diet preference and

125 activity period. We inferred dung beetle nesting behaviour based on genus, grouped as (1)
126 rollers, which roll portions of dung away from the dung pile in small balls; (2) tunnelers,
127 which take a small portion of the dung and bury it directly below or around the dung pile; and
128 (3) dwellers, which nest inside the dung (Halffter & Matthew, 1966).

129 To determine dung beetle diet preference (coprophagous or necrophagous) and
130 activity period, we conducted two independent surveys in January-February 2012 and
131 November-December 2013. We set up 14 traps, spaced 100m apart, in two paired transects.
132 We alternated the baits between 30 g of the human-pig dung mixture and 30g of rotten
133 bovine spleen (to represent carrion) to avoid having the same bait in adjacent traps. If more
134 than 75% of individuals were sampled in dung bait or carcass we classified them as
135 coprophagous or necrophagous, respectively; for those species with lower percentages we
136 classified them as generalists. For species with less than five individuals we sought the
137 advice of neotropical dung beetle specialist Dr. Fernando Z. Vaz-de-Mello. We assessed
138 activity period (diurnal vs. nocturnal) by setting up five pitfall traps 100 m apart. All traps
139 were baited with 30 g human-pig dung mixture. Traps were opened and baited at 7:00 and
140 19:00 and exposed for 11 hours during the day or night.

141 We considered total abundance as the sum of individuals of all species, and richness
142 as the number of different species at each site. We oven-dried 15 individuals (or the
143 maximum number available) of each species at 40 °C for 48 h, and obtained the mean dry
144 mass. For species with low numbers of specimens, we weighed individuals from collections
145 held at CREN - UFLA. We obtained the total body mass by multiplying each species mean
146 weight by their abundance and summing across sites. For community-level weighted mean
147 (CWM) body mass we replaced the abundance of each species by their relative abundance.
148 Extrapolated richness was obtained from individual-based extrapolation for the maximum
149 number of individuals found (591 individuals; Colwell *et al.*, 2012). We determined
150 community composition as the occurrence (presence or absence of species) and structure
151 considering the abundance of species. We also plotted a species accumulation curve with
152 95% confidence intervals for each year using the *specaccum* function in the *vegan* package

153 (Oksanen *et al.*, 2014). All analyses were performed using R version 3.2.1 (R Core Team,
154 2014).

155

156 *Environmental variables*

157 We measured canopy openness at pitfall trap locations, using semi-hemispheric
158 photography at 1.5 m above ground level. All pictures were analysed in GLA - Gap light
159 analyser software (Frazer *et al.*, 1999). As rainfall events may change community
160 composition, due to temporal turnover in species within a season, we obtained the rainfall
161 from three days before sampling from meteorological stations (Ramirez, 2014). To
162 determine soil texture, we took soil cores at 0-10 cm depths in 2013 and measured the
163 content (g/kg) of fine sand, coarse sand, silt and clay. For analysis, we selected fine sand
164 content because it was not correlated with any other content ($r_s < 0.238$ and ≥ -0.392), and
165 coarse sand content, as it was negatively correlated with silt and clay content ($r_s = -0.937$, r_s
166 $= -0.916$, respectively). All environmental variables were standardized to a mean of zero
167 and standard deviation of one before the analysis (Schielezeth, 2010).

168

169 *Data analyses*

170 *Spatial variation of dung beetle communities*

171 To assess the effects of environmental variables on the spatial variation of dung
172 beetle communities we built models for each year with environmental metrics as explanatory
173 variables. For total and functional group abundance (number of individuals with same trait),
174 richness, and extrapolated richness we ran generalized linear models (GLM) using a
175 negative binomial error distribution for total and functional group abundance, and quasi-
176 Poisson for the richness metrics. We fitted total body mass and CWM body mass using
177 linear models with Gaussian distribution. The significance of each environmental variable
178 was determined by z tests for abundances and t tests for the other variables.

179 We built Bray-Curtis and Jaccard's dissimilarity matrices for community structure and
180 composition, respectively, and for each year separately, using the function *vegdist*. We then

181 compared each dissimilarity matrix with a matrix of geographic distances among sites,
182 determined with Quantum GIS 2.4.0-Chugiak (Quantum GIS Development Team, 2015),
183 using Mantel tests to evaluate the influence of spatial distribution on community structure
184 and composition. To relate environmental variables to spatial variation in community
185 structure and composition for each year, we used DistLM models with environmental
186 variables as explanatory variables, using the function *adonis* with 999 permutations. All
187 analyses were carried out using the R package *vegan* (Oksanen *et al.*, 2014).

188

189 *Inter-annual variation in dung beetle communities*

190 To evaluate temporal variation in community metrics, we ran generalized linear
191 mixed-effects models (GLMM) for both total and functional group abundance and richness,
192 using a negative binomial and Poisson distribution, respectively. For total body mass, CWM
193 body mass, and log-transformed extrapolated richness we ran linear mixed-effect models
194 with a Gaussian distribution. We considered year as fixed and sampling site as random
195 effects. Likelihood ratio Chi-square tests were used to compare each model against a null
196 model to evaluate if year had an influence on community metrics. We also ran pairwise
197 comparisons amongst years for all metrics, followed by a Holm-Bonferroni correction, using
198 the *testInteractions* function in *phia* package (Rosario-Martinez, 2015; SAS Institute Inc.,
199 1999). We explored if the temporal variation had any effects on functional group proportions
200 by plotting the relative abundance of functional groups by year. We ran PERMANOVA
201 analysis using the *adonis* function, to evaluate changes in community structure and
202 composition over years. First, we used the respective Bray-Curtis and Jaccard matrices of
203 dissimilarity as response variables and year as an explanatory variable. Then, we ran
204 multiple pairwise comparisons among years, using Holm-Bonferroni corrected *p*-values.

205

206 *Evaluating the effects of natural inter-annual variation in dung beetle communities on*
207 *anthropogenic changes*

208 To evaluate the effect of temporal shifts on dissimilarities between undisturbed
209 forests and *Eucalyptus* plantations we standardized abundance, total richness, and total
210 body mass (chosen as these metrics represent the most commonly used community metrics
211 of dung beetle biodiversity) for both land cover classes in each year to have a mean of 0 and
212 standard deviation of 1. Then, we plotted standardized means and their standard error for
213 each metric to evaluate how they varied from the expected if there was no variation over
214 years (zero-value) within land covers. We also calculated Hedge's *g*-value effect size
215 between undisturbed forest and *Eucalyptus* plantation for the same metrics and years, using
216 *mes* function in *compute.es* package, where zero values means no change, while positive
217 and negative values represent a decrease and increase in means from undisturbed forest to
218 *Eucalyptus* plantation, respectively (Del Re, 2013). The effect size was calculated in two
219 ways: 1) comparing the value between undisturbed forest and *Eucalyptus* plantation in each
220 year separately, and 2) using each year in undisturbed forest compared to the mean value of
221 all five years in *Eucalyptus* plantation to isolate the effect of temporal variation in the
222 undisturbed forests.

223

224 **RESULTS**

225 A total of 10,482 dung beetle individuals belonging to 90 species and morphospecies
226 were sampled in undisturbed forest over the five years, wherein 48 species were identified to
227 species level and 42 as morphospecies. We obtained data on diet and nesting behaviour for
228 70 species (78% of the total species collected across all years and 98% of all individuals;
229 Table S1), and data on activity period for 61 species (68% of species and 93% of
230 individuals; Table S1).

231 We sampled the highest number of individuals in 2009 (3,560), and the lowest in
232 2010 (623). Similarly, the highest number of species was collected in 2009 (74 spp.), and
233 the lowest in 2010 (52 spp.). Species accumulation curves came very close to reaching their

234 asymptote in all years, indicating that our sites provided a good representation of the overall
235 dung beetle community in a given year (Figure S1).

236

237 *Spatial variation of dung beetle communities*

238 Rain from 3-days before sampling and canopy openness had no influence on total
239 abundance, richness, total body mass, or CWM body mass ($p > 0.05$ in all cases). Coarse
240 sand showed a positive relationship with abundance and total body mass (Figure 1, Table
241 S2), whereas fine sand had a negative influence on abundance and richness (Figure 1,
242 Table S2), and positive effect on CWM body mass (Figure 1, Table S2). Extrapolated
243 richness was not related to any of the environmental variables ($p > 0.05$, Table S2).

244 For functional group abundance, fine sand content had a negative effect on all
245 functional groups, except for necrophagous beetles, which were not affected (Figure 2).
246 Coarse sand content had negative effects on necrophagous beetles in 2013, while the
247 effects were positive on coprophagous and generalists species (Figure 2). There were also
248 negative effects of canopy openness on coprophagous beetles, but positive effects on
249 necrophagous species, while generalists were negatively related to canopy openness in
250 2009 and positively in 2011 (Figure 2). Coarse sand was also negatively related to rollers,
251 but positively to tunnelers, while dwellers showed both positive and negative relationships
252 (Figure 2). Canopy openness had no effect on dwellers, while rollers and tunnelers showed
253 positive and negative responses, respectively (Figure 2). Both nocturnal and diurnal beetles
254 were positively affected by coarse sand content (Figure 2). However, while diurnal beetles
255 were negatively associated with canopy openness, nocturnal beetles were positively
256 associated (Figure 2). Rain from 3-days before sampling was negatively related to
257 necrophagous species ($z = -2.575$, $p = 0.010$), and positively with generalist species ($z =$
258 2.257 , $p = 0.024$) only in 2009 and 2013, respectively.

259 Geographical distance significantly predicted overall spatial variation in community
260 structure ($r_s = 0.267$, $p = 0.023$) and composition ($r_s = 0.256$, $p = 0.041$) only in 2009. On the

261 other hand, both coarse and fine sand content influenced community composition and
262 structure in almost every sampled year (Table S3).

263

264 *Inter-annual variation in dung beetle communities*

265 All measured community metrics varied significantly among years (Figure 3, Table 2
266 and S3). There was a marked decline in abundance, species richness and total body mass
267 between 2009 and 2010 (Figure 3), but the values increased again during 2011 and 2012,
268 so that the final measurements in 2013 were similar to the values in 2009 (Figure 3, Table
269 S4). We observed a severe dry season in 2009 (Figure 3). Extrapolated richness was
270 significantly lower in 2010 compared to 2009 and 2013, and in 2012 compared to 2013
271 (Figure 3). CWM body mass was also higher in 2010 compared to 2011, 2012 and 2013, but
272 similar to 2009 (Figure 3).

273 Although there was significant variation in the absolute abundance of all functional
274 groups across sampling years that matched inter-annual variation in overall community
275 abundance (Figure 4, Table S5), the relative abundance of functional groups was
276 remarkably stable across years (Figure S2).

277 There was strong evidence of variation in community structure and composition over
278 years (Table S4). Ordinations revealed similar community structure and composition in 2009
279 and 2013, which differed from 2010 and 2011 (Figure 5).

280

281 *Evaluating the effects of natural variation in dung beetle communities on anthropogenic* 282 *changes*

283 Although both undisturbed forest and *Eucalyptus* plantation presented a similar
284 pattern of inter-annual variation of dung beetle communities metrics within each land cover,
285 undisturbed forest presented higher variation from the expected if there was no variation
286 (zero-value for standardized metrics) in abundance, richness, and total body mass when
287 compared to values in *Eucalyptus* plantations (Figure 6). We observed the negative effect of
288 conversion of undisturbed forest to *Eucalyptus* plantation on abundance, richness, and total

289 body mass (Figure 7A). For all metrics the effect size was higher in 2009 and 2011, followed
290 by 2010; 2012 and 2013 were almost similar (Figure 7A). Specifically, for abundance, the
291 last two years showed very little difference between undisturbed forest and *Eucalyptus*
292 plantation (values of effect size close to zero; Figure 7A). When we isolated the variation of
293 undisturbed forest there were much higher dissimilarities among years, with abundance and
294 total body mass showing no effects of land-use (values close to zero), or even, showing a
295 gain in abundance in 2010 (value lower than zero; Figure 7B).

296

297

298 **DISCUSSION**

299 This five-year study of dung beetle communities in Amazonian forests revealed
300 support for two of our three hypotheses. First, we confirmed our expectation that dung beetle
301 communities would vary in space, and this was driven predominantly by their responses to
302 soil texture. Second, in contrast to our expectation, we found that all evaluated metrics of
303 dung beetles community also differed markedly among years, although there was no
304 evidence of shifts in functional group proportion. Finally, we show for the first time how inter-
305 annual variation affects dung beetles in undisturbed forest, and that this can add noise to
306 evaluations of human-induced changes on tropical biota. We discuss our results examining
307 each hypothesis in turn.

308

309 *Soil texture is the main environmental variable affecting spatial variation in dung beetle*
310 *communities*

311 Our results indicated a strong relationship between soil texture and spatial variation
312 in dung beetle communities, which even overwhelmed any effect of geographic distance
313 between sites. It is very likely that the role of soil acts via beetle nesting behaviour (Figure 1
314 and 2). For example, the negative effects of coarse sand on rollers could be associated with
315 the lower retention of moisture in sandy soils, because they usually dig shallower nests than
316 tunnelers (Davis *et al.*, 2010; Hanski & Cambefort, 1991; Osberg *et al.*, 1993). As dwellers

317 live in or right under the dung patch, it is not surprising that their response was less related
318 to soil properties (only in 2009 and weakly in 2012 and 2013). Moreover, any weak
319 relationship could be potentially explained by the indirect effects of competition with rollers or
320 tunnellers), although it is also a possibility that soil properties influence dung humidity and
321 other characteristics directly.

322 Competition could also explain the lower abundance of beetles in areas with fine
323 sand, as large dung beetles require looser soil to dig their nests giving them a competitive
324 advantage over smaller species, and thus reducing the richness and abundance of the entire
325 community (Carpaneto *et al.*, 2010; Doube, 1990; Hanski & Cambefort, 1991; Figure 1). This
326 was supported by the positive effect of fine sand content on CWM body mass in 2009 and
327 2011 (Figure 1), which would be consistent with a loss of small individuals or increases in
328 larger ones. The strong influence of soil texture on dung beetle communities suggests that
329 this environmental attribute should be measured in further studies focussing on
330 anthropogenic-induced changes on dung beetles. However, depending on the context, it will
331 be important to recognise that other microhabitat conditions also may influence dung beetle
332 sampling (Mehrabi *et al.*, 2014).

333

334 *Inter-annual dynamics in dung beetle communities*

335 Dung beetle communities showed highly non-random variation over time (Figure 3, 4
336 and 5). The variation of all metrics from 2009 to 2010 was most likely related to a severe dry
337 season in 2009 (Figure 3). Even though most adults and immature dung beetles can shelter
338 from desiccation below ground or inside dung pats during the dry season, a severe drought
339 can expose the beetles to high temperatures and low humidity, which increases larval
340 mortality and affects the size of the population in the next year (Hanski & Cambefort, 1991;
341 Scholtz *et al.*, 2009; Sowig, 1995; Vessby, 2001).

342 The low inter-annual variation in extrapolated richness shows that the severe dry
343 season effects on species loss is related to the size of populations or frequency of capture in
344 each site and not the richness *per se* (Figure 3). Additionally, dung beetle body mass is

345 unlikely to be related to the decrease in species number, as we did not find high variation in
346 CWM body mass (Figure 3), suggesting that the species were equally affected by drought,
347 and that the slight elevation in CWM body mass was probably due the high numbers of small
348 species (Table S1).

349 It is expected that dung beetles in different functional groups will show different
350 responses to changes in habitat, as discussed in previous studies (e.g. Barragán *et al.*,
351 2011; Nichols *et al.*, 2013). However, our study suggests that the changes in community
352 metrics within undisturbed forest are not related to specific responses of functional groups,
353 as there was no conspicuous inter-annual variation in the relative abundance of functional
354 groups (Figure 4 and S6) despite the change in community composition and structure
355 (Figure 5 and Table S4). This indicates a turnover or loss of species within each functional
356 group, but not a loss of the community's functional groups structure. However, the results
357 might be influenced by the coarse-scale to which we have assigned the functional groups,
358 based on categorical traits; temporal changes may be influencing functional groups
359 classified at a finer-scale, and further research is important to fully understand how
360 functional groups shift in space and time (e.g. continuous traits, intra-specific variation).

361 The recovery of biodiversity after disturbance can be linked to the scale and intensity
362 of the initial disturbance. So while previous studies have shown that dung beetle
363 communities recover from severe disturbances such as habitat loss and fragmentation
364 (Quintero & Roslin, 2005), or the restoration of degraded pasture (Audino *et al.* 2014) on
365 decadal time scales, we showed a relatively quick recovery in just one to three years after
366 severe dry seasons in forest unaffected by other forms of disturbance (Figure 3 and 4).
367 However, although this resilience to climatic variation is positive, there are two important
368 caveats to this conclusion. First, the expected reduction in wet season length and prolonged
369 dry seasons with predicted climate change in Amazonian forests might disrupt the ability of
370 communities to recover before the next disturbance event (Li *et al.*, 2006; Malhi *et al.*, 2008;
371 Nimmo *et al.*, 2015). Second, at the time of the study the native forest areas of our study site
372 were protected from additional anthropogenic disturbances, such as logging, further

373 fragmentation, or wildfires – the combination of which are known to reduce the biodiversity
374 value of Amazonian forests (Barlow *et al.*, 2016). Dung beetle communities could be far less
375 resilient to climatic variation if affected by other forms of disturbance at the same time. The
376 synergistic effects of climate change (e.g. extension and severity of dry season) and direct
377 human-induced changes (e.g. habitat degradation, fragmentation) are known to affect
378 trophic networks and ecosystem services in other taxa (Balvanera *et al.*, 2006; Lewis *et al.*,
379 2011; Silveira *et al.*, 2015), and could affect how dung beetles alter plant communities via
380 their role in seedling establishment and soil properties (Lawson *et al.*, 2012; Nichols *et al.*,
381 2008; Pérez-Ramos *et al.*, 2013; Slade *et al.*, 2015).

382

383 *Baseline variation could influence research on anthropogenic change*

384 It is well known that anthropogenic modifications lead to negative impacts on tropical
385 forest communities (Arellano *et al.*, 2008; Korasaki *et al.*, 2013; Louzada *et al.*, 2010).
386 However, we demonstrate that dung beetle abundance, richness and body mass also show
387 inter-annual variation in both undisturbed forest and modified habitats (*Eucalyptus*
388 plantation; Figure 6), which is often neglected, particularly in ‘space-for-time’ designs or
389 short-term studies. Although both native forests and plantations showed similar trends in
390 inter-annual variation, we observed some inconsistency in the effect sizes of the
391 comparisons between these systems across different years. For example, effect sizes for
392 abundance are close to zero in 2012 and 2013, but are much larger in other years (Figure
393 7A), showing that studies could report very different findings depending on the year in which
394 they were carried out.

395 To isolate the effect of variation from the baseline condition (primary forest
396 communities), we repeated the analysis keeping plantation communities constant. Under
397 this scenario, the inter-annual variation of effect size significantly increased (Figure 7B),
398 revealing the strong importance of variation in the baseline communities. Thus, the effects of
399 baseline variation are likely to increase when comparing areas with temporal asynchrony, in
400 other words, areas where the disturbance has changed the communities’ responses to

401 temporal shifts. These results demonstrate the importance of understanding natural variation
402 within 'control areas', and disentangling these from anthropogenic-induced changes in
403 communities.

404 This study shows that a failure to appreciate inter-annual variation could lead to a
405 failure to detect the consequences of even severe forms of land-use change, such as the
406 conversion of native forests to exotic tree plantations, which are well known to harbour
407 different species composition and species-poor communities (Harvey *et al.*, 2006; Vieira *et al.*,
408 *et al.*, 2008; Zurita *et al.*, 2006). The influence of inter-annual variation may be even greater on
409 more subtle forms of anthropogenic change (e.g. restoration areas: Audino *et al.*, 2014;
410 selective logging: Bicknell *et al.*, 2014; França *et al.*, 2016; and natural gradients: Nunes *et al.*,
411 *et al.*, 2016). We are aware of all logistic issues related to longer-term assessments (e.g.
412 funding, human resources), and that short-term projects usually give faster returns.
413 However, by demonstrating the role of temporal variation, we highlight that rapid
414 assessment studies need to be viewed with caution, and at the very least should place the
415 survey conditions in a longer-term climatic context to highlight any abnormal conditions that
416 could influence the findings (Chase, 2007; Slade *et al.*, 2011; Trexler *et al.*, 2005).

417

418 **ACKNOWLEDGMENTS**

419 We thank the Grupo Jari for logistic support, soil texture analyses, and rainfall data.
420 Irmão, Edvar and Maria for their support in fieldwork. Marina Acero for preparing the
421 vegetation variables. Julius Cerqueira and Amanda Arcanjo for helping with beetle
422 identification. We thank the anonymous reviewers for their fruitful comments and
423 suggestions to improve our manuscript. Conselho Nacional de Pesquisa e Desenvolvimento
424 (CNPQ) and Fundação de Amparo à Pesquisa do estado de Minas Gerais (FAPEMIG)
425 funded the project (Site Peld 23). JS was funded by a postdoc fellowship from FAPEMIG
426 and WB a PhD scholarship from Coordenação de Aperfeiçoamento de Pessoal de Nível
427 Superior (CAPES; DS and BEX 3711-14-15).
