Long Memory and Changepoint Models: A Spectral Classification Procedure

Ben Norwood · Rebecca Killick

Received: date / Accepted: date

Abstract Time series within fields such as Finance and Economics are often modelled using long memory processes. Alternative studies on the same data can suggest that series may actually contain a ‘changepoint’ (a point within the time series where the data generating process has changed). These models have been shown to have elements of similarity, such as within their spectrum. Without prior knowledge this leads to an ambiguity between these two models, meaning it is difficult to assess which model is most appropriate. We demonstrate that considering this problem in a time varying environment using the time varying spectrum removes this ambiguity. Using the wavelet spectrum we then use a classification approach to determine the most appropriate model (long memory or changepoint). Simulation results are presented across a number of models followed by an application to stock cross correlations and US inflation. The results indicate that the proposed classification outperforms an existing hypothesis testing approach on a number of models and performs comparatively across others.

1 Introduction

It is not often the case that a given data set has a known explicit model from which it is generated. Analysts will look to fit an appropriate model to such a series in the hopes of understanding the underlying mechanisms or to make predictions into the future. The models proposed are expected to be distinct in their properties such that there is a clear prevalence of a suitable model for the data. However, models with certain structural features have been known to have similar properties to other models [11]. This overlap will be here referred to as an ‘ambiguity’ between the models. This is such that either model may appear similar to one another in some metrics, but provide very different interpretations on the data generating process, and lead to different predictions into the future.

In this paper we consider the ambiguity between long memory and changepoint models. This ambiguity has been documented in fields such as Finance and Economics which are modelled using long memory models [10,26] and changepoint models [19,28]. Thus it is reasonable to assert that there is an element of ambiguity between these two models. Following the discussion and in-depth analysis within [6], it has been shown that both models share some similar properties, especially within the spectrum. Often a decision on a model can not be made with the ‘luxury’ of prior knowledge, and as such assuming the data derives from either of these models comes at a risk of mis-specification.

Existing work in [30] conducts a hypothesis test to determined between the changepoint and long memory model. The authors choose to use the changepoint model as a null model with

the justification that this is the more plausible model. However in some circumstances this may not be the case so it leads to the question as to which model should be the null model. It would be entirely feasible to choose the changepoint model as the null model, not reject H_0 and then flip to have the long memory model as the null model and also not reject H_0 . This does not give a clear answer to the question of an appropriate model.

As an alternative this paper introduces a classifier, which places no such assumptions on which model is preferred. Instead the purpose of a classifier is only to give a measure of which category provides the best fit. In the context here, it can measure which model best describes a time series, without assuming that this model is where the data was originally generated from. Classification of time series has been previously used in [9] and [18]. It was shown in [30] that the autocorrelation function and periodogram of data generated from a changepoint model and a long memory model exhibit similar structures (i.e. slow decay in the autocorrelation and spectral pole at zero). However, if we consider a time-varying periodogram, then the stationarity of a long memory model can be seen (constant structure over time), whilst a changepoint model exhibits the piecewise stationarity expected (see for example [16]). As the time varying spectrum shows evidence of a difference between these models, we use it as the basis for our classification procedure.

The structure of this article is as follows. The background and methods to our approach are given in detail in Section 2. A simulation study of the proposed classification method, with a comparison to the Likelihood Ratio Test from [30], can be found in Section 3. Applications of the classifier are then given using US price inflation and stock cross-correlations in Section 4. Finally, concluding remarks and a discussion is given in Section 5.

2 Methods

2.1 Changepoint and Long Memory Models

The aim of our method is to distinguish between data which arises from either a changepoint or a long memory model. To define these, we first define the general Autoregressive Integrated Moving Average (ARIMA) model, characterised by its Autoregressive (AR) parameters $\phi \in \mathbb{R}^p$, Moving Average (MA) parameters $\theta \in \mathbb{R}^q$ and the Integration (I) parameter $d \in \mathbb{N}$.

For random variables X_1, X_2, \dots, X_n this is formally defined as,

$$\left(1 - \sum_{k=1}^p \phi_k B^k\right) (1 - B)^d X_t = \left(1 + \sum_{k=1}^q \theta_k B^k\right) \epsilon_t$$

where $\epsilon_t \sim N(0, \sigma^2)$ and B is the backward shift operator such that $BX_t = X_{t-1}$ and $B\epsilon_t = \epsilon_{t-1}$. A variation of this, Autoregressive Fractional Integrated Moving Average (ARFIMA) is such that $d \in \mathbb{R}$, allowing it to be fractional. This modification allows long memory behaviour to be captured through dependence over a large number of previous observations.

For the purpose of this paper, we define the changepoint and long memory models as:

$$X_t \sim \begin{cases} \mu_1 + \text{ARMA}(\phi_1, \theta_1) & \text{if } t = 1, 2, \dots, \tau \\ \mu_2 + \text{ARMA}(\phi_2, \theta_2) & \text{if } t = \tau + 1, \tau + 2, \dots, n. \end{cases} \quad (1)$$

$$X_t \sim \mu + \text{ARFIMA}(\phi, d, \theta) \quad t = 1, 2, \dots, n \quad (2)$$

Note that we depict a single changepoint $\tau = \lfloor n\lambda \rfloor$ for notational ease, but the software we provide (see Section 5) contains the generalisation to multiple changes through use of the PELT algorithm [17] and extending Equation (1) to include multiple τ . Other models such as ARCH models and Fractional Gaussian Noise [21] could also be used but we restrict our consideration to ARFIMA here. In the general case we allow $p, q \in \mathbb{N}$, but in the simulations and applications given in Section 3 and 4 we restrict their range for computational reasons.

2.2 Wavelet Spectrum

The ambiguity present between diagnostics of the competing models given in Equation (1) and (2) can cause issues in identifying the correct model. Figure 1 shows the average empirical periodograms from realisations of long memory (ARFIMA(0,0.4,0)) and changepoint (AR(1), $\lambda = 0.5$, $\phi_1 = 0.1$, $\phi_2 = 0.4$, $\mu_1 = 0$, $\mu_2 = 1$) models. It can be seen that the periodogram for the changepoint model has a pole at zero and shows similar behaviour to that of long memory.

Before discussing the wavelet spectrum, we provide a brief background to wavelets and the specific spectrum we propose to use.

Wavelets capture properties of the data through a location-scale decomposition using compactly supported oscillating functions. Through dilation and translation, a wavelet is applied across

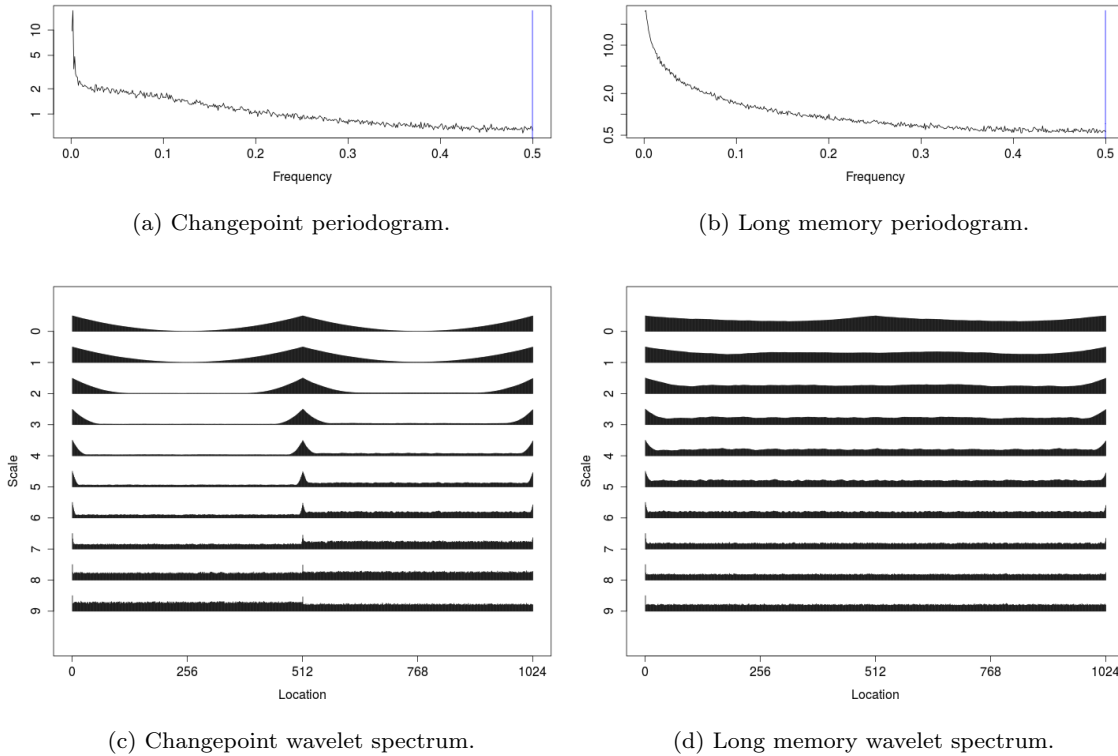

Fig. 1: Empirical periodogram and wavelet spectrum averaged over 500 realizations.

a number of a scales and locations to capture behaviour occurring over different parts of a series. Further information on them and their application can be found in [5] and [22]. In this work we use the model framework of the Locally Stationary Wavelet process which provides a stochastic model for second order structure using wavelets as building blocks.

We follow the definition in [7] for a Locally Stationary Wavelet (LSW) process.

Definition 1 Define the triangular stochastic array $\{X_{t,N}\}_{t=0}^{N-1}$ which is in the class of LSW processes given it has the mean-square representation

$$X_{t,N} = \sum_{j=1}^{\infty} \sum_k W_j \left(\frac{k}{n} \right) \psi_{j,k-t} \xi_{j,k},$$

where $j \in 1, 2, \dots$ and $k \in \mathbb{Z}$ are scale and location parameters respectively,

$\psi_j = (\psi_{j,0}, \dots, \psi_{j,L_j-1})$ are discrete, compactly supported, real-valued non-decimated wavelet vectors of support length L_j . If the ψ_j are Daubechies wavelets [5] then $L_j = (2^j - 1)(N_h - 1) + 1$ where N_h is the length of the Daubechies wavelet filter, finally the $\xi_{j,k}$ are orthonormal, zero-mean, identically distributed random variables. The amplitudes $W_j(z) : [0, 1] \rightarrow \mathbb{R}$ at

each $j \geq 1$ are time varying, real-valued, piecewise constant functions which have an unknown (but finite) amount of jumps. The constraints on $W_j(z)$ are such that if \mathcal{P}_j are Lipschitz constants representing the total magnitude of jumps in $W_j^2(z)$, then the variability of $W_j(z)$ is controlled by

$$\begin{aligned} & - \sum_{j=1}^{\infty} 2^j \mathcal{P}_j < \infty, \\ & - \sum_{j=1}^{\infty} W_j^2(z) < \infty \text{ uniformly in } z. \end{aligned}$$

As in the traditional Fourier setting, the spectrum is the square of the amplitudes and as such the Evolutionary Wavelet Spectrum can be defined as

$$S_j \left(\frac{k}{N} \right) = \left| W_j \left(\frac{k}{N} \right) \right|^2$$

which changes over both scale (frequency band) j and location (time) k .

Considering both scale and location, the two dimensions allow the differences between the proposed models to be seen. Examples of the differences in these spectra are given in Figure 1 for both the changepoint and long memory models. To interpret the wavelet spectrum: scale corresponds to frequency bands with high frequency at the bottom to low frequency at the top. Further details on the spectrum and its applicability can be found in [7], [22] and [16].

Note that there is a clear difference between the wavelet spectra of the two models with the changepoint model being piecewise stationary (pre and post change), with the change occurring in the spectrum where the change occurs in the data. In contrast the long memory model remains flat across each scale and time reflecting the stationarity of the original series.

Due to the fact that the wavelet spectrum gives a distinction between the two models we propose to use this as the basis for our inference regarding the most appropriate model. Whilst the Fourier spectrum could be used here as in [14], we choose to use the Evolutionary Wavelet Spectrum. As shown in Figure 1 this is advantageous for characterising the non-stationarity changepoint data due to the Scale-Location transformation used. This is since the $W_j(z)$ are constant for stationary models, but for non-stationary models the break in the second order structure of the original data causes breaks in the wavelet spectra, as described in [12].

In the next section we detail how to use the wavelet spectrum of the two models in a classification procedure.

2.3 Classification

Testing whether a long memory or changepoint model is more appropriate whilst under model uncertainty comes with the hazard of mis-specification. A formal hypothesis test places assumptions on the underlying model in both the null and alternative, but the allocation of the null is hazardous - should the changepoint model be the null or alternative? It would be entirely feasible to choose the changepoint model as the null model, not reject H_0 and then flip to have the long memory model as the null model and also not reject H_0 . Given the absence of a clear null model, which result to proceed with is unclear. Instead it may be preferable to quantify the evidence for each model separately. A classification method such as the one proposed here gives a candidate series a measure of distance from a number of groups, which can then be used to select the most appropriate group.

In the previous subsection it was demonstrated that the wavelet spectrum can be used to distinguish the changepoint model from the long memory model, and the classifier proposed here builds on this. However, to begin a classification method must first ‘teach’ itself on the structure of the classes through sets of training data.

These are data sets already determined to be in each category and are the basis for calculating the distances from each group. This previous knowledge allows for determination of patterns and features of each category (that are unique from other categories) for comparison to the candidate data set. A common example is the spam filter on mailboxes, which is trained on previous spam emails so that it can classify if a new email that arrives is spam or not. The decision is made by comparing it to a number of patterns already determined to be features in spam email for example, short messages or hidden sender identities. Further information on classification methods and training them can be found within [20].

In our example we only have a single data set of length n , the classifier has no previous information to train on. To remedy this we create training data through simulation. Given a candidate series we first fit the competing models in Equations (1) and (2) choosing the best fit for each model. For the changepoint model the best fit uses the ARMA likelihood within the PELT multiple changepoint framework to identify multiple changes in ARMA structure [13,17]. When considering fitted long memory models, a number of ARFIMA models are fitted [29] and selection occurs according to Bayesian Information Criterion (following [1]).

Following the identification of the best changepoint and long memory models, the training data is then simulated as (Monte Carlo) realisations from these, denoted by

$$\mathbf{X}_m^g = \{X_{i,m}^g\}_{i=1,2,\dots,n} \quad m = 1, 2, \dots, M. \\ g = 1, 2.$$

where the group, $g = 1$ for changepoint simulations and $g = 2$ for long memory simulations, M is the number of simulated series and n is the length of the original series. Note that we are not sampling from the original series, we are generating realizations from the fitted models.

Now we have the training data and the observed data, denoted \mathbf{X}^o , a measure of distance of the observed data from each group is calculated. As discussed previously we will use a comparison of their evolutionary wavelet spectra as the distance metric. Before detailing the metric, we first define the wavelet spectrum of the original series as

$$\mathbf{S}^o = \{S_k^o\}_{k=1,2,\dots,n*J}$$

where we remove the index over scale j by concatenating scales, hence $k = 1, 2, \dots, n*J$, where

$J = \lfloor \log_2(n) \rfloor$. Similarly we define the spectra for each simulated series:

$$\mathbf{S}_m^g = \left\{ S_{k,m}^g \right\}_{k=1,2,\dots,n*J}.$$

To obtain a group spectra, an average is then taken over the M simulated series at each position of each scale for each group,

$$\bar{\mathbf{S}}^g = \left\{ \frac{1}{M} \sum_{m=1}^M S_{k,m}^g \right\}_{k=1,2,\dots,n*J}.$$

Based on these spectra the distance metric proposed is a variance corrected squared distance, across all spectral coefficients as proposed in [18],

$$D^g = \frac{M}{(M+1)} \sum_{k=1}^{n*J} \frac{(S_k^o - \bar{S}_k^g)^2}{\sum_{m=1}^M (S_{k,m}^g - \bar{S}_k^g)^2} \quad (3)$$

Note that the variance correction occurs within the denominator to account for potentially different variability seen across simulations for each group. This is modified from [18] to allow different variances within each group. The theoretical consistency of the classification was shown in Theorem 3.1 from [8] where the error for misclassifying two spectra $\{S_k^{(1)}\}_k$ and $\{S_k^{(2)}\}_k$ (whose difference summed over k is larger than CN) is bounded by $\mathcal{O}(N^{-1} \log_2^3 N + N^{1/\{2 \log_2(a)-1\}-1} \log_2^2 N)$. However this result requires a short memory assumption that is clearly not satisfied for our long memory processes. Thus we prove a similar bound under the assumption that the spectra are created from ARFIMA processes. We first replicate the requilblack assumptions from [8] for completeness:

Assumption 21 (*Assumption 2.1 from [8]*)
 The set of those locations z where (possibly infinitely many) functions $S_j(z)$ contain a jump is finite. In other words, let $\mathcal{B} := \{z : \exists j \lim_{u \rightarrow z^-} S_j(u) \neq \exists j \lim_{u \rightarrow z^+} S_j(u)\}$. We assume $B := \#\mathcal{B} < \infty$.

Assumption 22 (*Assumption 2.2 from [8]*)
 There exists a positive constant C_1 such that for all $j, S_j(z) \leq C_1 2^j$.

Theorem 1 *Suppose that Assumptions 21 and 22 hold, and that the constants \mathcal{P}_j from Definition 1 decay as $\mathcal{O}(a^j)$ for $a > 2$. Let $S_j^{(1)}(z)$ and $S_j^{(2)}(z)$ be two non-identical wavelet spectra from ARFIMA processes. Let $I_{k,N}^{(j)}$ be the wavelet periodogram constructed from a process*

with spectrum $S^{(1)}(z)$, and let $L_{k,N}^{(j)}$ be the corresponding bias-corrected periodogram, with $J^ = \log_2 N$. Let*

$$\sum_{j,k} \left\{ S_j^{(1)}(k/N) - S_j^{(2)}(k/N) \right\}^2 = \mathcal{O}(N).$$

The probability of misclassifying $L_{k,N}^{(j)}$ as coming from a process with spectrum $S_j^{(2)}(z)$ can be bounded as follows:

$$P(D_1 > D_2) = \mathcal{O} \left(\log_2^2 N \left[N^{-1} + N^{\frac{1}{(2 \log_2 a - 1)}} \right] \right)$$

Proof The proof is given in Appendix A.

A summary of the proposed procedure is given in Algorithm 1.

Initialization:

\mathbf{X} : $\{X_i\}_{i=1}^n$ observed series.
 n : Length of series
 M : Number of bootstrap simulations
 $\bar{\mathbf{S}}^1, \bar{\mathbf{S}}^2$: Empty Spectra 1, 2.

Algorithm:

1. Fit: \mathcal{M}_1 - best changepoint model (Equation (1)) to \mathbf{X} .
2. Fit: \mathcal{M}_2 - best long memory model (Equation (2)) to \mathbf{X} .
3. Calculate training spectra
for $m = 1, 2, \dots, M$ **do**
 Simulate n observations from \mathcal{M}_1 , denote as \mathbf{Y}_1
 Calculate Evolutionary Wavelet Spectra \mathbf{S}_m^1 of \mathbf{Y}_1
 Let $\bar{\mathbf{S}}^1 = \bar{\mathbf{S}}^1 + \mathbf{S}_m^1$

 Simulate n observations from \mathcal{M}_2 , \mathbf{Y}_2
 Calculate Evolutionary Wavelet Spectra \mathbf{S}_m^2 of \mathbf{Y}_2
 Let $\bar{\mathbf{S}}^2 = \bar{\mathbf{S}}^2 + \mathbf{S}_m^2$
end
4. Calculate the average Evolutionary Wavelet Spectra for each group $\bar{\mathbf{S}}^1 = \frac{\bar{\mathbf{S}}^1}{M}, \bar{\mathbf{S}}^2 = \frac{\bar{\mathbf{S}}^2}{M}$.
5. Calculate Evolutionary Wavelet Spectrum of \mathbf{X}, \mathbf{S}^o .
6. Compute the distance D_1, D_2 , between \mathbf{S}^o and $\bar{\mathbf{S}}^1, \bar{\mathbf{S}}^2$ respectively (Equation (3)).

Output: Distances D_1, D_2 .

Algorithm 1: Wavelet Classifier Algorithm

3 Simulation Study

To test the empirical accuracy of our proposed approach, simulations were conducted over a number of models. Here, these models are chosen over a number of parameter magnitudes and combinations to show the effectiveness of

the approach outlined in Section 2. A number of these models also appear in [30] which uses a likelihood-ratio method to test the null hypothesis of a changepoint model. Their results for these models are correspondingly given as a comparison.

For each model given in the tables below, 500 realisations of each model were generated and classified, using $M = 1000$ training simulations for each fit. For computational efficiency, the maximum order of the fitted models are constrained to $p, q \leq 1$. Three different time series lengths were computed for each model; 512, 1024 and 2048. It is expected that as a series grows larger, more evidence of long memory features will become prevalent, and as such the effect of length of series on accuracy is investigated.

We have used $n = 2^J$ as the length of the series as the wavelet decomposition software [25] requires that the series transformed is of dyadic length. This is not a desirable trait as data sets come in many different sizes. Thus we overcome this using a standard padding technique [22] that adds 0's to the left of each series until the data is of length 2^J . The extended wavelet coefficients are then removed before calculating the distance metric.

3.1 Changepoint Observations

For the changepoint models we used the simulations given in [30]. Table 1 gives the parameters used in Equation (1) along with the correct classification rate. The results show that if the data follows a changepoint model then we have a 100% classification rate. A movement of the changepoint to a later part of the series, as in models 5 and 6, does not appear to have an effect upon classification rates unlike for the Yau and Davis method. It is not really a surprise that we are receiving 100% classification rates as if a changepoint occurs then it is a clear feature within the spectrum.

It should be noted that as the Yau and Davis method is a hypothesis test we would expect results around 0.95 for a 5% type I error.

3.2 Long Memory Observations

In contrast to the changepoint models, the classification of a long memory model is expected to be less clear. This is due to the variation within the wavelet spectrum of long memory series that could be interpreted as different levels

and hence a changepoint model would be more appropriate. To demonstrate the effect of the classifier on long memory observations, a larger number of models were considered. We simulated long memory models with differing levels of long memory as measured by the d parameter, values close to 0 are closer to short memory models and values close to 0.5 are stronger long memory models (values > 0.5 are not stationary and thus not considered).

The results in Table 2 give an indication of the accuracy of the classifier in a number of different situations. Overall, as the length of the time series increases we see an increase in classification accuracy. This is to be expected as evidence of long memory will be more prevalent in longer series. Similarly as we increase the long memory parameter d from 0.1 to 0.4 we improve the classification rate.

Some interesting things to note include, when there are strong AR parameters (ϕ) such as models 7-10 and 19-22 we require longer time series to achieve good classification rates. However, in contrast if there are strong MA components as in the remaining models the classifier performs better. A larger effect is found when the MA parameter is negative, seen through models 11-14 where the classifier performs strongly even at $n = 512$. This effect is further exemplified by models 23-26 which include a further MA parameter and achieve near 100% classification at $n = 512$. Here the maximum used p, q was 2.

Comparing our results to that of Yau and Davis we note that the opposite performance is seen. For the likelihood ratio method there is high power for models with strong AR components and poor performance for strong MA components. Notably the strong MA performance is much worse than our method on the strong AR components.

4 Application

To further demonstrate the usage of our approach, two applications to real data are given in this section. The first is an economics example based on US price inflation and this is followed by financial data on stock cross-correlations. A sensitivity analysis was conducted over the possible maximum values of p, q . It was found that no additional parameters were required beyond maximum $p, q = 4$, thus these results are presented here.

4.1 Price Inflation

US price inflation can be determined using the GDP index. The dataset used here is available from the Bureau of Economic Analysis, based on quarterly GDP indexes, denoted P_t , from the first quarter of 1947 to the third quarter of 2006 (227 data points). Price inflation is calculated as $\pi_t = 400 \ln(P_t/P_{t-1})$ (thus $n = 226$). A plot of the inflation is given below in Figure 2a. Studies of the persistence of this data have been conducted to determine the level of dependence within the series. A high amount of persistence, indicating long memory, was found in [26]. However [19] found a structural break, which when accounted for showed the series to have low persistence, indicating the presence of changepoints with short memory segments. Applying our classification approach to this series will give an additional indication as to which model is statistically more appropriate.

The parameters of the fitted changepoint and long memory models are given in Table 3. Diagnostic autocorrelation and partial autocorrelation function plots are given in Figure 3. The level shifts are given in respect to their po-

sition in the series, but correspond to 1951 Q3, 1962 Q4, 1965 Q2, 1984 Q2. The classifier returns a changepoint classification for this series.

4.2 Stock Cross Correlations

Stock Cross Correlation data has been obtained from the supplementary material of [3]. The data consists of Open to Close stock returns for 6 companies from January 1st 2001 to 30th July 2008 ($n = 2156$). The data is first transformed using a Fisher Transformation, then correlations are calculated between each stock. Here analysis will look at the correlation between American Express and Home Depot.

This data has been analysed previously by [2] to determine between fractional integration (long memory behaviour) and level shifts and is given in Figure 2b. Parameters for the models fitted by the algorithm are also in Table 3. It can be seen that one of the AR coefficients is close to 1 indicating an element of non-stationarity, however we conducted a test of stationarity on this segment using the `locits` R package [24] which implements the test of

stationarity from [23] (no rejections) and also the `fractal` R package [4] which implements the Priestley-Subba Rao (PSR) test [27] (time varying p-value 0.061). This coupled with autocorrelation and partial autocorrelation function plots given in Figure 4 means we conclude that the segment is stationary. Here the estimated changepoints at times 715, 841, 847 and 896 correspond 15/12/2002, 20/04/2003, 26/04/2003 and 14/06/2003. The distance scores given by the classifier indicate a strong preference for long memory over changepoints. This result stands against that found in [2] which indicated a preference for a model with similarly 4 changepoints. The difference is likely due to the fact that in [2] the changepoint model does not contain any short memory dependence and we have shown here that if that short memory structure is correctly taken into account within the sub-series then the series shows greater evidence of long memory properties.

5 Conclusion

The wavelet classification process presented within this paper provides the user a distinct choice over a number of proposed models, and when explicitly applied to an ambiguity such as long memory or a changepoint as in Section 3, it provides an additional piece of information to aid decision making. The accuracy of the classifier over a number of simulated models has been presented within Section 3 and applied to data from the Financial and Economic fields in Section 4.

The Evolutionary Wavelet Spectrum provides a representation of non-stationarity which is lacking in the commonly used (averaged over time) spectrum. This gives an advantage when drawing comparisons between non-stationary and stationary series, since the wavelet spectrum may appear substantially different. Quantifying this visual difference allows for a direct comparison between the series and each proposed model.

The variance-corrected squared distance metric used in the proposed classifier has been demonstrated to be quite accurate under the ambiguity of long memory and changepoint models. It is particularly effective at identifying changepoint models correctly, as the results in Table 1 demonstrate. It was noted that there is relatively lower variation between the simulations generated for the changepoint than the long memory model, which reduces the distance

metric significantly even though it is variance corrected.

As mentioned in Section 1 there are many series that can be found in fields such as Economics and Finance which show evidence of the ambiguity investigated here. This classification is not intended to propose a final model for these series, but instead give additional information, treated perhaps as a diagnostic. This could be to begin investigation of a series, or to confirm a previously found model fit. As this is not a formal test, the lack of assumptions allows for more flexibility in how the classification can be used. This work however is not restricted only to the ambiguity mentioned here, further work could extend it to determine between other features, such as local trends and seasonal behaviour or combining the behaviour of both models i.e., a long memory model with a changepoint.

An aspect not covered in this paper is the precise form of ARMA and long memory models in the LSW paradigm, i.e. how the model coefficients relate to the $W_{j,k}$'s. This is an interesting area for future research which would cement the LSW model as an encompassing model but is beyond the scope of this paper.

An R package (`LSWclassify`) is available from the authors that implements the method from the paper.

A Proof of Theorem 1

Proof We replicate the steps of the proof within the Appendix of [8] up until (A.6), where following this step the short memory condition is used. To briefly

summarise previous steps,

$$\begin{aligned}
 P(D_1 - D_2 > 0) &= P(X - t > 0) \leq E(\tilde{X}^2)/t^2, \\
 &\quad \text{(by Chebyshev's Inequality)} \\
 E(\tilde{X}^2) &=: I + II, \\
 I &\leq C J_0 J^* \sum_{j=-1}^{-J_0} \sum_{i=-1}^{-J^*} 2^{i+j} E\{b_{i,j}^2\}, \\
 E\{b_{i,j}^2\} &=: 2A + 2B.
 \end{aligned}$$

Definitions for these components can be found in the original proof. Component A is where we alter the proof.

Recall $I_{k,N}^{(i)}$ is the wavelet periodogram at a fixed scale i , at position k with total length N , with $d_{k,N}^{(i)}$ the wavelet coefficient corresponding to it through the relationship $I_{k,N}^{(i)} = \left(d_{k,N}^{(i)}\right)^2$. We continue the proof from (A.6) using the ARFIMA assumption instead. Following from above (A.6):

$$\begin{aligned}
 A &= E \left\{ \sum_{k=1}^N \left\{ I_{k,N}^{(i)} - E \left(I_{k,N}^{(i)} \right) \right\} c_{j,k} \right\}^2 \\
 &\leq 2^{2j} \sum_{k,k'=1}^N \left| \text{cov} \left(I_{k,N}^{(i)}, I_{k',N}^{(i)} \right) \right| \\
 &= 2^{2j} \sum_{k,k'=1}^N 2 \text{cov}^2 \left(d_{k,N}^{(i)}, d_{k',N}^{(i)} \right) \\
 &\quad \text{(by Isserli's Theorem)} \tag{4}
 \end{aligned}$$

[15] gives bounds for the covariance of wavelet coefficients;

$$\begin{aligned}
 \text{cov} \left(d_{k,N}^{(m)}, d_{n,N}^{(j)} \right) &= C_1 |\alpha|^{2d-1-2M} + R_{2M+1} \\
 \alpha &= 2^{m-j} k - n, \quad m \geq j \\
 |R_{2M+1}| &\leq C_2 |\alpha|^{2d-2-2M},
 \end{aligned}$$

where $M \geq 1$ is the number of vanishing moments in the wavelet used. Using $|\alpha| = |2^{i-i} k - k'| = |k - k'| \geq 1$ and substituting into Equation (4):

$$\begin{aligned}
 A &= 2^{2j+1} \sum_{k,k'=1}^N (C_3 |\alpha|^{2d-1-2M} + R_{2M+1})^2 \\
 &= 2^{2j+1} \sum_{k,k'=1}^N |C_3 |\alpha|^{2d-1-2M} + R_{2M+1}|^2 \\
 &\leq 2^{2j+1} \sum_{k,k'=1}^N (|C_3 |\alpha|^{2d-1-2M}| + |R_{2M+1}|)^2 \\
 &\leq 2^{2j+1} \sum_{k,k'=1}^N (C_4 |\alpha|^{2d-1-2M} \\
 &\quad + C_5 |\alpha|^{2d-2-2M})^2
 \end{aligned}$$

As $|\alpha|^{2d-2-2M} \leq |\alpha|^{2d-1-2M}$ we have:

$$\begin{aligned}
A &\leq 2^{2j+1} \sum_{k,k'=1}^N (C_6 |k - k'|^{2d-1-2M})^2 \\
&= 2^{2j+1} \sum_{k,k'=1}^N C_7 \frac{1}{|k - k'|^{-2(2d-1-2M)}} \\
&= 2^{2j+1} \sum_{s=1}^{N-1} (N-s) C_7 \frac{1}{s^{-2(2d-1-2M)}} \\
&= 2^{2j+1} C_7 \left[N \sum_{s=1}^{N-1} \frac{1}{s^{-2(2d-1-2M)}} \right. \\
&\quad \left. - \sum_{s=1}^{N-1} \frac{1}{s^{-4(d-M)+1}} \right]
\end{aligned}$$

Given that $|d| < 0.5$ and $M \geq 1$ then $4 < -2(2d-1-2M) = \delta_1$ and $3 < -4(d-M)+1 = \delta_2$. We can then replace the sums using the definition of Generalised Harmonic Numbers and their convergence:

$$H_{n,m} = \sum_{k=1}^n \frac{1}{k^m}$$

$$H_{n,m} = \mathcal{O}(1) \quad \text{as } n \rightarrow \infty \quad (m > 1)$$

Thus

$$A \leq 2^{2j+1} C_7 (NH_{N-1,\delta_1} - H_{N-1,\delta_2}) = 2^{2j+1} C_7 \mathcal{H}_N,$$

where $\mathcal{H}_N = NH_{N-1,\delta_1} - H_{N-1,\delta_2}$. Returning to consider (A.4) from [8], we find a bound for component I , where $J_0, J^* = \log_2 N$ and $\Delta = \frac{1}{(2 \log_2 a - 1)}$:

$$\begin{aligned}
I &= C_8 J_0 J^* \sum_{j=-1}^{-J_0} \sum_{i=-1}^{-J^*} 2^{i+j} [2^{2j+1} C_7 (NH_{N-1,\delta_1} \\
&\quad - H_{N-1,\delta_2}) + N^{1+\Delta} 2^j] \\
&= C_8 \log_2^2 N \sum_{j=-1}^{-J_0} 2^j [2^{2j+1} C_7 \mathcal{H}_N \\
&\quad + N^{1+\Delta} 2^j] (1 - 2^{J^*}) \\
&= C_8 \log_2^2 N \left[\sum_{j=-1}^{-J_0} C_7 2^{3j+1} (1 - 2^{J^*}) \mathcal{H}_N \right. \\
&\quad \left. + \sum_{j=-1}^{-J_0} 2^{3j} (1 - 2^{J^*}) N^{1+\Delta} \right] \\
&= C_9 \log_2^2 N (1 - 2^{-J^*}) \mathcal{H}_N \sum_{j=-1}^{-J_0} 2^{3j+1} \\
&\quad + C_8 \log_2^2 N (1 - 2^{-J^*}) N^{1+\Delta} \sum_{j=-1}^{-J_0} 2^{3j} \\
&= C_9 \log_2^2 N (1 - 2^{-J^*}) \mathcal{H}_N \frac{2}{7} (1 - 2^{-3J_0}) \\
&\quad + C_8 \log_2^2 N (1 - 2^{-J^*}) N^{1+\Delta} \frac{1}{7} (1 - 2^{-3J_0}) \\
&= \log_2^2 N (1 - N^{-1}) (1 - N^{-3}) \\
&\quad [C_{10} \mathcal{H}_N + C_{11} N^{1+\Delta}] \\
&= \log_2^2 N (1 - N^{-3} - N^{-1} + N^{-4}) \\
&\quad [C_{10} \mathcal{H}_N + C_{11} N^{1+\Delta}] \\
&\leq C_{12} \log_2^2 N (\mathcal{H}_N + N^{1+\Delta})
\end{aligned}$$

Following this, using results in [8] the probability of misclassification is:

$$P(X > t) = \mathcal{O}(\log_2^2 N [N^{-1} + N^{\Delta-1}]).$$
