Ethnic Externalities in Education and Second Generation Immigrants

Firat Yaman¹

I analyze the role of ethnic and native human capital – defined respectively as the average years of schooling of ethnic groups and of natives within a specific region – and of ethnic concentrations in the educational attainment of second generation immigrants in Germany. Compared to natives' children, parents' education has a small and insignificant effect on second generation immigrants' education. Ethnic concentrations have a negative effect, while ethnic capital is insignificant. The effect of native capital, too, is insignificant but much larger in magnitude than the effect of ethnic capital. For women, mother's education is relatively more important. For men, ethnic concentrations constitute a stronger impediment to educational attainment than for women.

JEL classification: I20, J15, R23

Keywords: 2nd generation immigrants, ethnic capital, ethnic concentration

This paper was written as part of the Marie Curie Research Training Network on 'Transnationality of Migrants' TOM, which is funded by the European Commission through the Human Resources and Mobility action of its Sixth Framework Programme (EC Contract No. MRTN-CT-2006-035873). I am indebted to my thesis supervisors Jason Abrevaya and Daniel Hamermesh.

1 Introduction

In many European countries the educational achievements of immigrants' children trail those of natives' children.² A recent OECD (2009) study compares educational and labor market outcomes of children of immigrants and finds that for the classical immigration countries Australia, Canada, New Zealand and the United States "the children of migrants have education and labor market outcomes that tend to be at least at par with those of the children of natives." Similarly, Dustmann et al. (2010) demonstrate that in the United Kingdom immigrants' children close initial test score gaps over the course of their compulsory schooling. A very different picture emerges for Austria, Germany and Belgium. Test scores from the OECD's Programme for International Student Assessment (PISA) reveal that test score gaps between children whose parents were born in Germany and native children of immigrants amount to the equivalent of about at least two years of schooling. Part of the gap can be explained by the children's socio-economic background, notably the education of parents, but even after controlling for those factors a substantial and significant gap remains. The study confirms the results by Riphahn (2003) on the educational attainment of 2nd generation immigrants in Germany. Riphahn finds that substantial gaps in education relative to natives' children exist and moreover that they do not seem to shrink over cohorts. The children of immigrants from guest-worker nations, notably Turkey, the former Yugoslavia, and Italy, are particularly disadvantaged.

In light of the very different selection of immigrants to the Anglo-Saxon countries compared to continental Europe (e.g. a point-based immigration policy in Canada, or highly educated immigrants from Commonwealth countries in the UK vs. low-skill immigration to other European countries), the concept of ethnic capital as introduced by Borjas (1992) emerges as a possible explanation for these different experiences with the second generation. The idea put forward by Borjas is that the average human capital endowment of a certain immigrant group exerts an externality on the human capital accumulation of a child belonging to that group. In a follow-up paper Borjas (1995) specifies the transmission mechanism of ethnic capital as neighborhoods and reports some evidence for the importance of this channel.

²See Dustmann and Glitz (2011) for a comprehensive overview of the literature on education and migration, including the inter-generational transmission of human capital among immigrants.

The innovations of the present paper are 1) the theoretical and empirical extension of the human-capital model in Borjas (1992) to include both ethnic and native capital, 2) allowing for the marginal effects of those variables to vary with the ethnic concentration in the region of a 2nd generation immigrant's upbringing, and 3) linking educational outcomes of immigrants directly to completed educational outcomes of their children using a 25-year running panel study. The last point requires me to confront the substantial panel attrition (partly due to return migration) that inevitably occurs over such an extended period of time. Furthermore, the possibility that immigrants sort along unobserved characteristics into different regions has to be accounted for. To check for the robustness of results to attrition bias I exclude the 10% of the sample who were most likely to drop out of the panel (but did not). To correct for endogeneity of ethnic concentration I use ethnic concentration measured in the year of the mother's year of arrival in Germany or ethnic concentration in 1975 if the mother had arrived before that year (because the ethnic concentration measure is not available for earlier years).

The main findings of this paper are:

1. The effect of the parents' schooling in the educational attainment of immigrants' children is much smaller (about a fifth) than for natives' children. This finding confirms results of earlier work by Gang and Zimmermann (2000) and Dustmann (2008). Parental schooling is more important for women's educational attainment while it seems to play no role for men.
2. Immigrants' children who lived in regions with high ethnic concentrations attain lower levels of education.
3. Ethnic capital is economically and statistically insignificant. An additional year of schooling of the *native* population is associated with 0.3 years of additional schooling for immigrants' children (albeit with a high standard error).
4. The mother's education is an important determinant for women's education, and ethnic concentration's effect on education is stronger for men.

The absence of any ethnic capital effect is an important finding and echoes similar results for Denmark in Jakobsen and Smith (2003). The exploration of native capital externalities on 2nd generation immigrants is a novelty in this paper. While the literature has considered the effect of ethnic capital and neighborhood effects in

educational or employment outcomes of second generation immigrants, the role that native capital might play in this context has not been explored theoretically nor empirically, with the exception of Borjas (1995) who found that a small number of neighborhood characteristics including the educational composition of the neighborhood accounts for most of the ethnic capital effect.

The question addressed in this paper lies at the nexus of several research areas. It is related to the vast literatures of intergenerational human capital mobility both in general – recent examples including Black et al. (2005) or Bleakley and Chin (2008), and for the German case Heineck and Riphahn (2007) or Casey and Dustmann (2005) – and for immigrants in particular.³ The paper is further related to the neighborhood or, more generally, the social capital literature, in particular studies of children's outcomes. An early and influential paper in economics is Case and Katz (1991), who find substantial neighborhood effects for disadvantaged youth in Boston. Ginther et al. (2000) review some of the earlier literature and demonstrate the sensitivity of neighborhood effects on children's outcomes (including high-school graduation) to the inclusion of household variables. More recent studies finding significant effects of peers and neighborhoods on children's educational outcomes include Goux and Maurin (2006) and Rury (2004). Raaum et al. (2006) find negligible, if any, neighborhood effects for Norway. Bobonis and Finan (2009) provide evidence of peer effects on secondary school enrollment in Mexican villages using a randomized controlled trial conducted to evaluate a policy intervention.

A closer relation exists to studies which have explicitly looked at the role of ethnic capital or network effects in the context of the intergenerational transmission of education, Borjas (1992) and Borjas (1995) being the pioneering papers. Gang and Zimmermann (2000) study the schooling attainment of second generation immigrants who were born in Germany or arrived before the age of 16. The authors find that immigrants' education has no effect on the educational attainment of their children (contrary to natives' education on their children) and that there is a positive group size effect. However, the latter is measured as the number of immigrants belonging to the group in Germany and must be considered a rather crude measure of network effects. Åslund et al. (2011) find a positive externality of ethnic capital on children's GPA rank. Their study enjoys the advantage of an exogenous initial allocation of refugee immigrants to Swedish municipalities. A comparison of estimates based

³For example Van Ours and Veenman (2003), Belzil and Poinas (2010), and Riphahn (2003) for Germany.

on initial locations with later residence locations reveal that less educated immigrants sort into ethnically concentrated neighborhoods, creating a severe downward bias of ethnic concentration coefficients on educational attainment. Nielsen et al. (2003) consider the role of ethnic capital and neighborhood characteristics in various school-to-work transition measures of second generation immigrants with a rather mixed set of results: ethnic capital seems to prolong the waiting time till entering the first job, but only for females, and seems to play no discernible role other than that. Ethnic concentration increases the same duration for males, and decreases it for females, and is associated with a longer first-job tenure for females, and a shorter first-job tenure for males. The authors control for several neighborhood characteristics, but do not have a measure for native capital. Jakobsen and Smith (2003) find that the concentration of 1st and 2nd generation immigrants in the childhood municipality reduces the probability of finishing a qualifying education, whereas ethnic capital has no impact.

The concept of ethnic – or social – capital is admittedly vague. It is thus important to stress what this paper does and does not do. What this paper does is to analyze the presence, direction and magnitude of externalities exerted by the educational quality of immigrants and natives on the second generation of immigrants. It does not attempt a dissection of the concept of ethnic capital. In other words, it can not distinguish between different channels through which these externalities might operate on an individual level (e.g. peer effects, exogenous effects, or endogenous effects in the sense of Manski (1993)), which is the main limitation of this study. The next section extends the Borjas (1992) model to include native capital and ethnic concentrations. The third section discusses the data and the construction of the variables of interest, the fourth section describes the estimation and the strategy to deal with panel attrition and selection into regions. The fifth section presents results before I conclude with the sixth section.

2 Theory

Consider the ethnic capital model of Borjas (1992). An ethnic household consists of a parent and a child. The parent has a CES utility function defined over the child's human capital h_{t+1} and his own consumption C_t

$$U = [\delta_1 h_{t+1}^\rho + \delta_2 C_t^\rho]^{1/\rho} \quad (1)$$

with $\rho < 1$ and $\sigma = 1/(1 - \rho)$ is the elasticity of substitution between consumption and child quality. The parent can divide his time between “renting out” his own human capital at a rate R and devoting it to his child’s human capital production. With the price of the consumption good normalized to 1, the budget constraint is

$$R(1 - s_t)h_t = C_t \quad (2)$$

where s_t is the fraction of time devoted to the child, C_t is the parent’s consumption, and h_t his human capital. I modify the production function for the child’s human capital production in Borjas (1992)

$$h_{t+1} = \beta_0 (s_t h_t)^{\beta_1} \bar{h}_{t,e}^{\beta_2(\theta)} \bar{h}_{t,n}^{\beta_3(\theta)} \quad (3)$$

The child’s human capital is produced with parental input, consisting of time devoted and the parent’s own human capital, with *ethnic* capital $\bar{h}_{t,e}$, and with *native* capital $\bar{h}_{t,n}$. The relative weights of ethnic and native capital are allowed to vary according to the share of ethnics in a pre-defined locality (neighborhood, school district, city, etc), denoted by θ .⁴ Thus, the parent’s problem is characterized by

$$\max_{s_t} U = \left[\delta_1 \left(\beta_0 (s_t h_t)^{\beta_1} \bar{h}_{t,e}^{\beta_2(\theta)} \bar{h}_{t,n}^{\beta_3(\theta)} \right)^\rho + \delta_2 (R(1 - s_t)h_t)^\rho \right]^{1/\rho} \quad (4)$$

The inclusion of native capital and the role of the share of ethnics is motivated by the possibility that natives and ethnics can be substitutes (or complements) in the constitution of the relevant externality in human capital production. Imagine two ethnic households with equal parental human capital, one living in an ethnic enclave, the other in a mainly native region. It is conceivable that ethnic capital plays a larger role in the education of the former child (e.g. through peer effects, role models, etc) while for the latter child the natives in the region form the only reference group (see Currarini et al. (2009) for a theoretical motivation of the interaction between group sizes and network formation). The dependence of the weight of the two forms of capital on the share of ethnics is left unspecified, but it seems reasonable to expect a priori a larger role for ethnic capital when the exposure of the child to it is higher.

⁴There are different ways to introduce ethnic and/or native capital externalities into the education of a child. An earlier version of this paper has used a model in which children had a preference over conforming to other children of the same ethnicity.

Solving the parents maximization problem results in the following equations:

$$\begin{aligned}\frac{\partial \log s_t}{\partial \log h_t} &= \frac{\rho(1-s_t)(\beta_1-1)}{(1-s_t)(1-\beta_1\rho) + s_t(1-\rho)} \\ \frac{\partial \log s_t}{\partial \log \bar{h}_{t,e}} &= \frac{\rho(1-s_t)\beta_2(\theta)}{(1-s_t)(1-\beta_1\rho) + s_t(1-\rho)} \\ \frac{\partial \log s_t}{\partial \log \bar{h}_{t,n}} &= \frac{\rho(1-s_t)\beta_3(\theta)}{(1-s_t)(1-\beta_1\rho) + s_t(1-\rho)}\end{aligned}$$

Taking logs of the human capital production equation, differentiating, and using the preceding results give:

$$\frac{\partial \log h_{t+1}}{\partial \log h_t} = \frac{\beta_1(1-\rho)}{(1-s_t)(1-\rho\beta_1) + s_t(1-\rho)} > 0 \quad (5)$$

$$\frac{\partial \log h_{t+1}}{\partial \log \bar{h}_{t,e}} = \frac{\beta_2(\theta)(1-\rho s_t)}{(1-s_t)(1-\rho\beta_1) + s_t(1-\rho)} > 0 \quad (6)$$

$$\frac{\partial \log h_{t+1}}{\partial \log \bar{h}_{t,n}} = \frac{\beta_3(\theta)(1-\rho s_t)}{(1-s_t)(1-\rho\beta_1) + s_t(1-\rho)} > 0 \quad (7)$$

Thus, the child's human capital is increasing in its parent's human capital, in ethnic capital, and in native capital. The signs of

$$\frac{\partial^2 \log h_{t+1}}{\partial \log \bar{h}_{t,e} \partial \theta}$$

and

$$\frac{\partial^2 \log h_{t+1}}{\partial \log \bar{h}_{t,n} \partial \theta}$$

are an empirical question. I conjecture that the former is positive, and the latter negative. Intuitively, if ethnic concentration is high, ethnic capital should exert a stronger and native capital a weaker externality.

3 Data

The sample of immigrants, their children, and their individual characteristics come from the German Socio-Economic Panel (SOEP). The earliest wave of the SOEP that allows identification of the county of residence of households is the 1985 wave. I include all children aged 0 to 16 (some of whom were not born in Germany) in the 1985 wave and, tracking those individuals over all waves up to and including 2010, extract their years of schooling. The most numerous immigrant groups in the SOEP will be considered in this paper. Those are immigrants from Turkey, the former Yugoslavia, Italy, Spain, and Greece. Regional aggregates for the years

1975-1995 are projected from the Employee Sample (IABS) – a 2% sample of the employee population in Germany subject to social security payments. See Bender et al. (2000) for a detailed description of this dataset.

3.1 Individual and household characteristics

The outcome variable of interest is educational attainment of immigrants' children, measured as years of schooling. Explanatory variables at the individual or household level are a gender dummy, the mother's years of schooling⁵, monthly net household income⁶, a dummy for the mother having had any schooling in Germany, a measure of the mother's German speaking ability, the mother's age at migration, the number of adult household members, the number of children in the household, a dummy for the child not being born in Germany, and the year of birth.

The inclusion of the language variable is due to the evidence that the language spoken at home is an important determinant in the educational achievements of immigrants' children presented in Dustmann et al. (2010) and Dustmann and Glitz (2011). It is measured on an integer scale from 1 (speaking very well) to 5 (not speaking at all). I use the average speaking ability reported in the survey years 1985-1995 to minimize issues of measurement error. The year of birth is intended to capture a secular increase in the educational attainment in Germany over the last decades, documented by Heineck and Riphahn (2007) and Bildungsbericht (2008). Younger cohorts are more likely to finish high-school and to attend higher education.

3.2 Regional variables

Regional variables are ethnic capital, native capital, ethnic concentration, and interactions between ethnic capital and ethnic concentration as well as native capital and ethnic concentration. For a given year these aggregates are defined for 142 different regions (every region being tied to a local office of the German Employment Agency) in Germany, including West Berlin, and the five aforementioned ethnicities using the IABS. These regions are

⁵Regressions with the father's characteristics are run as a robustness check. See results section.

⁶Averaged over the reported incomes when the child was aged 6 through 10, and deflated to 1985 values by assuming an annual inflation rate of 2%.

metropolitan areas and their suburbs, or groups of economically tied counties. The population of West Germany in 1990 was 63.7 million, making the average population of a region approximately 450,000. The choice of the number of regions is a compromise between choosing small regions, thus more accurately capturing the geography in which most interactions of its inhabitants take place, and larger regions, thus preserving larger samples per region to more accurately measure regional variables and decrease attenuation bias.

Ethnic concentration is defined as the share of employees aged 18 to 64 of an ethnicity in a region in all employees aged 18 to 64 of that region. Ethnic capital is defined as the average years of schooling of all employees of an ethnicity in a region. The construction of these regional variables has some shortcomings. First, the variables are based on region of employment rather than region of residence (though the regions are rather large, so that the two are often likely to coincide). Second, the fragmentation of the sample into 142 regions and 5 ethnicities introduces considerable measurement error due to small cell-sample sizes. Third, measurement error is also due to the sample including only employees or transfer recipients. Individuals not in the labor force are not in the population from which the sample is drawn. This might be an important omission if different ethnicities have different participation rates. Finally, the education variable in the IABS exhibits some inconsistencies over time (such as a regression in the educational attainment of an individual) and a high number of missing values. I use the imputation and correction procedures from Fitzenberger et al. (2005) to construct the years of schooling.⁷

The regional variables enter the regressions through the degree of exposure that the immigrants' child had to them at the ages 6 through 10.⁸ Every year is equally weighted. For example, if child i of ethnicity j is 8 in 1985 and lives in region 1 in 1985 and 1986, and in region 2 in 1987, then the following ethnic capital value is assigned to it: $C_{i,j} = (1/3) * C_{r=1,j,t=1985} + (1/3) * C_{r=1,j,t=1986} + (1/3) * C_{r=2,j,t=1987}$ where r denotes the region, t the year, and C denotes ethnic capital. The same weighting is applied to ethnic concentration and to native capital. Children whose residence at or before age 10 is not known are assigned 0 for the regional variables, but are marked by a dummy variable (denoted *after10*). The ages 6 through 10 are chosen as the relevant exposure time because of the structure of the German educational system in the 1980s and early 1990s.

⁷The results reported here use the imputation rule 1. Results with imputation rules 2 and 3 are similar and can be requested from the author.

⁸I have also tried exposure windows of 6 to 12 and 6 to 15. The results remained unchanged.

Children typically were enrolled in primary school at the age of 6. During fourth grade teachers recommended one of several secondary education school types for the child, depending on what they believed to be the child's educational potential. Traditionally there have been three different school types, the *Hauptschule* providing a basic secondary education, the *Realschule* being more advanced than the former, and the *Gymnasium* intended to prepare schoolchildren for university. Few school switches occurred after this initial assignment.⁹

3.3 Descriptive Statistics

Summary statistics for individual characteristics are presented in table 1. The table reports statistics on the variables of interest separately for natives' and immigrants' children separated by ethnicity. Children of immigrants attain lower levels of education than their native peers. The ranking of their years of schooling corresponds roughly to the ranking in education among their mothers, suggesting an important role for the intergenerational transmission of education. Turkish mothers have considerably worse German skills than other ethnicities, and Greek households have the highest income levels. 36% of the Turkish children were not born in Germany. We also see that Turkish and Greek children had exposure to lower degrees of ethnic capital, and Turkish and Yugoslavian children had the highest exposure to their respective ethnic concentrations, reflecting the fact that these immigrant groups were the largest in the 1980s.

Table 2 reports unweighted averages of the regional variables (averaged over all regions). Ethnic capital averages are reflected closely in the sample statistics in table 1. Ethnic concentrations in the sample are higher because immigrants are more likely to live in and be sampled from regions with high ethnic concentrations. The table also illustrates that regional variables will be measured with considerable error, especially for smaller immigrant groups such as Greeks and Spaniards. There are 1,196 Spaniards in the IABS in 1985, observed in 121 regions. Thus, for Spaniards regional variables will be based on average on only 10 Spanish observations per region.

Table 3 reports the inter-regional correlations of ethnic concentrations. All correlations are positive and

⁹According to the Bildungsbericht 2008, a report on education in Germany published by the state ministries of education and the federal ministry of education and research, 3% of children in grades 7-9 switched school types in 2006/2007.

highly significant, pointing to the fact that immigrants of different ethnicities cluster in the same regions. This reflects that these groups of immigrants were recruited for similar work tasks in similar industries.

4 Estimation

I estimate the following equation:

$$y_i = \beta_0 + \beta_1 y_{i,mother} + \gamma' X_i + \delta' Y_i + \varepsilon_i \quad (8)$$

with y_i being years of schooling of observation i , and $y_{i,mother}$ the years of schooling of the mother of i . X_i is a vector of other control variables, Y_i is a vector of regional variables (ethnic and native capital, ethnic concentration, and interactions) and ε_i is the residual. To handle multiple children belonging to the same household all regressions will be clustered at the 1985 household level. Results for this benchmark model are reported in table 4 and will be discussed in the results section.

4.1 Attrition and Endogeneity

To observe the completed years of education of a new-born child in 1985, the child would have to be followed for at least 16 years, and in some cases for as long as 25 to 30 years. Panel attrition is thus substantial, and it is more so for immigrant households since return migration is an additional source of attrition. There are 1,133 observations of immigrants' children with information on all explanatory variables, but only 687 for whom completed years of schooling are observed (61% retention). For natives 1,389 out of 1,935 observations have information on years of schooling (72% retention). Furthermore, the residence of an immigrant is clearly a choice variable and it is likely – at least for some immigrants – that the educational “environment” for their children plays some role in that decision. If immigrants with stronger preferences towards their children's education move to “better” regions (with higher ethnic and/or native capital), then a simple regression might attribute higher educational attainments of these children to ethnic and/or native capital, even though it might to some extent be due to more parental investment.

To assess the impact of these issues I exclude those 10% of the sample who had the highest predicted probability to attrite. Probabilities were predicted from a probit regression with the dependent variable being an indicator for whether the observation has information on completed years of schooling. This information is missing for observations which have discontinued participation in the panel (through refusal, return migration, death, etc). The explanatory variables are all variables included in the regression of equation 8 and additionally a full set of year-of-birth dummies and an indicator equalling one if in the 1985 survey the parents stated an intention to return to their native country within a few years. The coefficient on the intention to return was -0.241 with a standard error of 0.1 (Pseudo-R2 in this regression was 0.23, see table 8 in the appendix).

Even though all regional variables come as a “packet” with the choice of residence, for lack of good instruments I treat only ethnic concentration as endogenous given its prominence in the regression results and the high cross-regional correlations of ethnic concentration among different immigrant groups. The instrument in the regression of ethnic concentration is the mother’s year-of-immigration ethnic concentration in the region of residence in 1985 if the mother immigrated in or after 1975, and the 1975 ethnic concentration in the region of residence in 1985 if the mother immigrated before 1975 (ethnic concentrations before 1975 are not available). Call this the initial ethnic concentration. The initial region of residence prior to 1973 was usually determined by Germany’s federal employment agency. The guest-worker recruitment was stopped in 1973, and immigration from the countries considered in this paper continued in the 1970s mainly for family reunification. Ethnic concentrations in the year of immigration and in the initial period after immigration are thus assumed exogenous to immigrants’ ability and inclination to invest in their children’s education, but exhibit strong correlations with subsequent ethnic concentrations.

5 Results

A first set of results is reported in table 4. The first four columns are results for immigrants’ children, the last two columns are results for natives’ children. The difference in the determinants of years of schooling between natives’ and immigrants’ children is striking. Intergenerational transmission of education is much stronger for natives, confirming the finding in Gang and Zimmermann (2000) and Dustmann (2008). Equally, household

income in native households is a strong predictor for educational attainment, but not in immigrant households. Daughters of natives attain more schooling than sons, but not significantly so. Again, the effect is absent for immigrants' children. Looking at determinants specific to immigrants, we see that German skills (1 speaks very well, 5 does not speak at all) increase the child's education, but not significantly so. Children who were born in Germany enjoy an educational advantage of some 7 months of schooling. Even when only household variables are included and when the same regressors are used a significant difference between mother's education coefficients between the native and the immigrant samples remains (not reported).

For the regional variables – ethnic and native capital, ethnic concentration (native concentration for natives), and an interaction term of the two – we observe a nuanced picture. If only ethnic capital and ethnic concentration are included (column 2), ethnic concentration has a significantly negative effect. The coefficient of ethnic capital is virtually zero. For natives (column 5), the effects of both of those variables are small and insignificant. The effect of native capital (in column 3) is statistically insignificant but much larger in magnitude compared to the coefficient of ethnic capital.¹⁰ Including interaction terms (column 4, and column 6 for natives' children) predictably changes the coefficients of the other regional variables, but they are neither individually nor jointly significant. Both are negative which is contrary to our expectation with regard to ethnic capital, but in line with our expectation with regard to native capital (any positive effect of native capital is diminished as the ethnic concentration increases). The individual and household determinants are mostly unchanged by the inclusion of regional variables (except for the dummy indicating whether the mother has had any education in Germany).

Table 5 shows results for the regional variables obtained after excluding the observation who were most likely to attrite and for the 2SLS results with ethnic concentration instrumented by initial ethnic concentration. We see that the coefficient of ethnic concentration becomes smaller in magnitude in the restricted sample suggesting that attrition could be biasing the concentration coefficient downward. We also observe that the magnitude of the coefficient on ethnic concentration is 10% smaller in the 2SLS regression than in the OLS regression. The upward correction of the ethnic concentration effect is in line with the selection of regions with low ethnic concentrations by immigrants who have stronger preferences over their children's education, and who might be

¹⁰The correlation coefficient between ethnic and native capital among those observations for whom the variables are measured – that is those observations whose region of residence is observed for at least some time when they are aged 6 to 10 – is 0.28.

moving to those regions in the expectation that it will benefit their children.

Table 6 reports separate results for males and females. The first two columns use mother's years of schooling as parental capital. Mother's education does not play a role in the schooling of men, but it has a significant effect on women's education. Still, the effect of mother's education is only about two thirds of the effect for natives. Ethnic and native capital seem to play more important roles for men. The insignificance of the mother's education for men could be due to boys choosing their fathers as role models, but as the results in columns 3 and 4 indicate, the father's education plays no role for men, and is insignificant and smaller compared to mother's education for women.

Table 7 reports some robustness and sub-sample results. Column 2 reports results when including two additional regional variables – the share of employees working in mining, manufacturing, or construction, and the median wage in the region. The magnitude of the ethnic concentration coefficient increases by 40% while the other coefficients remain largely unchanged relative to the benchmark model (column 1). Including a set of state dummies defined over the state of residence in 1985 (column 3) has no discernible effect. The fourth column reports results from a sample using only observations for whom information on their residence at any point between ages 6 and 10 is available. Results are similar to the benchmark model (column 1). Looking at observations who were born in Germany only, some important differences arise. First, mother's education becomes completely unimportant, and second, the regional variables' importance increases, with the familiar result that native capital exerts a positive, and ethnic concentration a negative influence.

6 Discussion and Conclusion

This paper has analyzed the determinants of educational achievement of immigrants' children in Germany, with a focus on the role played by regional aggregates such as ethnic concentration, ethnic capital, and native capital. Results show that 1) household variables – and in particular the parents' education – play a minor role, especially in comparison to natives' children, 2) ethnic concentrations have a negative effect, 3) ethnic capital has no effect, 4) native capital has a positive (though insignificant) effect, and 5) there are important differences in the relative

importance of those variables between men and women.

The first result could be a feature of low and rather homogenous educational levels of first generation immigrants, especially within, but also between immigrant groups. One has to keep in mind that the immigrant groups considered in this paper were for the most part recruited for work with little skill requirements. The second result points strongly to the possibility that ethnic neighborhoods act as an impediment to educational attainment. It seems unlikely that this is a regional effect, since the effect is absent for natives, and it persists even after controlling for other regional variables and 1985 state-of-residence dummy variables. The impeding effect of ethnic neighborhoods could be due to the children failing to learn proper German before school enrolment or to more network based alternatives in the local labor market, increasing the opportunity cost of staying in education.

The third result constitutes a refutation of the ethnic capital model, at least for the case of Germany. The native capital coefficient has the predicted sign and its magnitude is much larger than the ethnic capital coefficient. Furthermore, the results show that there is some interplay between those two variables. Inclusion of native capital typically decreases the coefficient on ethnic capital. While it is improbable to shed more light into this relationship with household survey data, the results highlight the importance of considering native capital as much as ethnic capital when immigrants' educational attainments are analyzed.
