ABSTRACT

The turbulent wake region of the magnetically rotated D.C. plasma jet was investigated. The study was carried out because more and more industries are looking towards low temperature plasma technology in order to make use of the relatively high temperatures and fast reaction rates associated with the comparatively compact plasma and hybrid plasma-flame reactors. For successful application, however, more needs to be known about the scale of entrainment of the surrounding gases and the mixing patterns in the wake of such arcs. Shadow records obtained by one microsecond duration spark photography and by high speed cinephotography using framing rates of up to 10,000 frames/second were used to visualize the structure of the interfaces of hot and cold pockets of gas and the overall flow patterns in the wake. The extent of the influence of the arc rotation on the flow behaviour downstream was noted. A recently developed corona probe which uses the gas itself as the thermometric medium and therefore presents no thermal inertia problems was used to monitor the temperature fluctuations and thus the "mixedness" of the gas stream. A "schlieren velocimeter" was designed to measure local horizontal and vertical turbulent gas velocities throughout the test region. These velocity distributions were corrected for the effect of the integration along the optical path of the laser beam passing through the turbulent wake and other effects revealed by a statistical analysis. Flow patterns were deduced from local mean velocities and relative local densities were calculated by mass conservation. The density distribution in the wake suggests that part of the energy may be transferred from the arc to the gas in a non-translational form. The volume of air entrained from the surrounding and its distribution throughout the wake was determined.

ACKNOWLEDGEMENTS

I would like to sincerely thank Prof. F.J. Weinberg for his consistent guidance and encouragement. His patience and availability at all times, independent of his many other commitments, must not go unmentioned. Many thanks are also due to Dr. A.R. Jones, who so often acted as a "testing ground" for many ideas in conjunction with this research. His constructive criticism contributed much to the better understanding of the physical processes involved.

Without the technical assistance of Mr. T. Barnes, head of the student workshop, Mr. L. Moulder, the departmental photographer and the staffs of the electronics workshop and departmental stores, much of this work would not have been possible.

My appreciation is due also to the Electricity Council Research Centre for their generous financing of this project.

Last, but not least, I express my gratitude to my family for their continued support in every form possible.

I.J.J.

Chapter I

INTRODUCTION

In an age of continued technical advance, but constrained by energy conservation and efficiency considerations, low temperature plasma reactors are attracting more and more interest for chemical reactions and augmentation of combustion as well as heat transfer problems. We are at present in no position to replace, purely for its thermal effect, relatively disorganized heat energy as obtained for example in combustion by highly organized and therefore thermodynamically more valuable electrical energy. This might well change in the foreseeable future with the arrival of relatively abundant electrical energy produced by nuclear fusion. Meanwhile, however, there are a number of important advantages intrinsic in the use of plasmas in technology that have caused industry to look towards them for answers to some of its more short term problems.

I.1 Plasmas - Reasons for their Use

Electric arcs exist at very high temperatures; 8,000-50,000 °K depending on the atmosphere through which they pass. This makes it possible to raise reactants to uncommonly high temperatures extremely rapidly and in comparatively confined spaces. As a result many reactions will proceed very quickly, as indicated by the exponential term of the reaction rate in the Arrhenius Equation:

$$K = \exp(-E/RT)$$

where K is the reaction rate, T the temperature and R the gas constant.

The liberation of these large quantities of thermal power at such high temperatures allows the throughput of reactants to be kept at a considerable level. Products after passing through a number of intermediate, metastable stages can therefore be generated at very high rates in comparatively small plasma reactors. Careful quenching of the reacting gases can either yield the expected compounds or be used to obtain economically viable quantities of intermediate products depending on the mechanism of the reaction. In the case of the production of solids correct quenching can assure that the particle size distribution obtained lies within limits convenient for their further use as well as resulting in a particular yield.

Apart from these purely thermodynamical advantages, the arc can supply excited and dissociated species as well as ionized gases in large quantities. These species can be used to accelerate even further a given reaction or alternatively to influence the reaction mechanism to make the yield more compatible with the requirements of the industry.

Lastly, the high concentration of power makes it possible to reduce the reactors in dimensions and weight with the resulting advantages in transportation as well as the reduction in heat losses and construction cost.

Compared with high temperature plasmas, as used for example in nuclear processes, the low temperature plasma that is dealt with here can be handled and controlled using present-day technological means and a little ingenuity. Some industrial processes are already using plasma reactors while other applications are still in the laboratory or pilot plant stages. Only some of these can be covered in this introduction.

I.2 Plasmas - Their Applications

I.2.1 Formation of Gaseous Products

The formation of unsaturated hydrocarbons from methane or by the cracking of higher hydrocarbons using an argon driven plasma jet has been investigated (Ref: 1,2,3,4,5). The Hüls process as developed by the Badische Anilin und Soda Fabrik (BASF) in Germany and a plant operated in Montague, Michigan, by du Pont, already use this technique. Acetylene is formed as an intermediate with a life-time of up to 1 msec and temperatures of 3000-4000 °K. Careful quenching arrangements have made it possible to achieve conversion of up to 80% of the available carbon to acetylene. If the reaction is allowed to proceed further, carbon black is deposited.* By replacing the argon in the plasma partially or completely with nitrogen, hydrogen cyanide with conversions of up to 30% has been obtained (Ref. 3,4,6). Both these reactions are strongly endothermic and in both cases only correct quenching will result in the gaseous products.

In comparable work coal has been used as a starting material to form methane, acetylene and hydrogen cyanide gases using an argon plasma. (Ref. 2,4,5). The coal has been introduced either by using it as an anode material or by injecting it into the carrier gas in the form of particles of size up to 200 microns. The formation of unsaturated hydrocarbons is favoured at the high temperatures prevailing in the plasma. Methane and hydrogen cyanide were produced in the main. The precise yield of the resulting gases depended on the type of coal used (Ref. 4)

*The BASF electric arc furnace employs an 8000 kW arc of approximately 1 m length and is capable of producing 15 tons of acetylene per day. (Plate 15).

PLATE XV

HÜLS PROCESS REACTOR

(Photo: Deutsches Museum - München, W. Germany)

but acetylene production was found to be increased by the addition of hydrogen to the carrier gas, while the partial or complete replacement of argon by nitrogen favoured the hydrogen cyanide formation. As a result of dissociation, the introduction of hydrogen and nitrogen, however, always increases the minimum electrical power input required to keep the arc from extinguishing.

Another gas that can be synthesized by passing nitrogen, this time in the presence of oxygen, through a plasma, is nitric oxide. (Ref. 3,6). Where this is not a specifically desired end product this reaction causes an important air pollution problem. Work is, however, being carried out at present at these laboratories that seems to indicate that the addition of excess nitrogen might actually suppress the NO_x emission (Ref. 7).

Another process that has been investigated is the formation of acetylene and hydrogen cyanide using a nitrogen plasma. Passing these gases through a further plasma produces acrylonitrile (Ref. 3). Carbon monoxide and hydrogen have been obtained by passing methane and water vapour through a plasma. The resulting reducer gas has many uses, for example in the extraction of phosphorus from calcium phosphate or calcium fluorophosphate. If the fluorophosphate is used, calcium fluoride is a by-product (Ref. 2,3).

I.2.2 Production of Particles of Predetermined Size

A good example of the use of plasmas in the production of a solid in a desired particle size range is the oxidation of titanium tetrachloride to titanium dioxide (Ref. 2,8). Suitable quenching results in particles in the size range of around $0.25 \mu\text{m}$. These are ideally suited for the manufacture of pigments of white paint.

Ultra-fine thixotropic silica particles for use in, for example, the manufacture of tyres and the reinforcement of fibreglass, can be

produced by injecting a mixture of moist air and pure sand into a plasma jet. The resulting particles of diameters of the order of 10^{-8} m are heavily studded in OH groups provided by the water vapour and link together via hydrogen bonding to form long chains (Ref. 2). It is these chains that encourage the thixotropic properties when added to fluids. Again it is quenching which causes the formation of the very fine particles. Similarly fine boron particles of high purity can be manufactured by reducing boron trichloride in a hydrogen plasma (Ref. 2).

I.2.3 Extraction of Metals

The use of plasmas in the extraction and purification of metals is already widely accepted (Ref. 9). Iron used in the manufacture of steel, for example, can be extracted from its ore using a hydrogen plasma or a plasma flame combination (Ref. 2). Only recently the British Steel Corporation has completed a new arc steel furnace at Llanwern. Other metal extractions at present under investigation include the reduction of zirconium trichloride to zirconium used in nuclear reactors (Ref. 2), of titanium tetrachloride to titanium for use in the aircraft and chemical industries (Ref. 2) and aluminium oxide to aluminium (Ref. 3). In the first two reactions sodium is used as a reducing agent in conjunction with a plasma-jet. Molybdenum disulphide can also be reduced to molybdenum, an important steel additive.*

* Very pure phosphorus for use even in the food industry has been extracted as early as 1900 by the reduction of phosphate rock with coke and silica in an electric furnace at the Chemische Fabrik Griesheim (Bitterfeld-Germany). By 1927 four 10,000 KW furnaces were in operation.

I.2.4 Flame-Arc Hybrids

A separate group of plasma applications is represented by the use of arcs in flame-plasma hybrids. Large throughputs of premixed reactants have had their flames stabilized on relatively small burners by the addition of small amounts of electrical energy in the form of arcs. Although these effects were first reported as early as 1924 by Southgate et al. (Ref. 10) it was more recently that the true extent of the possibilities presented by augmented flames had been demonstrated (Ref. 11,12,13,14). Flow rates of up to 700% of normal "blow off" rates for a given burner size were stabilized by addition of electrical energy representing only 10% of the total chemical energy liberated. This was clearly not only the result of thermodynamic effects. In fact an increase of only 50% in the reaction rate had been predicted kinetically.

An active part was played by certain radicals like OH, H and O, which were either generated directly in the plasma or by dissociated species in the carrier gas like nitrogen which was created while the diatomic gas passed through the plasma jet. Investigations have shown that flame heights remained virtually unchanged for these large flow rates, indicating that the combustion intensity had increased linearly with the raising of the volumetric throughput because of the radicals supplied by the arc.

Aerodynamic considerations along with 3 body recombinations of dissociated species enables one to arrange for high heat transfer rates in the wake region. In practice this rapid energy transfer to solid bodies can be used not only for cutting and welding, but also for rapid cooling of the reacting gas mixtures and the resulting quenching out of metastable intermediates, as in the plasma processes previously mentioned. Although the electrical energy required for the augmented combustion is lower than that for pure plasma reactions because of the

energy supplied by the combustion part, the oxygen present tends to reduce the lifetime of the electrodes considerably.

The possibility of either passing the combustibles along with the carrier gas through the plasma, or introducing them further downstream along with the choice of carrier gas, to yield specific radicals or dissociated species, makes the augmented flame a very versatile tool.

Flame plasma combinations can be expected to enable a designer to reduce the bulk of conventional combustion chambers in industry or to cope with sudden and transient increases in power requirements as in the case of the vertical take-off jet or relighting following "flame-out" at high altitudes. Augmented flames can also be used to oxidize previously non-combustible materials or lean gas mixtures below the lower limits of flammability. An investigation of the latter is presently being carried out in these laboratories. Again the arc preheats the reactants in order to allow them to pass the activation energy hump as well as providing radicals that increase the combustion intensity. Care must be taken, however, to ensure that the amount of electrical energy required does not become more substantial than the released chemical energy, unless the generation of specific chemical products keeps the process cost-effective.

Examples of chemical syntheses using flame-plasma hybrids are the production from lead of litharge used in the manufacture of batteries, ceramic cement or in oil refining and the oxidation of benzene to phenol (Ref. 3).

I.2.5 Plasmas as Analytical Tools

Plasma jets have proved powerful tools in academic and experimental investigations. They have been used in thermodynamic and reactor mechanism studies (Ref. 8). Especially for the latter the possibilities of injecting selected radicals and dissociated species have been extremely useful. The high temperatures prevailing in the arc have also been used to simulate re-entry conditions for the testing of materials to be used in spacecraft construction.

I.3 Plasmas - Problems of their Application and Solutions

Most of the above mentioned applications require the plasma effects to be distributed nearly uniformly throughout the gas flow. Unfortunately the natural behaviour of the arc does not facilitate this. As the conductivity of a gas increases with temperature, most of the arc current tends to pass through the hotter centre of the arc column, thereby heating that channel even further and thus acting as a self-focusing system. The arc further collapses into a very narrow, very hot filament. As any gas approaching the arc expands rapidly, only a small fraction passes the close proximity of the plasma. This extremely high by-pass ratio causes considerable problems as the reactions downstream of the plasma jet become controlled by the mixing of the hot and cold parts of the reactants. These mixing times are in most cases long compared with the rates of quenching discussed above. A great deal of emphasis has therefore been placed on the more uniform distribution of the plasma energy throughout the gas stream.

Attempts have been made to spread the arc by seeding the gas flow with easily ionizable materials. Some success has been obtained with caesium and potassium salts (Ref. 2) which ionize at temperatures as low

as 2500-3500 °K. By choosing an appropriate seeding level all salts could be completely ionized before any of the gas itself ionized and a fall of ionization with increasing temperatures was observed past a temperature of some 3000 °K. This inhibited the contraction of the arc column. Seeding may not, however, always be convenient or even possible and attempts have been made to spread the arc using turbulent flow (Ref. 2,11,13). In order for this to be successful, however, the scale of turbulence needs to be of the same order of magnitude as the arc diameter (of the order of 2 mm). Otherwise the arc might well appear "smeared out" but is really just following the gas flow pattern and is always in contact with the same pockets of gas. Seeding has been used successfully to spread the arc sufficiently to make it compatible in diameter with the scale of turbulence and arc columns have been expanded by as much as a factor of ten by these combined effects.

Other more complex configurations have been used in an effort to increase the arc width. In one particular case the arc was enclosed along the axis of a rotating cylinder, setting up a centrifugal field that removed the colder gases to the cylinder walls. If, however, an appreciable gas flow was passed through this configuration the arc was cooled by convection, or by radiation if particles were included in the gas stream. Due to this cooling the arc then collapsed. An attempt to cause arc spreading carried out in the course of this investigation is discussed in Section III.3.

A completely different form of plasma generation is that using induction heating (Ref. 2,5,6,13,15). A R-F coil surrounding a quartz tube is driven by a generator capable of supplying power at a few kW and a few MHz. A plasma that acts as a secondary, short circuited induction winding is formed inside the tube. By introducing the gas flow tangentially into the ionized region back pressures are set up which cause a recirculatory flow. This reduces heat losses from the plasma,

which therefore expands. Much of the gas, however, still by-passes the plasma and while the ionized core is spread it is by no means uniform unless the gas stream is seeded. While R-F discharges have the advantage of no cooling or contamination by electrodes, their generating equipment is bulky and expensive.

As an alternative to the above mentioned arc spreading attempts, more uniform heating of the gases can be achieved by forcing the arc to move through the gas stream (Ref. 16). This has been attempted by injecting the carrier gas tangentially into an annular gap between the electrodes, in order to introduce swirl and relying on the resistance of the arc to the induced motion to cause the arc to rotate more slowly than the gas, therefore bringing it into contact with most of the gas stream. A more satisfactory, because more easily controllable, arrangement is to rotate the arc in the annulus by applying a magnetic field in the direction perpendicular to the plane of rotation of the arc (Ref. 1,8,12,13,14). By tuning the rotation rate of the arc through adjustment of the magnetic field to the flow rate of the carrier gas, it is possible to bring all parts of the gas into contact with the plasma at some time. This maximizes the evenness of the distribution of heat and radicals to the gas. Any non-uniformity remaining could be expected to be smoothed out by the extra turbulence generated by the arc which, because very little of the gas actually passes through it, behaves like a solid stirrer. The arc also induces swirl into the gas which further increases the heat transfer to surfaces in the wake region (Ref. 17). The rapid rotation rates of the arc, 2000 Hz and more, have caused investigators to even look into the possibility of using the centrifugal forces produced for isotope separation.

The expanding flow emerging from the nozzle and its turbulence causes considerable entrainment of the ambient atmosphere into the wake. Therefore a number of different possibilities of introducing reactants to the arc or its products present themselves. They could be allowed to pass through the rotated plasma jet along with a suitable carrier gas or be injected above the burner mouth. Entrainment of surrounding gases can also play an important part.

As this seems to be the most promising plasma reactor arrangement at least for a great many applications, the magnetically rotated arc was further investigated. In order to be able to ensure the most efficient flow arrangements, including entrainment, and to arrange quenching surfaces such as to maximize desired yields, something needs to be known about the flow patterns and the distribution of physical properties in the wake region. It is in order to shed some light on these previously neglected problems that this research was undertaken.

Chapter II

COMPARISON OF PROBES WITH OPTICAL TECHNIQUES

The wake region of the magnetically rotated plasma-jet analyzed in this investigation consists of a non-uniform hot argon-cold air mixture, part of which near the burner nozzle was expected to be at a temperature of a few thousand degrees absolute, and to contain ionized argon. The flows were predicted to be very turbulent, resulting in large and rapid variations of local gas conditions. The wake gases further than 1 cm downstream of the arc are non-luminous and any form of solid particles introduced into the carrier gas flow would inevitably have led to instabilities in the running of the arc.

This was borne in mind when a strategy for investigating the test region was decided upon. The use of radiation methods (radiative spectroscopy, line reversal, etc.) as well as the seeding of the gas flow for particle tracking were therefore eliminated from the start. The choices remaining could be subdivided into two main groups: probe techniques and optical methods using changes in refractive index.

II.1 Probes

While probes give measurements of very good spatial resolution they suffer from a number of disadvantages. All probes have some influence on the flow pattern around them, especially if that is of a complex nature and small scale as in this case. Because of the high temperature of the gas immediately downstream of the plasma-jet nozzle, solids would have melted in this region. A little further downstream, where average temperatures are sufficiently low not to have damaged the

probe, some pockets of ionized argon and possibly dissociated oxygen or nitrogen are nevertheless present. The probe surface would in this region have acted to promote the recombination of ions or dissociated species in the form of three-body reactions. This would, of course, have influenced the readings taken.

In the measurement of temperatures using solid thermometers, for example thermocouples, resistance thermometers or suction pyrometers, the thermal condition of their working substances rather than that of the surrounding gas is recorded. Errors are therefore introduced even under constant conditions by the imperfect convective heat transfer from the gas to the probe. This heat transfer Q_c is given by

$$Q_c = h_c (T_g - T_T)$$

where T_g is the gas temperature, T_T the probe temperature and h_c the coefficient of convective heat transfer which is a function of Reynolds and Nusselt numbers (Ref. 18). Radiation from the solid thermometer further decreases its temperature. The error ϕ_R introduced by these radiative heat losses is given by

$$\phi_R = \epsilon \sigma (T_T^4 - T^4)$$

where ϵ is the emissivity of the wire and T the temperature of surrounding solids (Ref. 19). A further heat loss is caused by the thermal conduction along the leads holding the probe and connecting it to the measuring instruments. This error, E_c , is given by

$$E_c = \frac{T_T - T_B}{L(4h/d\lambda)^{1/2}}$$

where T_B is the exit temperature of the probe supports, L and d their length and diameter respectively, and λ their conductivity (Ref. 19).

These losses are partly compensated for by the fact that the probe measures the static temperature rather than that of the flowing gas. Kinetic energy of the gas stream is therefore converted to heat, increasing the local gas enthalpy. The temperature increase ΔT resulting from this aerodynamic heating is given by:

$$\Delta T = 1/2 v^2 / J c_p$$

where v is the local gas velocity, c_p the specific heat of the gas at constant pressure and J the mechanical equivalent of heat (Ref. 18,19).

These errors are in practice minimized by making the probes as small as possible, of material of low emissivity and possibly coating or shielding them with such materials, making their leads long and allowing them to follow isotherms for as long as possible. They can be further compensated by using the equations above.

It was, however, the rapid and irregular fluctuations in the localized temperature conditions caused by the fast flow of very small pockets of gases of widely varying temperatures that finally made these probes unsuitable for the present investigation. Every thermocouple requires a finite time to allow the probe material to reach a temperature close to that of the gas. This response time is given by the expression (Ref. 19):

$$\frac{dT}{dt} \times \frac{\zeta cd}{4h c} = T_g - T_T$$

where c and ζ are the specific heat and the density of the probe material respectively. Although this thermal inertia can be reduced by making

the probe very small, there is a lower limit to the wire diameter if the probe is to be reasonably stable in handling and against the gas flow. Pt, 13% PtRh wires of this minimum diameter produced a thermocouple that was far too slow for the present application.

Thermocouples or resistance thermometers could not even have recorded a correct average temperature, at least if that mean \bar{T} would have been defined in terms of mass fractions as

$$\bar{T} = \frac{\sum_J T_J \times M_J}{\sum_J M_J}$$

where M_J is the mass of gas present at a temperature T_J . Hot gases passing the thermocouple would have occupied a larger volume per unit mass than pockets containing an equal mass of colder gas and would therefore have been in contact with the probe for a relatively longer period of time. This would have resulted in the measured average temperature being higher than the true mean. Cox and Weinberg (Ref. 20) have dealt with the averaging properties of suction pyrometers and concluded that the average temperatures computed by the enthalpy probes deviate from the true mean temperature, indicating too high or too low depending on the flow regime within the probe. The discrepancy between measured and existing mean temperatures was found to be a function of the thermal unmixedness of the gas stream.

Hot wire anemometers of conventional design used for measuring local gas velocities have a response of approximately 100 Hz. This has been improved upon by the introduction of feedback into the electronic circuitry. However, they also suffer from the other drawbacks of probes.

A probe developed recently was used to indicate temperature fluctuations. It is based on the principle of the corona discharge and uses the

gas itself as a working substance. This eliminates any distortion in the probe output introduced by thermal inertia. The probe and its applications are described in detail in Chapter VI.

II.2 Optical Techniques

For the main body of the investigation optical techniques were used. The wake region has too complicated a structure for the use of optical interferometry which would also have been too sensitive a tool for the steep refractive index gradients that were expected there (Ref. 21). Shadow and schlieren methods were, however, found to be ideally suited. Although these are less sensitive at high temperatures (Ref. 21) the refractive index changes encountered are so sharp that sensitivity was not found to be a problem. This also influenced the precise setting up, as indicated in Chapter IV. Still and moving shadow records were obtained to give an overall qualitative structure and flow visualisation of the gases in the plasma-jet wake and a schlieren technique was adapted to yield localized velocity measurements, as discussed in the following chapters.

PLATE XVI

THE PLASMA-JET BURNER

Chapter III

THE MAGNETICALLY ROTATED PLASMA JET

III.1. Apparatus

The plasma jet burner consisted of two concentric electrodes and a magnetic field coil. A cross section is shown in Figure 3.1. The cathode was made up of a 2 mm diameter thoriated tungsten rod ground to a tip at the top end and fitted into a 1 cm diameter brass bar. The thorium lowers the work function of the tungsten. This improved the electrode performance, as electrons were ejected more easily. The cathode was held firmly in position at the centre of the anode nozzle by a perspex insulating block. A copper tube of internal diameter 4 mm and shaped into a cone was placed around the cathode on the perspex and served to separate the gas flow immediately surrounding the cathode from that in the remainder of the nozzle.

Two separate gas flows entered the burner through ducts in the perspex near the bottom. The inner one passing over the cathode surface left through the inside of the cone, and then out of the nozzle. This was always argon and acted to protect the cathode from chemical attack by any of the components of the main stream. That stream moved over the outside of the cone and through the nozzle. Although in this investigation this was mostly also argon, any other gas or mixture of gases could have been used as described in Chapter I.

The anode was made of copper and had a nozzle vertically through its centre, consisting of a straight hole 1 cm in diameter and 1.5 cm in depth in the upper part, opening out at an angle of 45° to a 2.5 cm hole in the lower part. This is shown in Figure 3.2. The cathode was positioned along the axis of the anode at a height such that an arc

Fig. 3.1 CROSS-SECTION THROUGH THE PLASMA JET BURNER

Fig. 3.2 CROSS-SECTION THROUGH THE ANODE

could be struck from its tip to the bottom end of the straight part of the nozzle.

Both electrodes were surrounded by a horizontal magnetic field coil made up of about 3500 turns of 22 s.w.g. copper wire around a cooling water jacket. The wire was cooled with high temperature insulating material. The coil as well as the cathode holder and anode were cooled using deionized water at a pressure of a few p.s.i. The water was monitored separately for coil and cathode and for the anode for flow rates using rotameters and for temperatures with mercury in glass thermometers. Deionized water was used in order to reduce the deposition of calcium salts in the cooling ducts, which would have reduced cooling efficiency. It was conveniently available at pressure at the bench.

Figure 3.3 shows the electrical connections supplying the plasma jet. A moving coil ammeter in the cathode line and a voltmeter across the electrode gap allowed continuous monitoring of current in and voltage across the plasma and thus of the power consumption of the arc. The electrical power for the arc was provided by one or two DC Miller SHR 222 welding rectifiers with power output ranges of 1 to 10 kW, capable of delivering up to 150 amps maximum each. The rectifiers had been modified to give both floating anode and cathode potentials so that they could be used coupled in series or parallel as well as singly. The anode had therefore to be earthed at the burner. The AC ripple had also been reduced by the manufacturers to less than 2%. These rectifiers are fixed power devices. For a chosen power output the ratio of arc current to arc voltage depended on the separation of the electrodes and therefore the relative vertical position of the cathode with respect to the anode.

A seirotron HF spark generator was fitted between the cathode line and earth. It worked off the open circuit voltage of the welder (75 volts

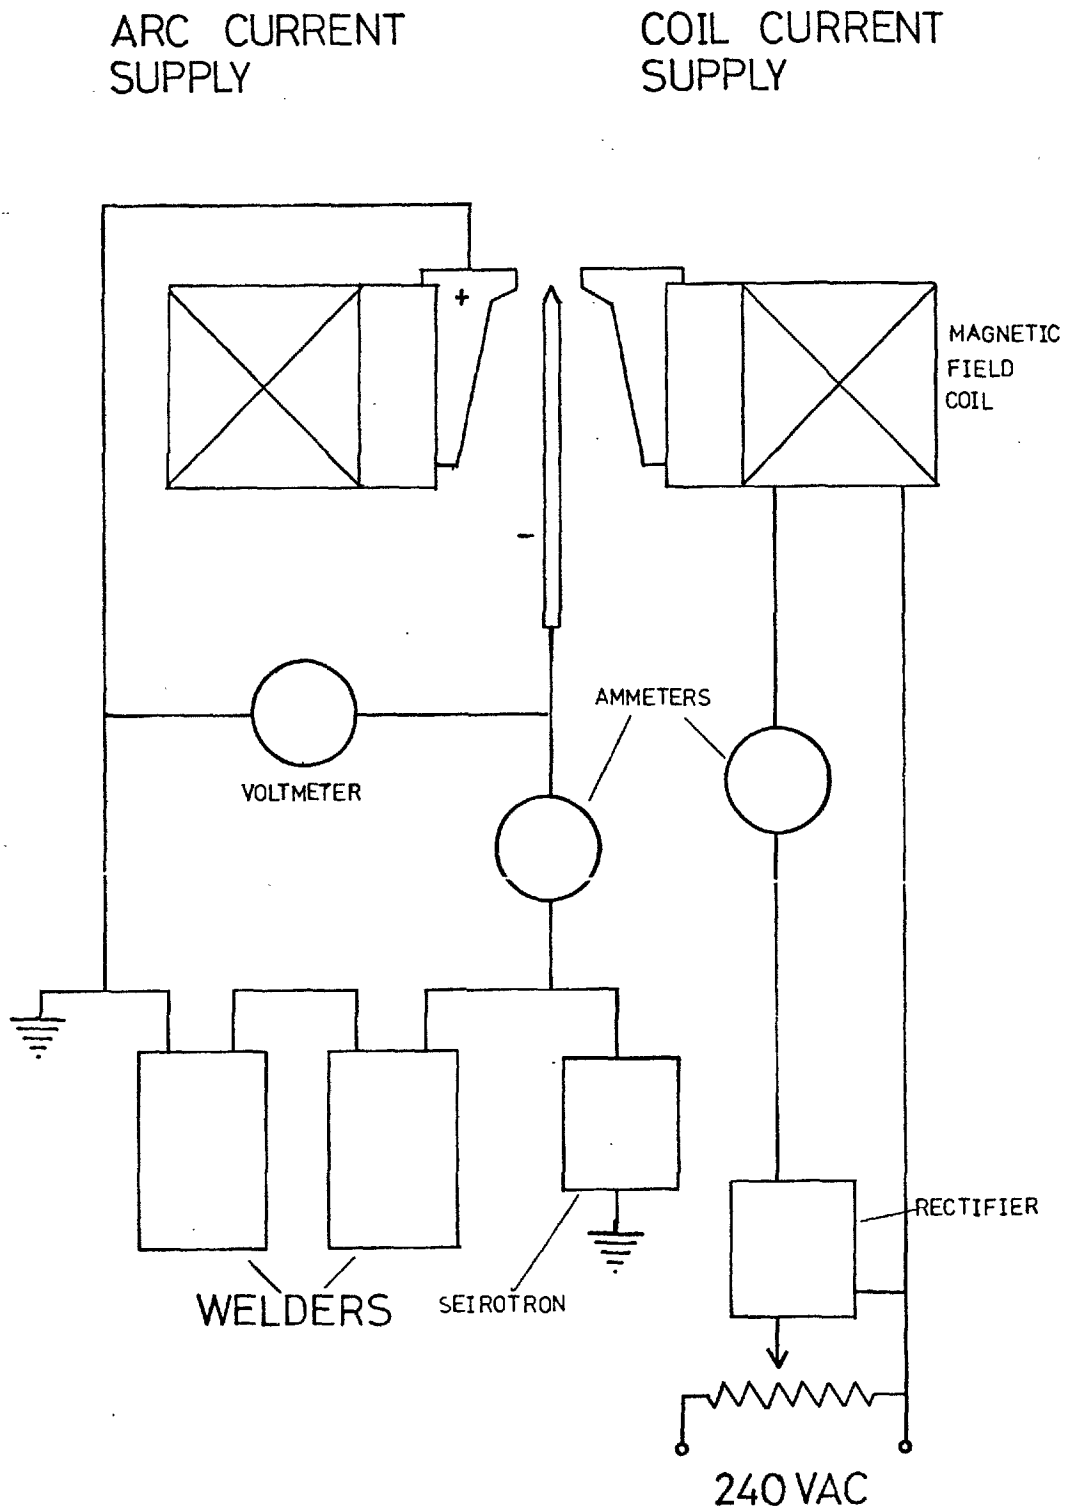

Fig. 3.3 ELECTRICAL CONNECTIONS TO THE PLASMA JET

DC) and supplied a series of high frequency sparks across the electrodes which initiated the arc. As the arc was struck, the voltage across the welder dropped, switching the seirotron off automatically. The seirotron could be kept on line to restrike the arc should it be extinguished (Ref. 37).

The DC current of up to 2.5 amp for the magnetic field coil was supplied from a rectifying and smoothing circuit as shown in Figure 3.4. The output voltage across the coil, and thus the output current, were adjusted by setting the input conditions from the mains voltage to a suitable level using a rotary transformer. Both voltage and current could be measured separately. Once the coil reached thermal equilibrium the current supplied by the rectifier was found to be extremely stable. No changes in current were observed even for very extended runs. Current levels were also easily reproducible, and the AC ripple was found to be less than 2%.

The current in the coil gave rise to a magnetic field in the region between the electrodes in the direction parallel to their axis of symmetry, the value of which varied in accordance with the setting on the Variac. The directions of the field B and current in the arc I were mutually perpendicular. They resulted in a Lorenz Force of $I \times B$ on the arc. This caused the arc to rotate in the annulus formed by the electrodes.

When the power dissipation by the arc had been chosen by presetting the welder, and the electrodes were in position with respect to each other (effectively determining the arc current to voltage ratio) there were clearly only two easily variable quantities. One was the argon flow rate which was controlled by a needle valve and monitored by a rotameter, a mercury manometer and a mercury in glass thermometer. The other was the rotation rate of the arc, which was determined by the

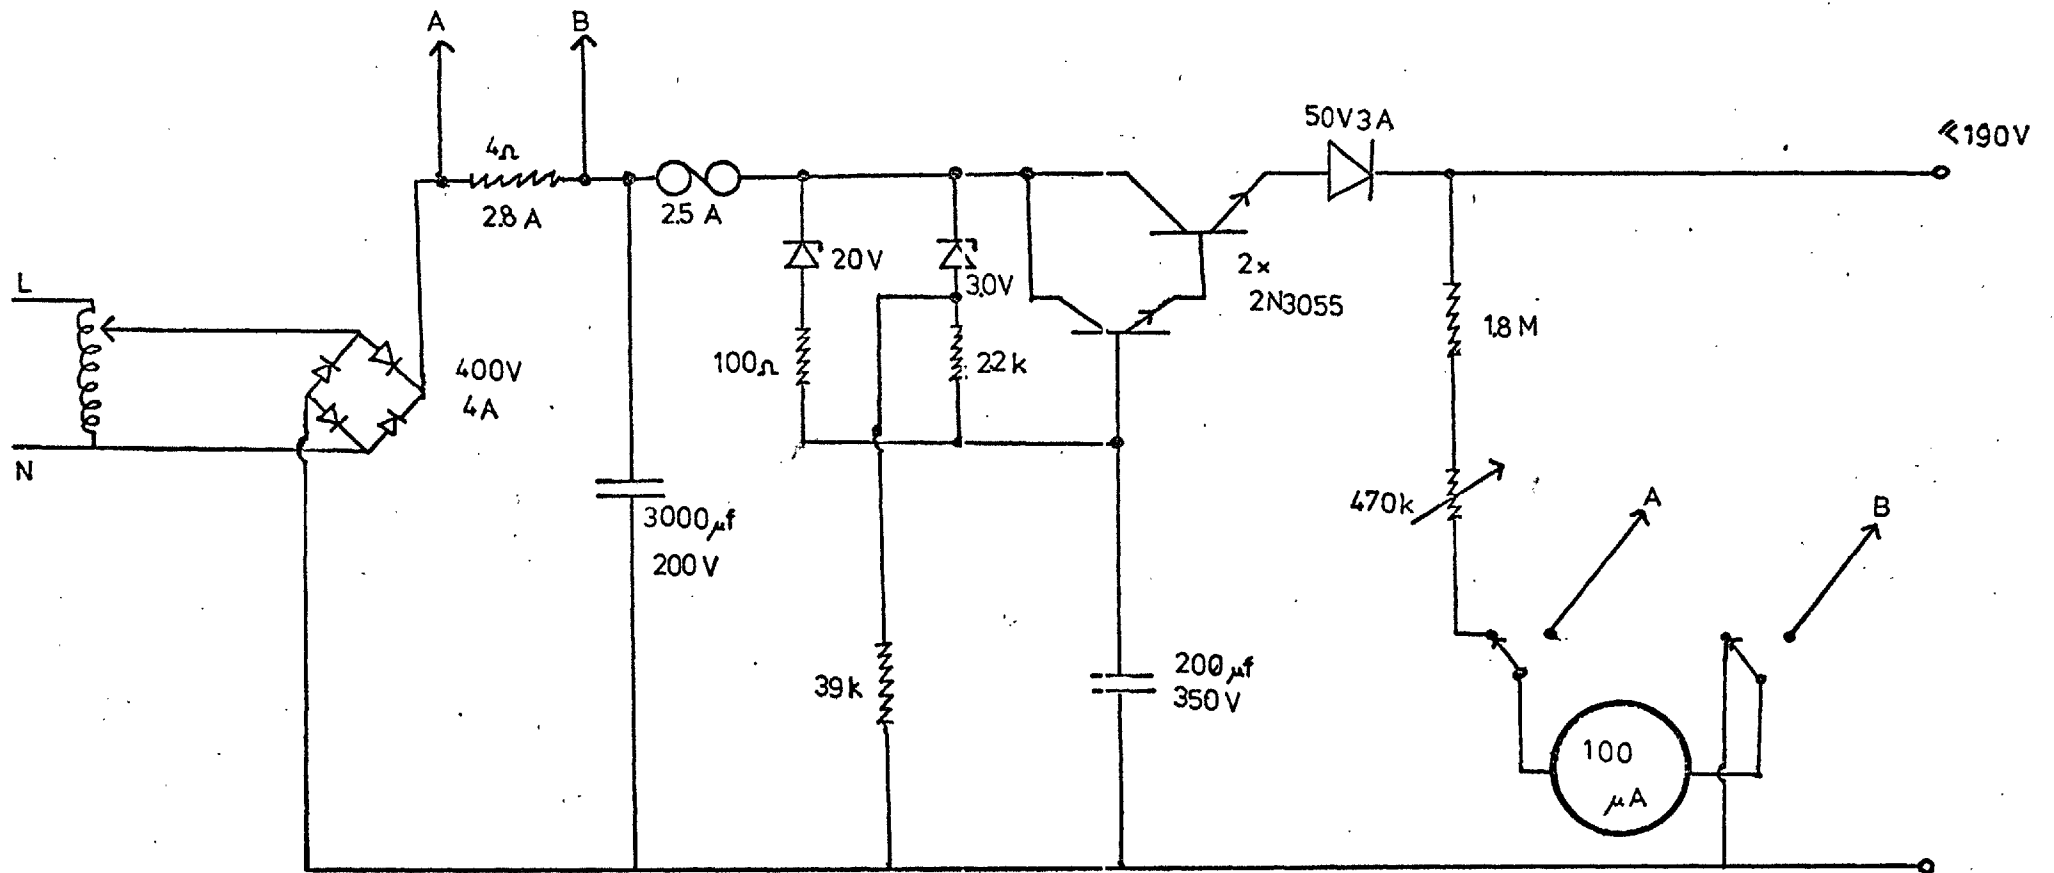

Fig. 3.4 DC SUPPLY FOR COIL CURRENT

arc and coil currents and selected by varying the magnetic field.

The rotational frequency was monitored with the aid of a small Reed Coil (Radio Spares No.2) positioned near the plasma jet and pointing towards its centre (Figure 3.5). As the arc rotated in its annulus the magnetic field associated with the arc current varied in direction. Its field lines cut the axis of the search coil with the same frequency as the arc rotation and it was this variation that was detected by the coil. The EMF induced in the coil was applied across a $1\text{ M}\Omega$ resistor and displayed on an oscilloscope. From the recorded trace the arc rotation frequency could be obtained directly.

In the magnetically rotated arc the force exerted on the plasma by the magnetic field is balanced by the drag of the gas on the moving arc. Under equilibrium these two forces balance:

$$BI = \frac{1}{2} \zeta u c_D d$$

where B is the magnetic field, I the arc current, ζ the gas density, c_D the drag coefficient, u the linear arc velocity and d its diameter (Ref. 22). In a previous investigation (Ref. 22) the arc rotation rate was related to the magnetic field and arc current by the empirical relation

$$f \propto B^{0.6} I^{0.33}$$

where f is the rotational frequency of the arc, I its current (amps) and B the magnetic field strength (gauss) showing the rotation rate to be more sensitive to changes in the magnetic field than in the arc current. This relationship was reconfirmed in more recent measurement (Ref. 13,23). As the rotation rate is dependent on the arc current, which in turn depends on the precise electrode position for a given power

Fig. 3.5 SEARCH COIL, CIRCUIT AND POSITION

output, the arc rotation was monitored after each change in conditions and during experimental runs as well as after each dismantling and cleaning of the electrodes.

III.2 Arc Propagation

The propagation of magnetically rotated arcs has already been documented in the literature (Ref. 23,24,25); the arc in rotation remains a narrow channel of ionized gas and takes on a convolute shape. It is this shape that ensures that every part of the arc, irrespective of position, heats an equal amount of gas in any given time interval (Ref. 23,24,26). As the arc rotates the anode root remains almost stationary. The arc column stretches along the direction of rotation into the convolute shape until a condition is reached when the potential difference between some point on the column and the anode near that point is raised above the breakdown potential for that particular gap width and gas mixture. A new anode root is then formed as the arc jumps to that point and the excess length of the arc is extinguished (Ref. 22) (Figure 3.6). The process then recommences.

III.3 Attempts to Spread the Arc

So far all attempts to truly 'spread out' the arc into a diffuse disc of plasma covering the whole or even most of the nozzle uniformly have failed. Although from time to time reports are received of successful smudging of the arc they are almost always repudiated by other workers in the field using more precise techniques.

Most frequently direct optical records taken at insufficiently high shutter speeds appear to indicate a diffuse plasma. This is mostly due to the afterglow in the wake of the arc. Published material containing

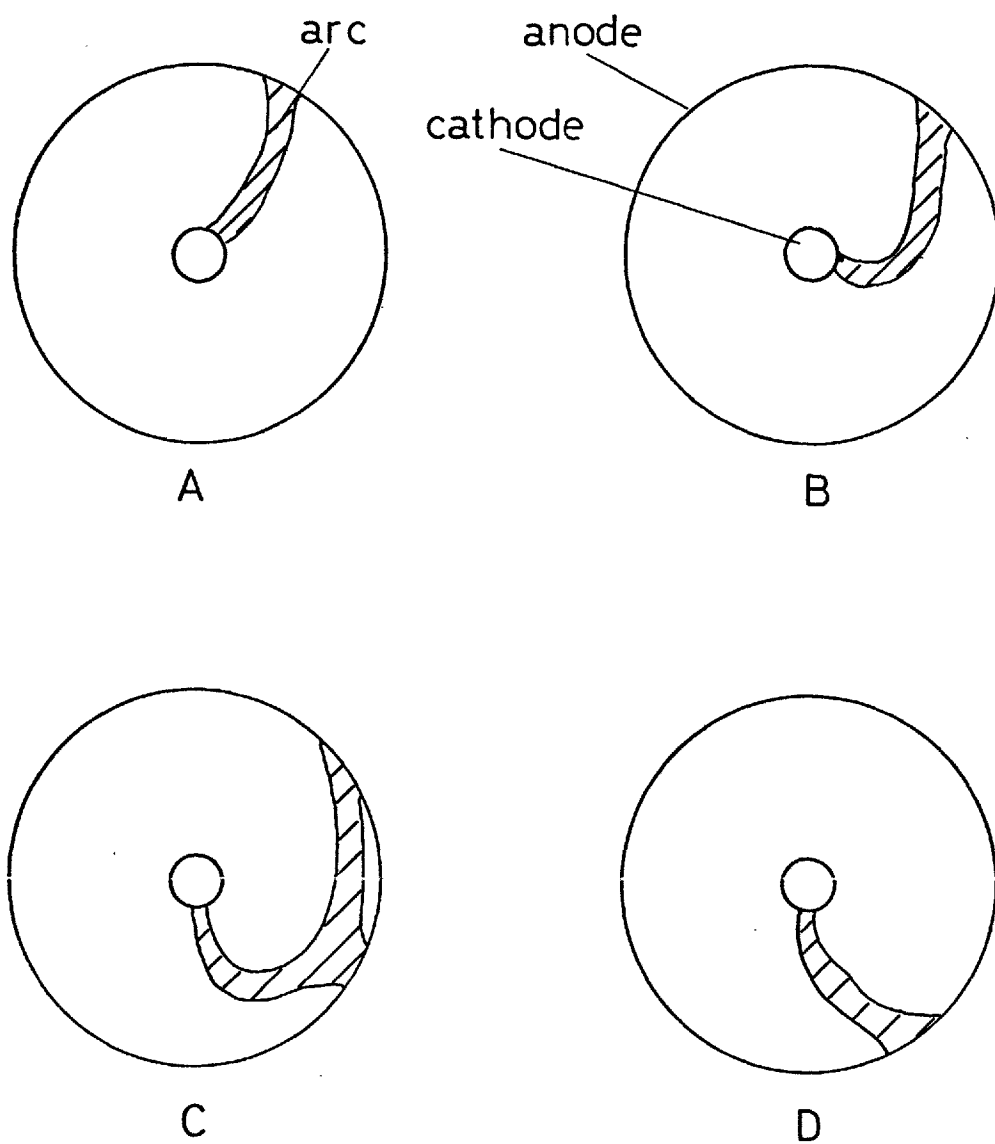

Fig. 3.6 ARC PROPAGATION (SCHEMATIC)

these photographs has in the past been amended by latter workers using faster cameras. While it might be true that a slow moving gas through the plasma jet "sees" the plasma as diffuse but turbulent, in absolute terms, however, the plasma remains in a distinct, even if expanded, channel.

It was hoped that it might be possible to spread or even diffuse the plasma by allowing it to pass through an atmosphere of ionized carrier gas. In order to test this theory the plasma jet described was slightly modified.

A second anode made of copper was placed on top of the first and electrically insulated from it, using asbestos paper. This anode consisted of two semiannular halves stuck together and insulated from each other using Araldite (Figure 3.7). The central circular hole of the second electrode was of the same size as, and was placed in line with, the lower nozzle. Each of the top anode halves was connected via a separate 10 cm long copper rod to the common positive output of one of the welders. The positive output of the other welder was connected to the lower anode. Both negative outputs were joined to the common cathode. The potential drop along one of these rods was monitored as the arc moved along the upper electrode. Although the resistance of the rod was extremely low, the high current (~ 70 amps) produced a measurable voltage along each rod. This potential was displayed on a Tektronix oscilloscope. As an arc rotated in the upper anode a positive potential was recorded as long as the arc moved on the electrode half and current flowed through the rod being investigated, while zero potential was displayed while the arc was joined to the other annulus half.

As long as only the upper arc was struck a square wave signal was displayed on the oscilloscope indicating a rotating arc spoke. Its frequency of rotation which could be varied by either changing the arc

Fig. 3.7 DOUBLE ANODE CONFIGURATION

current or the DC current in the magnetic field coil was noted from both the frequency of the square wave and from measurements with the search coil. Both values were in good agreement. Plate 1 shows the change in frequency with increasing current in the upper arc as a voltage variation in one of the rods. The increase in voltage along the rod due to the higher current is also clearly noticeable from the change in signal amplitude.

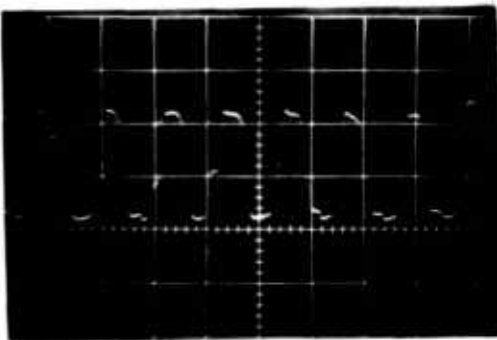

When the lower arc was struck in parallel the square wave output from the upper electrode persisted. This indicates that the upper arc remained as a confined spoke. The upper rotational frequency is now found to be unaffected by the current in the upper arc at constant magnetic field (Plate 2). It varies, however, linearly with the current in the lower arc even when the upper arc remained constant (Plate 3).

It therefore appears that the upper arc hooks onto the lower one while transgressing the annulus. There could be two possible reasons for this. Either a high degree of ionization is mainly present in the immediate vicinity of the lower arc and the upper arc rather than spreading, follows the lower arc in its immediate wake. Alternatively, the ionization from the lower arc is insufficient to cause a spreading of the upper arc and the two arcs are linked together by the interaction of the magnetic fields of the two arc currents. The almost exclusive effect of the lower arc current on the rotation rate might in this case be due to the fact that this arc rotates closer to the centre of the coil experiencing a larger field effect. The predominant rotation of the lower arc does however give extra weight to the theory that the upper arc is confined to the strongly ionized immediate wake of the lower one. The true cause of the link-up is probably a combination of the two possibilities, the first playing a more important part. It is in any case clear that a diffusion of the upper arc cannot be achieved in this way. From an

inspection of the rise and fall times of the square pulses it seems clear that even any increase of the upper arc diameter is only minimal.

III.4 Interaction of Arc and Gas Flow

In addition to the arc always being confined to a thin channel of plasma it needs to be considered that the temperature inside the column is of the order of a few hundred times higher than that in the surrounding gas, which results into a great expansion of the gas that is transformed into the arc plasma. Only a relatively small amount, therefore, actually passes through the arc core. This not only causes the arc to behave to some extent like a solid stirrer, but also means that most of the gas is heated by surface contact with the plasma, rather than actually passing through it. If one therefore wanted to achieve uniform heating of the gases passing through the plasma jet without relying on downstream mixing, the rotation rate of the arc needs to be tuned to the flow rate of the carrier gas through the nozzle.

For uniform heating it is desirable that each part of the gas flow should be in contact with the arc for the same duration of time. Theoretically, this is achieved by ensuring that in the time required for the gas flow to move through one arc thickness the plasma completes an integral number of revolutions. When this integer is 1 the arc is termed to be just running into its own wake, which is clearly discernible audio-metrically. This is the condition to be aimed for if uniform distribution of entropy throughout the wake gases is desired at reasonable flow rates and stable conditions. In practice, perfectly homogeneous energy distribution is of course never achieved. This, however, does not greatly matter as recent calculations (Ref. 36) have shown that the existence of small periodic pockets of hotter gases cause an increase in the rates of many

reactions because of the exponential Arrhenius factor.

If more generally some parts of the flow are in longer contact with the arc than others, this results in a rising spiral staircase of hotter gas in an intermediate atmosphere of colder gas. Considering a volumetric flow rate (v) of argon passing through a plasma jet nozzle of radius (R) the mean gas velocity upward (u) is given by

$$u = v/\pi R^2$$

If an arc rotates in the nozzle, inducing a swirl in the gas of angular frequency (ω) the rotational velocity (s) at a distance (r) from the centre is

$$s = r\omega$$

The angle of elevation of the spiral staircase is then found to be

$$\tan \alpha = u/s = v/\pi R^2 r\omega$$

In practice, however, the spiral of hot gases is quickly destroyed by the intense turbulence in the wake region. Only a slight indication of a spiral was noticeable during this investigation.

Some of the advantages of having chosen a rotating arc configuration are now clear. On a simple plane it is clear that from the point of view of electrode conservation constantly moving arc roots are desirable as long as the electrode materials are not required to take an active part in any chemical reactions in the plasma or its wake region. Probably more important, however, is the behaviour of the arc column as a stirrer. The rotation of this stirrer induced swirl into the gas and

its angular momentum causes the jet to expand considerably on leaving the nozzle. It can be seen from the Law of Conservation of Mass, that this funnel type wake along with recirculating vortices at the nozzle mouth, causes not inconsiderable entrainment of the surrounding atmosphere into the plasma jet gases. This process would give an engineer considerable choice in the mode of introduction of reactants into the wake region of the arc. They could be injected along with the carrier gas for entropy, dissociated species or radicals through the anode nozzle, or through the walls of the nozzle, or above it. The mixing is further facilitated by the turbulence induced into the flow of the plasma jet gases by the rotating arc.

Chapter IV

SHADOW AND SCHLIEREN METHODS

Considerable work has been done on magnetically rotated arcs, including apparatus similar to that used in the present investigation. Ref. 27 gives a review of many important articles concerning the behaviour of arcs; further references were given in the introduction. Little, however, is known of the general behaviour of the gases in the wake region of a plasma jet entering an open atmosphere.

As one is dealing here basically with a phenomenon of a hot turbulent swirling gas stream entering into and mixing with a cold stationary gas, shadow and schlieren methods suggest themselves, and could be expected to lead to a better understanding of the overall shape of the wake as well as the fine structure within the emerging gas flow.

IV.1 Short Duration Photography

As high flowrates and rapid turbulent fluctuations were anticipated it was necessary to use short duration exposure photography in order to freeze the motion. Two possibilities were considered. One was the use of fast shutters (mechanical or electronic) in conjunction with continuous or long duration light sources. It will be seen later in this chapter that the optical arrangements used made a focal plane shutter preferable. Alternatively a considerable part of the optical path would have had to be screened off in order to protect the film from stray light. No such shutter was easily available and it would have had to be obtained or made up at great expense and delay.

IV.1.1 The Light Source

It was therefore decided to opt for a short duration light source instead. The system chosen was a short duration spark, as developed by R.J. North at the National Physical Laboratories (Ref. 28,29), in conjunction with a slow focal plane shutter. The spark stand (Fig. 4.1) consisted of two stainless steel cylindrical electrodes fixed in position along a common horizontal axis of symmetry by two vertical supports. The support carrying the live electrode was made of perspex, the other of brass. Both verticals were fitted to a base plate, the ends of the electrodes facing each other were ground into hemispheres. The separation between the electrodes could be varied but was usually kept at about 1 cm. It was in this gap that the spark was fired.

One of the electrodes had a fine hole drilled along its axis through which argon passed via a flow indicator and a fine needle valve. The flow was adjusted to give a fine jet in the spark gap. The argon served two purposes, making use of its low ionization potential; it confined the spark into a narrower channel than was otherwise possible and simultaneously ensured better reproducibility of the exact position of consecutive sparks.

The second electrode had a somewhat larger hole drilled along its axis. This contained a 1 mm tungsten rod held firmly in position and insulated from the main electrode by a tube of mica. This rod was allowed to protrude into the spark gap by about 1 mm and acted as a trigger electrode. The other end was connected to the secondary coil of a 300 volt pulse transformer, the primary of which was joined to the trigger source. This pulse source consisted either of a manual or a neon-photodiode switching circuit attached to the shutter. Figure 4.2 shows the connections to the spark stand schematically. In some cases the trigger pulse came via an electronic delay from the light of a

-  INSULATOR
-  BRASS
-  STEEL

Fig. 4.1 SPARK STAND

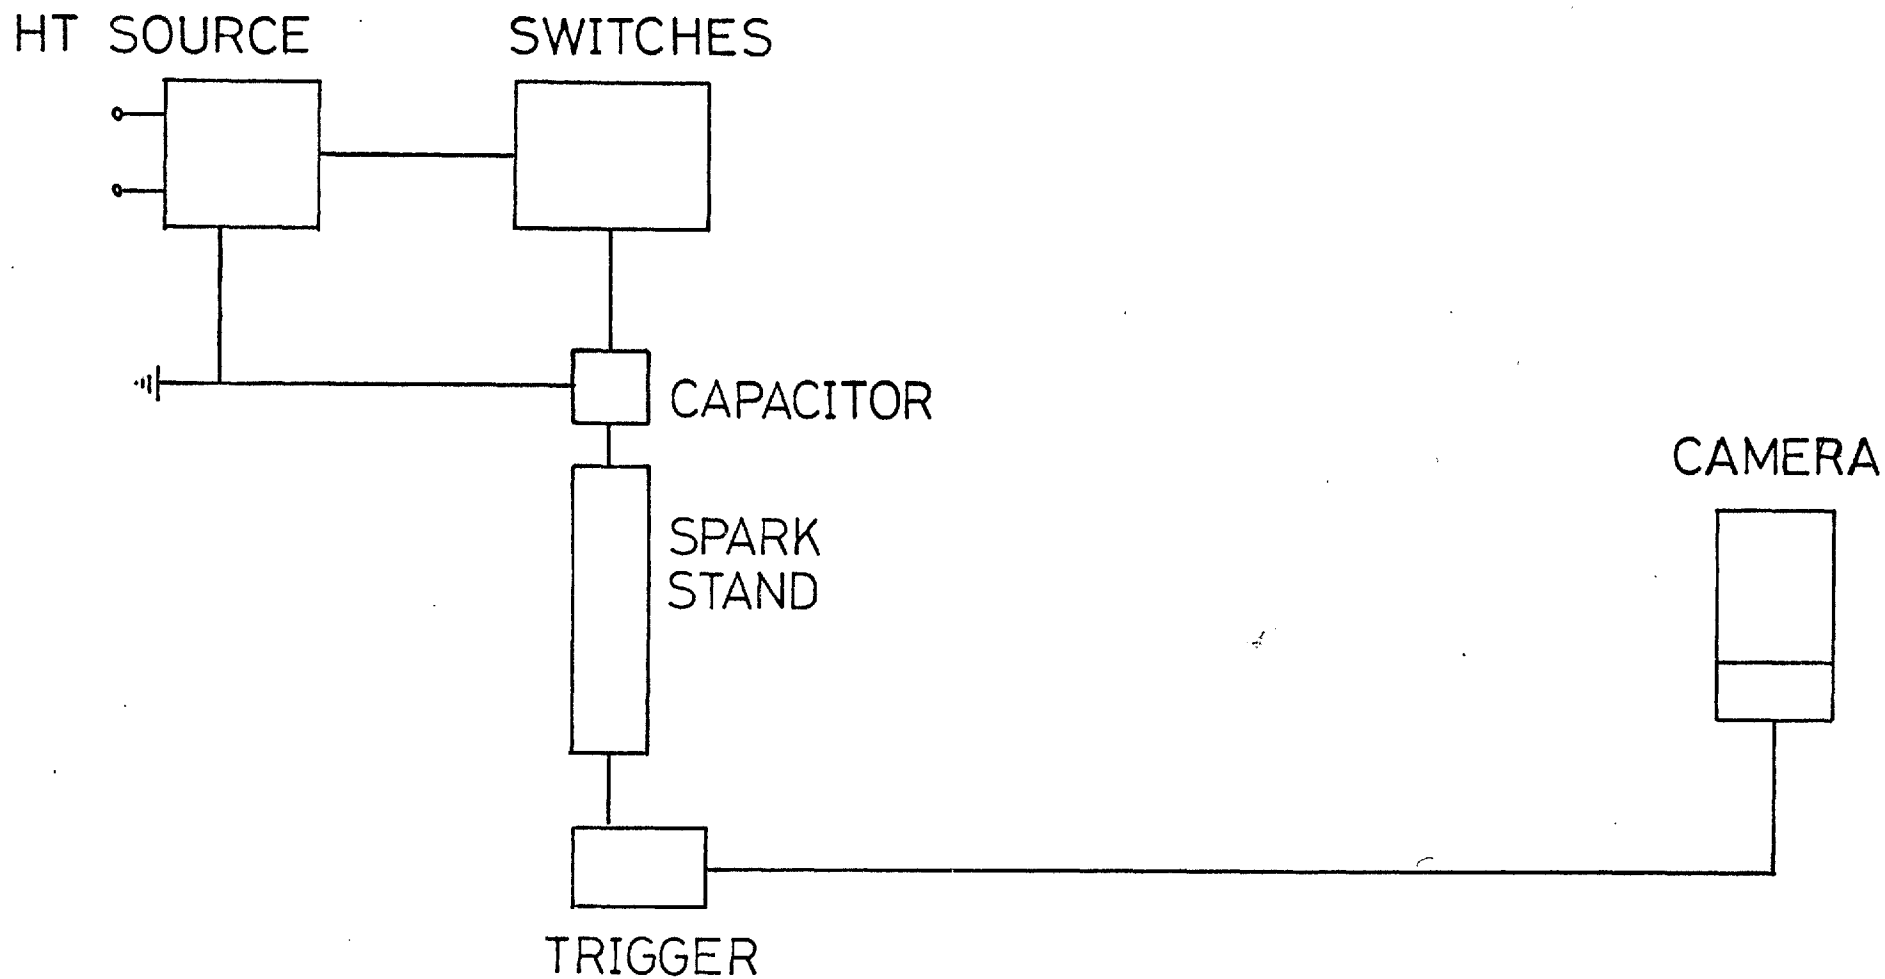

Fig. 4.2 CONNECTIONS TO SPARK STAND (SCHEMATIC)

preceding pulse, as explained later in this chapter. The pulse transformer could be replaced by an ordinary car coil if required.

The spark stand was covered by an aluminium shield with a large hole on either side to allow the light to emerge. This cover was always in place when the light source was in use in order to minimize the risks of electrocution. The shield also served to absorb some of the electromagnetic radiation liberated by the spark. This radiation caused electrical interference with other sparks - a major problem that will be discussed later.

The two electrodes were connected across a 1 μ F rapid discharge capacitor with low resistance copper cable (Fig. 4.3). The electrode containing the trigger was earthed, while the other one was maintained at a potential of 8 kV. The capacitor was charged to this voltage through a series of resistors via a switching system by a current limited HT-source of the type Brandenburg MR/50R. All switches and resistors were protected in a perspex box. The box as well as the covers for the spark stands and capacitors were secured by a micro switch system. This caused immediate safe discharge of the capacitors in case of accidental removal of any of the safety devices while the system was under HT.

To operate the light source, the capacitor was charged and the Brandenburg disconnected from it. The trigger spark then supplied preliminary ionisation causing the capacitor to discharge through the main spark gap.

In the first instance the light source was triggered by the focal plane shutter. A small neon light source on one side of the shutter and a photodiode on the other along with a separate pulse generating circuit (Fig. 4.4) supplied the necessary trigger pulse for the pulse transformer. The duration of the spark discharge was measured using a

HT SUPPLY

-SINGLE SPARK

photocell and an oscilloscope and the spark found to be liberating most of its high energy within the first microsecond. It was this that determined the exposure time irrespective of the shutter speed.

IV.1.2 The Optical System - Single Exposure

The arrangement chosen for the shadow and schlieren photography was the standard z-shaped schlieren system using two 3 m focal length and 0.3 m diameter schlieren mirrors with a parallel beam in the test region (Fig. 4.5).

A quartz halogen projector bulb was used to line up the system by focusing it onto the centre of the spark gap using a short focal length lens. The beam was then focused with another short focal length lens onto a pinhole placed at the focus of the first schlieren mirror which produced a parallel beam passing through the test region above the plasma jet burner onto the second mirror. Horizontal and vertical brass scales with 5 mm divisions were placed in the beam at the test region to act as a reference. The second mirror was used to refocus the beam.

From here on the arrangement was dependent on the precise optical system under consideration. In the case of shadowgraphy nothing was placed at the focus and a lens of appropriate focal length past the focus was used to provide a suitable magnification of the test region. The 4 x 5 sheet film used was held behind the focal plane shutter - an adapted old RAF reconnaissance camera shutter - and positioned a short distance away from the image of the test region.

Even though in this type of arrangement the beam in the test region is parallel, this is not strictly speaking a parallel beam shadowgram but one of the divergent beam type as classified by Weinberg (Ref. 21). Only the part after the focus of the second mirror contri-

butes to the sensitivity and the test region could be considered to be located at its image. From calculations in Reference 21 it can be shown that the test region, or in this case its image, should have been placed half way between the focus of the second mirror and the recording plane for maximum sensitivity to be achieved. As we are dealing here, however, with very steep refractive index gradients, a very low sensitivity was found to be quite sufficient, and the film was placed close to the image of the test region. This resulted in the much finer line markings, essential for the investigation of the fine structure that was found inherent in the shadow of the wake region. It also reduced the danger of overlapping of information from different parts of the test region. Placing the photographic plates close to the image of the test region also served to refocus the light from the arc just above the nozzle. No optical blind which might have influenced the gas flow was therefore necessary between the arc and the film to prevent fogging of the emulsion. This was especially important as radiation from the arc was not only very bright but also reached the emulsion during the entire time the shutter was open, much longer than the short duration of the spark.

The present type of arrangement using 2 schlieren mirrors, rather than an ordinary expanding shadowgraphy system, was employed for a number of reasons. It allowed easier variation of magnification without influencing the sensitivity of the shadowgrams or for that matter the line thickness of the marked record. More important, it also allowed for the film to be kept well away from the intense heat and stray light emanating from the plasma even for positions of low sensitivity and very thin lines where the film-test region (or image of test region) distance was kept small. Lastly, it was easily convertible into a schlieren system.

The predominant aberration in this arrangement is astigmatism, as is usual with the use of mirrors. As most deflections were in the vertical direction it was found that the best results were obtained by placing the film a little way behind rather than in front of the image of the test region. Most work was carried out at unit magnification.

For use as a schlieren system a stop was placed at the focus of the second mirror. This was again followed by a lens whose focal length was chosen for the required magnification of the test region. The film holder and its shutter were placed precisely in the image plane of the plasma jet wake. For this adjustment the "Method of the Disappearing Shadow" was used, which is based on the following principle. When focused, all rays from the test space return to their original position in the image. In practice a turbulent premixed flame was supported on the plasma jet burner with no plasma present and the schlieren stop removed. A finely ground glass plate was moved along the optical axis until the shadows produced by the refractive index changes in the flame disappeared.

The astigmatism inherent in the z-shaped schlieren set-up now presented some problems. It brought vertical deflections to a focus in a different plane perpendicular to the optical axis from horizontal deflections. It therefore prevented a true focal point from being formed by the beam. Instead a vertical focal line, followed by a focal disc, followed by a horizontal focal line appeared when moving the stop in the direction of the beam propagation. Attempts to correct for the aberration using cylindrical lenses (Ref. 41) were unsuccessful, as they always caused some distortion of the schlieren image. This gave a choice of three positions for the schlieren stop. In order to obtain

a stop just sufficient to cover the focal disc a photographic plate was placed at the "central focal position" and exposed to a flash of light from the spark with no activity in the test region. After development a transparent glass plate with a black spot exactly the size of the to be excluded direct beam was obtained and this was used as a stop. Alternatively a knife edge was used at the horizontal focal line to view horizontal deflections and at the vertical focus for vertical deflections.

The stop was positioned roughly using the continuous light source behind the spark. For more precise placement, especially of the circular blind, the spark itself had to be used. The short duration of the flash however made the exact positioning of the stop very awkward. It was found, however, that a card covered with luminous paint placed behind the stop made fine adjustments easier, as the afterglow of the paint gave an indication in which direction the stop needed to be moved in order to obscure the direct beam completely.

Photographic records were obtained for all possible positions of the schlieren blind. It was found that a knife edge placed at the horizontal focal line gave the best results. The use of the circular stop did - as could be expected - not result in a uniform illumination of the schlieren image of the test region, and was also more difficult to adjust correctly. It was generally found that dark field schlieren gave better results than light field schlieren for similar conditions.

In all circumstances, however, shadow photography gave results more easily analyzed than did schlieren. As can be seen in Plate 4, the shadow method gave a very precise record of a fine line structure. Higher sensitivity or narrower line width could be obtained by moving the film away from or towards the image plane of the test regions.

The markings on these films correspond to 2nd gradients of refractive index perpendicular to that part of the beam traversing the test region which arrived at the film at this particular point. The white lines on the film therefore indicate boundaries of cold and hot gas. As the film was placed very close to the image of the test region the relative positions of the markings reflect closely the relative positions of these boundaries. A closer inspection of the records thus indicates that the wake region is made up of a number of pockets of hotter and cooler gas. A detailed analysis is presented in Chapter V dealing with the results from the qualitative analysis of the wake region.

IV.2 Double Exposure Photography

While we now have a method of obtaining a more general picture of the overall shape and the type of structure of the hot and cold gases involved in making up the wake region of the arc, we still have no estimate of the order of magnitude of velocity that was to be expected. To observe this it was decided to record two consecutive short exposures separated by a variable delay of the order of a fraction of to a few milliseconds. In order to achieve this the light source arrangement in Figure 4.5 was replaced by that shown in Figure 4.6. Here a second spark was focused with a short focal length lens into the first spark gap. The quartz halogen bulb was placed behind the second spark stand and focused on it. The second spark was arranged to be somewhat stronger than the first by increasing the discharge voltage and using a somewhat larger capacitor, until both sparks resulted in approximately the same illumination in the plane containing the photographic plate. Figure 4.7 shows schematically the charging and triggering arrangements for the double spark light source. The first

Fig. 4.6 OPTICAL ARRANGEMENT SHADOWGRAM OR SCHLIEREN
-DOUBLE SPARK

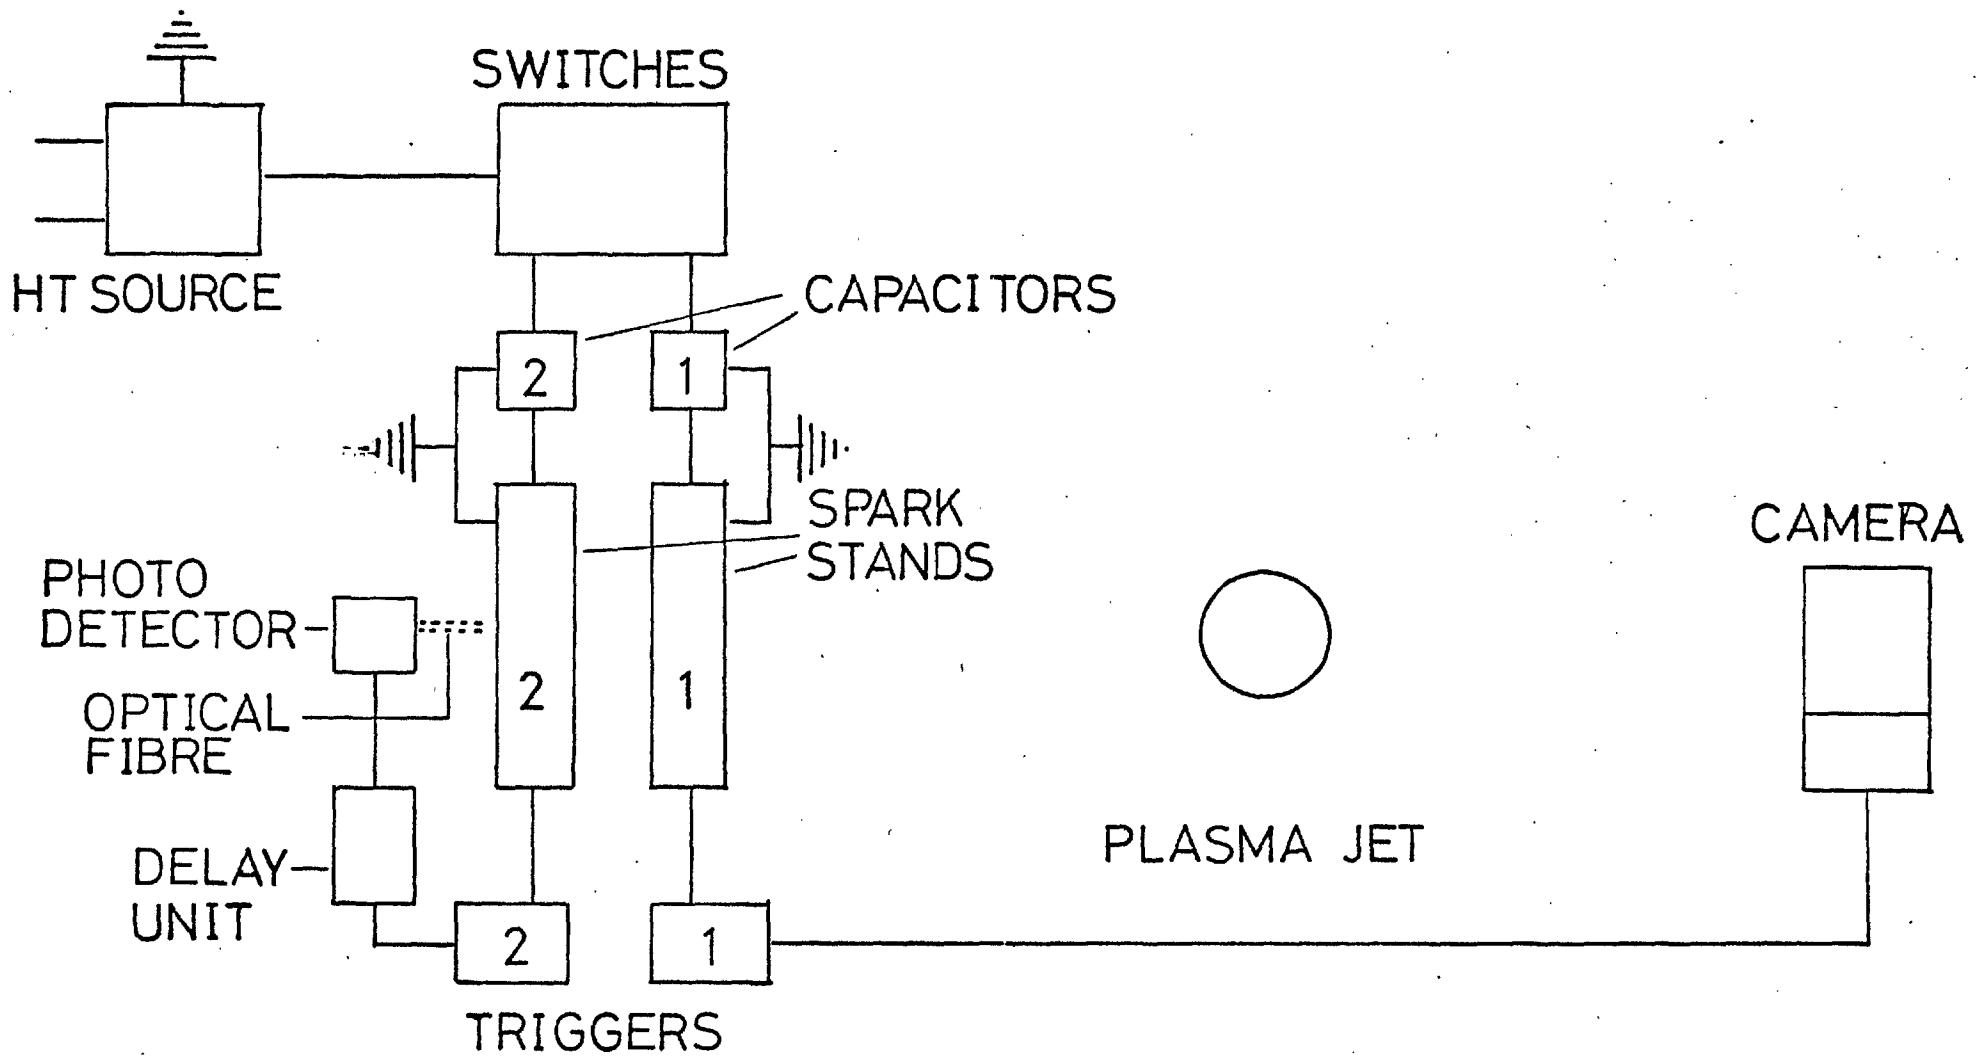

Fig. 4.7 CONNECTIONS TO SPARK STAND (SCHEMATIC)
-DOUBLE SPARK

spark was triggered as before from the shutter. Some light from the 1st spark was ducted away using an optical fibre onto a diode, which activated a variable delay. After a preselected time this sent a trigger pulse to the pulse transformer of the second spark stand. The revised triggering circuit for both sparks is shown in Figure 4.8, that for the variable delay in Figure 4.9. The delay gave separation times between sparks of 0.1 to 10 msec and was calibrated using an oscilloscope triggered by the output to the first spark and displaying the signal from the output of the second spark. The not inconsiderable amount of electromagnetic energy liberated by the first spark tended to cause the second one to discharge immediately. To prevent this it was found necessary to shield all components and leads as well as the electrodes themselves. Every part of the circuit was earthed separately to prevent the setting up of earth loops. All leads were kept as short as possible. It was still found that precise positioning of all components and leads was critical to prevent premature discharge of the second spark. Once a workable position was obtained by trial and error, a great number of runs could be executed before readjustment was required.

We now have a means of obtaining two superimposed shadowgrams of the wake region separated by about a millisecond. After correction for small errors in superimposition the distances through which the gas stream has advanced in the preselected time interval can be measured using the interfaces between hot and cold gas pockets as markers at various points in the wake region. As the preselected delays between exposures are known, it is possible to calculate the instantaneous magnitude and approximate direction of the velocity component perpendicular to the illuminating beam.

A closer inspection of the record obtained in Plate 4 gives an indication of some of the difficulties encountered in the analysis of

CIRCUITS

Fig. 4.9 VARIABLE DELAY AND TRIGGER CIRCUIT FOR DOUBLE SPARK

these velocities. First it is necessary to have arranged for the interfaces used as markers to have moved a distance within approximately critical limits of 1-3 mm between consecutive exposures. A smaller separation gives no clear double marking but rather a smudging of the otherwise clean lines. Too large a separation causes two difficulties. A second marking due to a lower interface may be too close to the first marking of a higher boundary. This causes confusion between first and second markings due to different pockets of gases. Pockets of gas can also be observed to change shape drastically on moving a relatively short distance. This is confirmed by cine records described in the next chapter. It is therefore often difficult to decide whether a pair of markings closely spaced but of different shape is actually a result of the same interface displaced and transformed in the set time interval, or two entirely separate pockets of gas. These problems are especially acute in the region of high density of schlieren near the nozzle exit and along the axis of the wake.

In an attempt to overcome this problem two different gases were used in the spark gaps. One was again argon, the other a 3:1 helium neon mixture. The latter made a precise spark gap and voltage adjustment essential in order to prevent familiar continuous neon discharge. Because of the different emission spectra of the two gases differently coloured sparks were to be expected. This was to give slightly different colour markings due to the two sparks and simplify the analysis. Surprisingly, the use of Polaroid Polarcolor film proved better for the purpose of colour differentiation than either Kodak High Speed Ektachrome or Agfa colour films. Even so, while the blue due to the argon discharge is clear, the lines due to the neon spark are much weaker and only show

a very slight reddish tinge. This is probably partly due to the stronger emission of lines in the ultraviolet end of the spectrum at the higher temperatures predominant in the spark discharge, and the voltage limitations within which a distinct He-Ne spark could be produced.

The distribution of velocities varies at any particular instance for any one condition over the whole of the wake region by more than one order of magnitude. A delay between sparks suitable to give separations within the critical distance limits in one part of the wake region was therefore obviously not suitable in another. It was therefore necessary not only to vary the conditions in the plasma jet burner but also to produce records of different delays keeping all other factors constant in order to obtain just one value of velocity in all parts of the test region for any one condition. The wake region of the arc constitutes a turbulent flow system. A great number of readings are therefore required to obtain meaningful average values for its properties at any one point. Many hundreds of double exposure photographs would therefore have had to be taken and analyzed in order to give a distribution of mean flow velocities throughout the test region for any one set of arc conditions. This method has therefore been used to give an indication of the order of magnitudes of the velocities present only.

IV.3 High Speed Cinephotography

From the double exposure shadowgrams it is a logical extension to move on to high speed cinephotography. For this the spark light sources were replaced by a continuous 5 mW Spectra Physics Type 162 argon ion laser. It was chosen because it emits blue light. This made it possible

to use a relatively slow film even for the highest framing rates, giving higher contrast since the photographic emulsion is by far at its most sensitive in the blue region of the spectrum.

The laser beam was focused onto a pinhole after which it was allowed to expand. As in the case of spark photography, the two schlieren mirrors were placed to give a parallel beam in the test region (Fig. 4.10). The second mirror along with a short focal length lens placed beyond its focus were used to produce a shadow of the test region in the plane of the film in the camera. The lens of the camera had been removed and the laser beam allowed to fall directly onto the film, the aperture being fully open. The lens in the system was chosen and positioned such as to give a reduction of the image of the active test region down to a size that just filled the 16 mm frame of the film. The camera used was a Hitachi 16 mm High Speed Camera that provided a framing rate up to 10,000 frames per second. The camera speed was set near the upper limits of its framing rate. The film used was the Ilford Micro Neg. Pan Type 204, 16 mm, doubly perforated, cut into 100 ft lengths. Only the latter three-quarters of each film could, however, be analyzed, as the camera needed nearly 25 ft to build up to its working speed.

Cine shadow records were taken for different flow and arc rotation rates. These were repeated for various arc positions and voltage to current ratios. They were facilitated by choosing different positions for the cathode along the axis of symmetry of the burner as explained in Section III.1. The films show clearly the flow patterns in each part of the test region for the different cases. They also indicate the relative magnitudes and directions of velocities in various parts of the wake. These are discussed in detail in the next Chapter.

Fig. 4.10 OPTICAL ARRANGEMENT FOR SHADOWGRAM USED IN HIGH SPEED CINEPHOTOGRAPHY

IV.4 Shock Waves as a Diagnostic Tool

The velocity of propagation of a shock front in a gaseous medium depends on the density of this medium and therefore its temperature and composition. As long as the temperature changes are considerable they have a greater effect than any variation in composition of the gas mixture (Ref. 38). It was hoped to make use of this phenomena to investigate the temperature distribution within the wake. To obtain a shock wave a spark stand was constructed similar to the ones used to produce the illuminating sparks (Fig. 4.1). The electrodes were connected across a 10 μ F capacitor charged to 10 kV. The shock spark was triggered by opening the camera shutter via a small trigger electrode embedded in the earthed steel rod. The energy released in the spark created a shock wave emanating from the gap between the electrodes. Shock fronts of velocities of the order of Mach 1.4 were obtained using this technique. The optical set-up was precisely the same as for the wake region of the arc on its own. The new spark stand was placed next to the plasma jet burner with its electrodes pointing in the direction parallel to the beam in the test region. Its spark was triggered by the opening of the shutter. Two lengths of thread had small loops tied into one of their ends. Both loops were fitted loosely over one of the electrodes. The threads were pulled taut and their other two ends were tied to a vertical pole positioned on the opposite side of the test region such as to form an angle of approximately 60 degrees between the two fibres (Fig. 4.11). The intersection of their shadows extended beyond the loops provided a position for the axis of symmetry of the spark electrodes, and thus indicated the centre of the spherical shock wave. The illuminating spark was triggered by the radiation of the shock producing discharge via an optical fibre, a photodiode and a

Fig. 4.11 DETERMINATION OF CENTRE OF SPHERICAL SHOCK WAVES

variable delay as in the case of the double exposure photography. (Fig.4.12)

By varying the delay the progress of the shock wave in the test region could be monitored in successive shots and a comparison of distance moved during different delay times gave an indication of the shock velocities. The reproducibility of these measurements was found to be quite good. The system could have been expanded to give two or more successive exposures of the same shock wave using a similar technique to that used for the double exposure wake studies. Shock velocities measured by these multiple sparks would not have suffered from errors that might have been introduced by any non-exactness of the reproducibility of the shock strength.

Records were taken of the shock front moving towards the wake and passing into it. The variation of distances moved by different parts of the shock wave was comparatively small as can be seen in the records shown at the end of Chapter V.5. Additional reasons why this method was not developed further are also discussed there.

Chapter V

SHADOW AND SCHLIEREN RESULTS

This chapter considers some of the photographic records obtained by the use of the short duration spark photography with single and double exposures and the high speed cinephotography as described in Chapter IV.

V.1 Single Exposure Shadowgrams

Plate 4 shows an example of a shadowgram - exposure time a few microseconds - of the wake region of the arc. The optical system and the light source used are described in Section IV.1. The circular field of view was limited by the size of the schlieren mirrors. The strip shadow on the right was cast by a vertical brass scale slotted in 5 mm intervals. The nozzle shadow is clearly visible as are the inlet and outlet pipes for the water cooling of the anode. The bright brush immediately above the nozzle resulted from the radiation emitted by the rotating plasma, extended past the upper nozzle rim by the carrier gas flow. This flow expands after passing through the arc and forms a V-shaped wake region whose boundaries become less distinct with increasing height above the nozzle. The magnification of this particular record is 2:5.

As discussed in Chapter IV each of the lines in the shadowgram of the gaseous region represents a nonzero second order differential of the refractive index with respect to distance perpendicular to it. Every bright line on the record has a less easily distinguishable dark band associated with it. These markings represent boundaries formed by steep changes in refractive index and indicate how the boundaries between

the pockets of hot gas, predominantly argon, and those of the colder gas, consisting mainly of air, are distributed throughout the wake. Although the gases present in the test region are not only at different temperatures, but also of different types - namely argon and air - adjacent layers of different gases of the same temperatures could not be expected to yield the distinct lines observed in Plate 4. This was confirmed in a control experiment in which the shadow of an argon jet entering the open atmosphere without the plasma was observed under equal optical conditions. As mentioned previously, the viewing plane was chosen less than 2 cm past the position of the image of the test region, and the markings correspond therefore closely to the relative interface positions in the test region. The complex structure of fine lines that makes up the wake suggests that this region consists of a great number of pockets of gas of various sizes and densities, some containing a hot medium, mostly argon, and others consisting mainly of cold air.

A closer inspection of the shadowgrams on Plates 4 and 5 indicates that the complex line structure consists of two different areas. The inner part of the cone, closer to the nozzle exit, seems to be made up of a great number of very small pockets of gas. Many of these do not seem to be closed volumes, but are randomly interlinked to form rugged chains interspaced with surfaces dividing zones of different temperatures. The appearance of chains could be due to overlapping pockets. The outer layer of the cone and the entire wake region further downstream show a different picture. Here the pockets of gas are much larger and fewer in number and seem to be inclined to form closed volumes of more or less constant gas conditions. The markings caused by the gas interfaces also seem to be more distinct.

The complex irregular boundary structure immediately downstream of the nozzle is probably due to a smaller scale of turbulence in that region where hot gases predominate with the possibility of remains of the

10.2 l/min ARGON, 1.5 kHz

PLATE IV SINGLE EXPOSURE SHADOWGRAM OF THE STRUCTURE IN THE
WAKE REGION OF THE MAGNETICALLY ROTATED PLASMA JET

arc channel still present. The likelihood of significant entrainment of the surrounding air into this central core region appears from observation discussed later to be small. The lines in this region are found to be somewhat less well defined, which might be due to less distinct boundaries between pockets of gases of different temperature distributions. Additional fuzziness of the lines may have been caused at least in part by the higher gas velocities that are present there.

The shadowgrams present a 2 dimensional record of a 3 dimensional test region. It was therefore important to determine whether the markings obtained near the centre of the wake are actually those caused by the integration of all the interactions of the hot to cold gas interfaces with the beam along its entire length in the test region, or whether only effects near the outside of the wake cone are recorded. As a different pattern is observed near the centre of the shadowgram, corresponding to the region immediately and vertically downstream of the plasma to that in the surrounding layers it was concluded that the activities throughout the wake region of the plasma jet are visible on the film.

V.1.1 Variation of Argon Flow Rate

The effects on the behaviour of the wake of the two easily variable properties of the plasma jet, the flow rate of the carrier gas and the rotation rate of the arc, were investigated. At first the arc rotation rate was kept fixed at about 1300 Hz and the argon flow rate was raised from 4.2 l/min in steps to 17.6 l/min (Plate 5). The most noticeable result of this is the gradual appearance and growth of the "plasma brush" as the increased carrier gas flow pushed the plasma out of the nozzle. With increasing flowrate the inner zone containing the small scale inhomogeneities is extended further downstream. The mean size of gas pockets in the outer regions and further downstream is also found

1.3 kHz

4.2 l/min

7.3 l/min

13.8 l/min

17.6 l/min

PLATE V SHADOWGRAMS SHOWING THE CHANGES IN THE PLASMA JET WAKE WITH INCREASING CARRIER GAS FLOW RATE AND CONSTANT ARC ROTATION RATE

to be diminishing with increased gas flow while the number of interfaces and the intensity of their markings increases noticeably. This indicates the presence further downstream of an increasing number of pockets of gas at various temperatures and of sharper refractive index gradient fluctuations most likely due to more abrupt temperature changes between the various zones. The wake funnel is also noted to have contracted with increasing argon supply at very high flow rates (Plate 5) suggesting that entrainment is lower in the region of small scale turbulence.

The heat losses to the plasma jet burner were monitored by recording the flow rates and temperature rises of the cooling water. The heat transfer rate from the arc to the gas increased with rising argon flow rate, even though the radiative losses from the arc probably increased because of the extended arc column length. The aerodynamic changes in the wake region due to the greater relative velocity between the carrier gas flow and the propagating arc are, however, at least partly masked by the increased turbulence due to the increase in the cold flow Reynold's number.

V.1.2. Variation of Arc Rotation Rate

To overcome this the argon flow rate was kept constant at 3.3 l/min and the rotation rate increased from 0.8 KHz to 2 KHz by varying the DC current in the magnetic coil from 0.8 amp to 2.5 amp. At these low flow rates the two regions were clearly visible (Plate 6). Dealing first with the upper part of the wake the changes in the propagation rate of the arc appears to have little effect on that pattern. Number density and size distribution of the pockets are relatively constant throughout this series of shadowgrams. This, however, is not true for the gas in the close vicinity of the plasma jet. In this region the

3.3 l/min ARGON

0.8 kHz

1.1 kHz

1.4 kHz

2.0 kHz

PLATE VI SHADOWGRAMS SHOWING THE CHANGES IN THE PLASMA JET WAKE WITH INCREASING ARC ROTATION RATE AND CONSTANT CARRIER GAS FLOW RATE

number of gas pockets increases while their size decreases when the arc is allowed to rotate more quickly in the nozzle, suggesting a decrease in the scale of turbulence with frequency of arc rotation.

Comparing the effect of the variation of carrier gas flow and of the arc rotation rate indicates that the properties of the lower part of the wake region depend on both these variables. The distance that this zone extends in the downstream direction is proportional to the flow rate of the gas while the level of turbulence predominating increases with the arc rotation rate. It is this region that has its flow pattern governed by the solid stirrer-like behaviour of the rotating arc. Further downstream the flow seems independent of the activities in the nozzle, but is a function of the flow rate of the gas; a phenomena also observed by other workers investigating flow downstream of nozzles (Ref. 30).

V.2 Double Exposure Shadowgrams

In order to test the variation of the gas velocity with distance downstream, two exposures of shadowgrams separated by a known time interval were superimposed on each other. The precise optical set-up used to obtain this is described in Section IV.2. As the delay between the flashes is known, localized velocity components in any direction perpendicular to the beam can be determined. Plate 7 shows a series of double exposure photographs that was obtained by keeping the carrier gas flow rate and the arc rotation rate constant and increasing the delay between exposures after each separate shot. The double contrast edges near the top of the photographs show the motion of the second blind of the focal plane shutter, the width of the dark grey region being an indication of the time elapsed between first and second flash. The

108 l/min ARGON

1.7 kHz

1.0 msec

15 msec

25 msec

35 msec

actual delay was measured by displaying the flash energies from the sparks via two photocells on an oscilloscope, as previously discussed. The interfaces between pockets of gases of different properties again form bright lines on the emulsion and it is these that are used as markers. The distance between lines resulting from successive exposures is measured, allowing for the magnification of the optical system, and divided by the time delay between sparks resulting in the instantaneous local vertical components of velocity.

The double lines are only clearly discernible if the interfaces have moved a distance within a definite range during the times between exposures. The reason for this is discussed in section IV.2. As increased time delays are considered, double lines therefore become visible in regions of predominantly lower velocities. The shadow series on plate 7 shows a shifting of the position of clearly noticeable double lines in the downstream direction with increasing delay times. This means that velocities decrease with distance downstream, a not entirely unexpected result.

An opportunity to apply the optical system to a practical problem presented itself soon after it was set up. In a parallel investigation (Ref. 8) a nozzle was developed to fit a cylindrical quartz reactor onto the top of the plasma jet orifice. The nozzle angles were chosen specifically to result in the best possible mixedness of the emerging gas stream. Plate 8 shows a comparison of the flow pattern with and without the nozzle, the argon flow rate and the arc rotation rate having been kept constant. The flow with the nozzle in place clearly consists of larger pockets of gas indicating less turbulence and a more uniform regime past the mouth of the water-cooled steel cone than without. As not only the plasma jet conditions, but also the delay separating the two sparks, was kept unaltered between the two exposures, the distribution

14 l/min ARGON

1 kHz

WITH NOZZLE

WITHOUT NOZZLE

PLATE VIII

SHADOWGRAMS SHOWING A COMPARISON BETWEEN PLASMA
JET WAKES WITH AND WITHOUT ATTACHED NOZZLE

of double lines gives some information about the velocity distribution. The fact that the dual markings are only visible in the lower part of the wake with the nozzle in place, while they are clearly discernible throughout the test region for an uncovered jet, suggests a much more rapid velocity decay in the directed flow.

It is not always possible by mere inspection of the records to determine the directions of flow as it cannot always be decided which of the two markings has been caused by the first and which by the second spark. This presents special difficulties in the case of horizontal displacements near the boundaries of the wake, where recirculation is to be expected. As mentioned in Chapter IV, an attempt was made to overcome this problem by "colouring" one of the light sources using neon as a spark gas. This only produced a faintly reddish tinge which is only just discernible on Polaroid Polarcolour film, less well on High Speed Ektachrome and not at all on Agfa Colour cut film. Polarcolour film, however, was found to be too slow to give intense markings, especially in view of the reduced light output from the neon spark. Its contrast properties are also much weaker than those of the polaroid Type 51 film that was used for the black and white records. These two facts resulted in rather smudged records. Plate 14 shows an exposure from an argon spark followed by a neon spark produced on High Speed Ektachrome. The blue and red region at the top and bottom of the record indicate the position of the shutter when the individual sparks were fired. The markings are considerably less well defined than those for the black and white records (Plate 4).

Plate XIV DOUBLE EXPOSURE SHADOWGRAM USING BLUE
AND RED SPARKS.

V.3 Instantaneous Schlieren Records

Plate 9 shows three schlieren records. The first one, reduced in magnification by a factor of roughly two, was produced by placing a horizontal knife edge at the horizontal focus as described in Section IV.1.2. The lower two of approximately unit magnification had their circular schlieren stop placed at the focal disc halfway between the vertical and horizontal focal lines. All three records are dark field schlieren. It is clear from the results obtained that because of the non-point focus due to the aberrations, no uniform dark field was obtainable, and that especially in the case of the circular stop the sensitivity of the system varied with position across the test region. This was because rays deflected through equal angles ended up absorbed by the schlieren stop or not, depending on their position of origin. The schlieren markings are also wider and less well defined than those of the shadowgrams. As schlieren markings correspond to refractive index gradients this indicates that the gas pockets do not entirely consist of gas of uniform refractive index and therefore density, but their properties change gradually near the limits of the gas pockets. At the boundaries themselves these changes suddenly become abrupt, resulting in the distinctive markings seen on the shadow records which correspond to variations in refractive index gradients. To re-emphasise this, it can be seen that pocket boundaries only are visible on the schlieren photographs in regions of low sensitivity.

14 l/min ARGON 1.3 kHz

HORIZONTAL STOP

CIRCULAR STOP

V.4. High Speed Cine Records

Plates 10 and 11 show prints of some consecutive frames of 16 mm high speed cine records obtained at a framing rate of approximately 10,000 frames per second of the moving shadows produced by the plasma jet wake. The shadowgram in each frame, while not as distinct as those produced by the instantaneous spark photography, is clearly legible everywhere except in the region immediately downstream of the nozzle, where velocities are too high even for this camera. Film records were obtained for different flow and rotation rates and were viewed on a Specto Motion Analyser which permitted the films to be projected at 16 or 2 frames/second or frame by frame.

The cine records enable the two separate zones of the wake to be distinguished even more clearly than the short duration stills. The flow immediately following the nozzle exit is seen to be very fast and in the case of high carrier gas throughput rates the motion could not be completely frozen. This region appears very stable in orientation to external disturbances. A fairly rapid transition from this flow regime to the much slower outer and downstream flows, is observed. In the outer sections the flow velocities are considerably slower. In the centre of the wake cone far downstream, large pockets of gas move in an overall upward direction but with a considerable random velocity component superimposed. Near the outside of the wake a number of moving, recirculating eddies are observed. The regressive velocities in these eddies are in general slower than the typical upward velocity in those regions. The flow patterns in the slower-moving areas are far more susceptible to outside influences like draughts. The entire plasma jet was therefore screened off as far as possible from the remainder of the laboratory for the quantitative measurements to be described in Chapter VII. The screens were placed a distance of more than a foot

10.5 l/min ARGON 12 kHz

42 l/min ARGON 1.2kHz

from the plasma jet burner.

As the velocity increases with decreasing distance from the axis of symmetry of the cone throughout the test region it is reconfirmed that the film received records from the entire beam integrated right through the wake region.

If the cathode is positioned such that its tip is in line with the exit edge of the anode and the arc allowed to rotate entirely on top of the nozzle mouth rather than with it, the inner fast-moving flow regime disappears completely. The entire wake region then consists of large, relatively slow-moving gas pockets. These have considerable, rapidly fluctuating horizontal velocity components and no clear conical wake shapes are therefore obtained. The erratic movement of the arc under these conditions contributes significantly to this behaviour. Anode corrosion becomes an important factor with this electrode arrangement probably due to the entrainment of air into the arc path. Good photographic records were difficult to obtain because of the large amount of radiation from the arc now completely exposed to the plates.

In past investigations it has been observed that the presence of oxygen, and to some extent nitrogen, leads to fluctuating arc behaviour and considerable electrode corrosion. The coincidence therefore of the existence of a fast inner region with a smooth arc rotation for the lower cathode position, and the absence of that central region in the case of the erratic arc motion with the protruding cathode, suggests the presence of entrained air near the arc only in the absence of the fast-flowing central region. This confirms the visual observation from the cine records that little entrainment takes place into this fast-flowing regime. What entrainment there is - a not inconsiderable amount, as discussed in Chapter IX - seems to occur in the outer layers of the wake cone.

V.5 Shock Front - Wake Interactions

Plate 12 shows a shock front approaching and entering the wake of the magnetically rotated plasma jet obtained with the equipment described in section IV.4. The intersecting line shadows indicate the position of the spark that produced the shock wave. As the shock front enters and passes through part of the wake, it changes slightly from its spherical shape due to the random encounter of gas pockets of varying temperatures. As the shock wave moves towards the centre of the wake cone its records become obscured by the markings from the refractive index gradients in the wake and it is no longer possible to distinguish them from the complex overall pattern in that region. Although it might have been possible to improve this by the use of stronger shocks, meaningful measurements would still have been confined to the outer layers of the wake. Velocity changes were also found to be relatively small. (Temperatures experienced in the wake are relatively low compared to those in the arc, where this method has been used in the past (Ref. 38)). The problem is compounded by the fact that the change in shock velocities due to varying temperatures would have had to be integrated along the path of the shock, unless a method of determining instantaneous shock front velocities (e.g. Laser Doppler velocimetry) was to be used. A great number of shock speed measurements would have been necessary to obtain the statistically significant number of readings required by the turbulent and complex flows in this region. A more suitable method making use of the markers conveniently supplied by the gas interfaces was therefore developed to obtain a quantitative analysis of the localized physical properties throughout the wake region, as discussed in Chapter VII.

Chapter VIPROBE MEASUREMENTS

In Chapter IV it is shown how a method was developed for determining the general shape of the wake region and its fine structure. The order of magnitude of velocities encountered in that region could also be estimated as well as the general flow pattern of the hot gases emerging from the plasma jet, all as a function of the arc conditions. We still, however, require an estimate of the homogeneity of the gas at various reference points in the wake region. For this a probe that had been developed in these laboratories and which is described later in this chapter, proved very useful.

As mentioned in Chapter II, the use of probes presents two main areas of difficulty: those present even in laminar flow conditions and those introduced by the turbulent flow of nonuniformly heated gas. The former includes the disturbance caused by the mere presence of the probe in the regime that is to be measured. Heat losses can be expected to be present, due to the radiation from solid surfaces of the probe as well as to conduction along its leads. In the absence of chemical reactions, solid probes would have acted to encourage only the recombination of ionized argon or the reassociation of possibly entrained, dissociated air. This was expected to have caused concern only in the area close to the nozzle.

Secondly, most probes require a finite time to adjust to changes in conditions. Thermocouples, for instance, can only record the temperatures of their surrounding gas correctly if their junctions are allowed to reach thermal equilibrium with these gases. They could not, therefore, have followed the rapid fluctuations present in this system. Allowing them to record 'average' values would not only have lost

information about the turbulence of the flow but also have produced incorrect values as discussed in Chapter II. The interference problems could not be completely overcome even with the corona probe, although, as will be seen later, careful design helped to minimize the inaccuracies introduced due to changes in flow pattern and correct use resulted in no recombination of ionized gases on the probe.

VI.1 The Corona Probe - Method

The problem that results from the rapid fluctuations can be eliminated completely by arranging for the gas whose properties are to be measured to act as the thermometer itself. The probe that was developed to do just this makes use of the physical properties of the corona discharge (Ref. 8). When a conductor charged to a high potential has at some point on its surface a much increased radius of curvature, a discharge will occur at that point. Once the potential of the conductor is fixed the magnitude of the discharge, as expressed by the current through the conductor, varies inversely as the density of the surrounding gas (Ref. 31) and thus directly as its temperature for a fixed composition of the gaseous medium. The temperature of the conductor has no influence on the discharge.

The probe itself consisted of two platinum wires, covered by quartz tubing except at the tips, mounted on a calibrated rack and pinion arrangement, mobile in a plane containing a central vertical cross-section of the plasma jet wake. One wire had a pointed end while the other was spherical (Fig. 6.1). The point and the sphere were separated by about 8 mm. The two wires were part of a circuit made up of a Hewlett Packard HP Harrison 6516A HT source, set for 2 kV and a 10 M Ω resistor as shown in Figure 6.1. The HT applied across the tips of the probe caused

Fig. 6.1 CORONA PROBE AND CIRCUIT (SCHEMATIC)

a corona discharge to occur at the pointed electrode. Electrons emitted there were collected by the positively charged sphere allowing a current to flow in the circuit. The amount of charge emitted from the tip, and therefore the current across the 10 M Ω resistor, was a function of the condition of the gas at the probe point. The voltage across the resistor was monitored on an oscilloscope via a HF filter. The filter protected the oscilloscope from possible HT voltage surges. As conditions at the tip varied, so did the current in the circuit and the voltage displayed on the cathode ray screen. Once a given HT voltage was applied the discharge and therefore the recorded voltage were dependent on the conditions prevailing in small volume immediately surrounding the tip.

For a perfectly mixed homogeneous gas stream there would be no fluctuations in voltage, so that a straight line would appear on the oscilloscope, DC levels of which are related to the type, composition and temperature of the gas or gas mixture. As soon as pockets of gas with different properties pass the probe, however, a varying signal is displayed. The number, size, velocity and extent of the differences in properties between these pockets are reflected in the frequencies and amplitudes of the fluctuations. The degree of variation is thus an indication of the mixedness of the system. The smaller the variations, the better the system is mixed.

The difference between conditions near the nozzle where a large number of very small fast-moving, very hot pockets produced a rapidly varying signal, and conditions near the upper boundaries of the wake - where a relatively small number of large pockets passed the probe less rapidly giving a slowly changing signal - is quite clear even on a casual observation of instantaneous records of the oscilloscope screen. Analysis of more similar sets of conditions of points closer together

however, requires a quantification of the output variation of the probe. As the extent of the mixedness of the gas stream is related to the voltage fluctuations, it is these, rather than absolute DC levels, that one is primarily interested in. In order to take account of the number of deflections, their shapes and amplitude, it was decided to use the root mean square (RMS) values of the AC component of the signal as an expression of mixedness. In practice a DISA Type 55D35 Root Mean Square Voltmeter was connected across the probe output. The meter disregarded the DC output and computed the RMS value of the AC part of the output only. These in turn were recorded on a chart recorder. The longest possible integration time was chosen over which the values were determined by the meter, in order to give the best possible mean values at any one point. These values as recorded by the chart recorder were averaged again manually from the fluctuations of the trace at each point. The readings were taken with the probe tip at various positions, spaced uniformly throughout a vertical cross-section through the axis of the wake region. The values obtained were mapped out and points of equal RMS values were joined together. The resulting lines correspond to regions of equal mixedness in the wake.

The probe as used in previous investigations in these laboratories is shown in Figure 6.2. Here both wires were introduced parallel from one side of the cross-section of the wake. Preliminary investigations (Ref. 8) showed that the precise orientation of the probe, whether tip and sphere were next to each other or one above the other, is not critical. This arrangement, however, caused several problems, resulting in a seemingly unsymmetric wake as discussed in the next section. Changing the probe into a pincer type shape (Fig. 6.3) reduced these errors and resulted in the expected symmetry about the vertical axis.

The probe measures the quantity of charge emitted from the point

Fig. 6.2 CORONA PROBE (OROGINAL DESIGN)

Fig. 6.3 CORONA PROBE (PINCER TYPE DESIGN)

and collected by the sphere. It was therefore important to ensure that there were no free changes from any source other than the tip present in the region of measurement or near the sphere, that could be absorbed by the probe. The probe could therefore not be used in the immediate vicinity of the arc. Only some way downstream, where temperatures were lower and charged species had a chance to recombine, are the probe results meaningful. In practice, the boundaries of the regions of useful results were obtained by temporarily switching off the HF supply when taking measurements relatively close to the arc. Unless the oscilloscope displayed a straight line, charged species or electrons were being collected by the probe from the arc, rendering that point unsuitable for measurement. In the presentation of results the region below which no valid results were obtainable is shown as a dotted line.

VI.2. The Corona Probe - Results

The Root Mean Square values obtained by the corona probe in the wake region were assigned to each point. Iso-RMS lines and therefore contours of equal mixedness were drawn throughout the test region. In Figure 6.4 the lines obtained by the original configuration of the probe are shown. They exhibit a marked decrease in RMS value in the outer layers of the wake and in the downstream direction.

The lower part of the region opposite to the side from which the probe was introduced shows a line distribution that does not seem to fit in with the remaining pattern. Although this could be due to non-symmetry in this zone, the probe geometry could have caused the extra loop. This is suspected because in this case the probe extended right through the wake region having maximum effect on the flow pattern. The collector sphere also entered the region of maximum concentration of

ionized species and therefore absorbed free charges not produced by the corona discharge, even when the probe tip was in an ionization-free region. This was remedied by changing the probe to the pincer type shape mentioned earlier in this chapter (Fig. 6.3).

Figures 6.5 and 6.6 show the resulting isomixedness contours for high and low flow rates respectively. The results are now clearly symmetric and exhibit the decrease in RMS value with increasing distance from the nozzle in all directions.

The fluctuations in the probe output are dependent on size and temperature distributions of the pockets of gas passing the probe tip as well as on their flow velocity. The root mean square values can therefore not be considered to be standard deviations of velocity only. Hence they are clearly not measures of the intensity of turbulence of the flow regime, especially when one considers the much larger pocket sizes present in the outer part of the wake as compared to its centre.

VI.3 Thermocouple Probes

As discussed at the beginning of the chapter, thermocouple probes cannot follow the temperature fluctuations present in the wake region and average incorrectly, by volume rather than by mass. Nevertheless, measurements were taken in a central cross-section through the wake region at equal intervals in the horizontal and vertical direction, similar to those using the corona probe. The probe output voltage was recorded on a Phillips chart recorder which further damped the fluctuations so that a mean voltage was noted at each point. These values were constant even for prolonged measuring times. Values of mean thermocouple output are plotted in millivolts in Figures 6.7 and 6.8 for a flow rate of 12.4 l/min and 5.7 l/min of argon respectively. Positions of equal mean thermocouple voltage are joined by lines. These

are labelled in terms of millivolts output rather than converted to degrees centigrade, in order to emphasize that these are not true mean temperatures.

A trend towards lower temperatures near the outside of the wake region and further downstream is, however, clearly deducible. Equally important, a high degree of symmetry is observed in the wake. This is an expected result, reconfirmed by different earlier measurements and observations, important in itself and for the analysis in Chapter VIII. As in the case of the corona probe the results immediately downstream of the nozzle are invalidated by the interference from ionized species and free electrons.

Chapter VII

VELOCITY MEASUREMENTS

Having established the general qualitative behaviour of the plasma jet gases in the wake region, we turned our attention to a more quantitative approach. It was decided to concentrate on obtaining a full range of values for localized velocity distributions at as many points in the wake as possible.

VII.1 Laser Doppler Velocimetry

VII.1.1 Theory

The method selected in the first instance was laser Doppler velocimetry. The principles underlying this technique have been extensively described in the literature (Ref. 32,33,34,39) where it is commonly applied to the measurement of shock front velocities.

Briefly a parallel laser beam is allowed to traverse the test region, (Fig. 7.1). Most of the beam does not encounter an inhomogeneity and is brought to a focus by a schlieren mirror or lens. That part of the beam that does interact with a phase object is deflected through an angle θ and brought to a focus in the same plane as the main beam, but somewhat displaced from it in a direction perpendicular to the optical axis. If the disturbance in the test region is moving with a velocity that has a non-zero component in any direction perpendicular to the direction of the beam, then the deflected part of the laser beam has its frequency Doppler shifted to a new frequency ν_2 given by

$$\nu_2 = \nu_1 [1 + (u/c) \sin \theta]$$

Fig. 7.1 LASER DOPPLER VELOCIMETRY (SCHEMATIC)

where v_1 is the frequency of the incident beam, u the component of velocity of the schliere perpendicular to the beam, θ the angle of deflection and c the velocity of light. If a blind with a narrow slit cut into it is now placed on the focal point of the second lens or mirror, one can, by adjusting the relative position of the slit, select a pencil of light that has been deflected through any one suitable angle θ only. A second slit placed at the focal point of the undeflected beam allows a part of that to pass too. As the two beams expand and overlap they interfere. A white card placed in the overlapping region displays a clean interference fringe pattern. For maximum visibility of these fringes the intensity of both interfering beams must be approximately equal. The spacing of these fringes is given by the relation familiar as the Young's Double Slit expression

$$\mu = \lambda l/a$$

where λ is the wavelength of the incident beam, l the distance from the double slit to the point of observation of the fringes and a the separation of the two slits. As long as the schliere in the test region is stationary the pattern is stationary. Plate 12 shows such an interference pattern produced by a stationary glass rod. Once the disturbance moves the fringes begin to travel in the direction parallel to that of the motion in the test region. The frequency with which these fringes pass a stationary reference point is given by the beat frequency (v_b) of the two interfering beams, i.e. by the amount the Doppler shifted beam has been changed in frequency:

$$v_b = v_2 - v_1 = v_1 \frac{u \sin \theta}{c} = u \frac{\sin \theta}{\lambda};$$

u can be determined from this equation directly or via the fringe spacing. The velocity (v) of the fringes is given by

$$v = \mu \times v_b$$

and the velocity of the phase object in the test region by

$$u = v/M$$

where M is the magnification of the optical system. This analysis is correct when using the undeflected beam as the reference beam. Has the reference beam been deflected through an angle α with the optical axis, the measured fringe velocity v_f needs to be adjusted for the off axis position of the reference beam using the equation: (Ref. 32)

$$v = v_f [1 - (\alpha/\theta)]$$

If v is now divided by the magnification the velocity component of the phase object perpendicular to the beam in the test region (u) is obtained.

There are two ways of explaining the formation of the moving fringes. Either one considers the pattern to be caused by the interference of two beams of slightly different frequencies ν_1 and ν_2 resulting in the creation of fringes moving with the beat frequency of the two interfering beams. Alternatively, the fringe pattern may be considered to form an image of the phase object made up of fringes with its velocity related to that of the object in the test region allowing for the magnification of the system. If the undeflected beam provides the reference the fringe system moves with the same velocity as the record of the phase object. Otherwise the correction quoted above from Ref. 32 needs to be used.

It has been shown (Ref. 39) that these approaches are entirely equivalent.

VII.1.2 Application

In practice the optics was set up as shown in Figure 7.2. A beam from a 5 mW He-Ne laser was focused onto a pinhole and allowed to expand onto a schlieren mirror of focal length 3 m at whose focus the pinhole was placed. The parallel beam then passed through the test region and was brought to a focus by another similar schlieren mirror. The size of the test region was determined by the diameter of the two mirrors. The beam was arranged in a Z-type configuration.

A screen containing two small closely spaced slits was then placed at the focus of the second mirror. The slits were positioned either for one to be at the focus of the undeflected beam and the other at the focus of a beam deflected through a pre-chosen small angle θ , or alternatively for one slit at a point corresponding to a small upward deflection ($+\theta$) and the other an equal deflection in the opposite direction ($-\theta$). A piece of polaroid was placed in the path of the brighter of the thus selected beams and rotated to arrange for approximately equal intensity of the interfering beams in order to obtain maximum possible legibility of the fringes. The polaroid acted as a continuously variable ND filter of transmissivity between 80% and 3% depending on its alignment with respect to the direction of polarisation of the laser beam. This was necessary if one of the beams was the undeflected beam. If only deflected components of the laser light were used to produce the interference pattern, the polaroid compensator was not required and equal intensities could be ensured by fine adjustment of the positioning of the double slit. In both cases the intensities were compared and adjusted by covering each slit in turn and comparing

Fig. 7.2 OPTICAL ARRANGEMENT LASER DOPPLER VELOCIMETRY

the DC level displayed by the oscilloscope as a result of the light incident on the photo-multiplier through the other slit.

The screen was followed by a lens whose focal length was chosen to give a suitable magnification of the image. For the first half of the measurement a focal plane shutter and a photographic plate in its holder were placed near the image plane of the test region. A stationary schliere, i.e., a glass rod, was placed in the test region with the plasma jet switched off in order to produce stationary fringes. These were recorded using Type 57 polaroid film (Plate 12). This gave a value for μ , the spacing of the fringe pattern for the particular angle θ as chosen by the slit position. This corresponds to a set of distance markers.

The shutter and film were then replaced by a screen containing a single slit or grating whose spacing distances were equal to the wavelength of the fringe spacing. The reason for the slit width and the possible use of the grating will be discussed later in this section. An EMI photomultiplier was placed behind the slit and charged using a Hewlett Packard Harrison 6516A, HT power pack. A screen containing a small triangular aperture was placed in the parallel beam just before the test region to select one small part of the wake region only for investigation at any one particular time. The shape of the aperture was chosen to give a suitable diffraction pattern at the focal point of the second mirror, i.e. at the double slit. For a triangular aperture the pattern was in the form of a three-pointed star.

The optical arrangement was tested by spinning a glass rod about an axis perpendicular to itself through its centre at a rate of about 2000 RPM using a constant speed motor. The rod was allowed to cut the beam in the test region and its linear velocity was recorded. Velocities determined from these measurements compared well with those computed from

PLATE XII

FRINGES PRODUCED BY A STATIONARY ROD USING LASER
DOPPLER VELOCIMETRY SET-UP

cf: GRID USED IN FRONT OF PHOTOMULTI-
PLIER TUBE

the rotational frequency of the rod. The plasma jet was then switched on and the hot gases in the selected part of the test region produced a moving fringe pattern on the screen in front of the photomultiplier. As the fringes passed the slit the output from the photomultiplier as displayed on the oscilloscope varied with the frequency ν_b , the beat frequency of the interfering beams. This corresponds to a very accurate clock in the normal velocity measurement techniques.

It would appear on first inspection, that the optimum width for the slit in the image plane of the test region is half the wavelength of the interference pattern, although a smaller slit would suffice for bright fringes. A larger slit is equivalent to having a slit with width (w'):

$$w' = w - n \times \mu$$

where w is the actual width of the slit, and n the number of complete sets of dark and bright bands contained within the slit width. The $n \times \mu$ part of the light transmitted through the slit only contributes to the DC level of the signal produced by the photomultiplier.

As the fringes were, however, not very bright, it was necessary to consider a way in which to amplify the AC part of the photomultiplier output. To do this an arrangement was used which was first suggested by Schwar and Weinberg (Ref. 40) but not actually employed at the time. The slit was replaced by a grid of spacing equal to the wavelength of the interference fringes. This is equivalent to allowing a number of bright bands of width $\mu/2$ to pass an equal number of slits of equal width simultaneously and therefore produces an amplified AC component with no DC component at all at the output of the photomultiplier. A signal thus produced has a higher legibility than that obtained from any other slit configuration or width.

Problems, however, presented themselves in the use of both positions for the double slit as the focus of the second schlieren mirror. The intensity of the deflected light through any angle is a function of the refractive index gradient of that particular interface between a hot and a cold pocket of gas used as a marker at that particular instance in time. As these pockets and therefore the interfaces varied in their physical properties from one another, the intensities of successive beams refracted through a fixed angle θ were not equal. This can be seen on the instantaneous shadow photographs in Chapter V by the differences in intensity and width between various lines representing different interfaces. This obviously created a difficulty in finding a condition under which both beams were of similar intensity for all or most of the many hundreds of passing schlieren. This problem persisted even with the use of upward and downward deflected beams as there was no guarantee that rays deflected in both directions simultaneously would always be of the same ratios of magnitudes even if an entire pocket of gas would always have been contained in the small test triangle.

Another requirement was that no more than one pocket may be in the test region selected by the aperture at any one time. On the other hand if upward and downward deflected beams were to be used, two refractive index gradients opposed to each other in direction would have had to be present. The ideal condition would therefore have been one in which one closed pocket only was present at any time in the triangular beam. This was virtually impossible to achieve, although two opposing surfaces of different pockets travelling with the same velocity would have been sufficient.

It can be seen, again from the shadow photographs, that it was possible to arrange for only one interface to be considered at any time

by choosing a sufficiently small triangle (e.g. of sides 2 mm) to act as aperture at least for regions near the slower-moving periphery of the wake, where large pockets predominated. Simultaneous up and downward deflections, however, were unlikely and the undeflected beam had to be used. In the region of the small fast moving pockets near the centre of the wake the interfaces are very close together. 'Images' of the markers spread out into fringe patterns overlapped and it was nearly impossible to arrange for one interface to be contained in the test beam only. The overlapping fringe systems made meaningful measurements in this area virtually impossible.

VII.2. Schlieren Velocimetry

It was therefore decided to make some adjustments to the optical system and transform the Doppler velocimeter into a schlieren velocimeter. The optical configuration remained unaltered up to the double slit (Fig. 7.3). That was replaced by a schlieren knife edge in a horizontal position for measurement of the vertical velocities and in a vertical position for horizontal velocities. The next lens was replaced by one that gave a magnification of the test space of approximately 1:1 in the image plane. The single slit screen was removed and a screen containing three small, narrow slits spaced closely together was positioned in the image plane of the test region. The photomultiplier was placed immediately behind these slits. The slits were made by multiple photographic reductions of three 1 cm thick black lines drawn on A4 sized papers until the entire configuration occupied a space of less than 3 mm × 3 mm. Ilford Lithographic Film was used, the final negative being on Ilford Lithographic plate. This optical arrangement gives a dark field schlieren image on the screen in the image plane of the test region. Schlieren optics in contrast to shadowgraphy or

Fig. 7.3 OPTICAL ARRANGEMENT SCHLIEREN VELOCIMETRY

the production of interference fringes always produces a focused image on the screen. All measurements executed by the three slits at a point, or more precisely over a small area, are therefore results of conditions that existed in the test region at the corresponding position. We now have a way of executing localized investigations at different points without having to preselect a part of the beam with an aperture but by only moving the treble slit with respect to the image of the burner. In practice this movement was achieved by a mirror that could be tilted about a horizontal axis and turned using rack and pinion gearing about a vertical axis, thus moving the beam with respect to the fixed treble slit. An outer edge of the anode was used as a reference point. In the moving schlieren image the interfaces were once again used as markers, this time in the form of bright lines on a dark background. As one of these lines passed the three slits three bursts of light fell on the photomultiplier and gave three pulses at its output which could be visualised on an oscilloscope (Plate 13). The separation between the slits acting as distance markers was known as was the time required for the passage of the schlieren image across the slits from the readings from and the settings of the oscilloscope, which again represented an accurate clock. The magnification of the optics is easily establishable and the local velocity of a gas pocket has therefore been measured.

The wake region of the plasma jet is a turbulent system defined as containing a range of velocities of the form

$$v_{x,n} = \bar{v}_x + \delta v_{xn}$$

where x denotes the position and n the number of that particular measurement at position x . It was therefore obviously meaningless to talk about individual velocities and necessary to compile a large number of values at each point. A distribution of these data could then be drawn up from

which average values of velocity for each point could be estimated. The standard deviations of these distributions contain information about the intensities of turbulence at the various points.

By changing the slit orientation by 90° both horizontal and vertical velocity components could be measured separately. At first the 3 slits were equispaced. This gave rise to a great number of groups of three peaks. There were, however, groups of two peaks and even single spikes recorded. This could have been due to two reasons. It is possible that the velocity components along the slits were greater than those across the slits preventing the markers from reaching the third or even the second slit. This was especially likely for horizontal measurements near the centre and for vertical measurements near the edge of the wake cone. Alternatively the shape of the pocket of gas had changed drastically within the time required to move past the slits, a phenomenon not unlikely to occur, as can be seen from the high speed cine film (Chapter V.4). Average velocities as well as standard deviations were therefore obtained at various points in the wake from two and three peak values separately, while the plasma jet conditions were kept constant. A comparison between these sets of values obtained are discussed in Chapter IX. They were found to be consistent within experimental accuracy with the possible exception of the region very close to the boundaries of the wake. In that region of comparatively low velocities the effects of the change in velocities turned out to be relatively large as these changes were considerable and even changes in direction were not uncommon for moving pockets near the outside of the wake, as can be seen from the high speed film. The lower velocities and smaller concentrations also caused a smaller number of interfaces to pass the slits. This resulted in fewer readings in the fixed time interval over which measurements had to be taken at each point, as will

be explained later. The smaller the number of readings the larger the statistical error introduced. Results obtained near the edges are therefore less reliable than those near the centre. All this considered, it was deemed justifiable to consider readings obtained from three peaks only. This has the further advantage of enabling the slits to be placed at different separations, the third at a distance roughly twice that between the closer two. The peaks thus obtained are unequally spaced which not only gives information about the magnitude of the velocity components but also of their directional sense (Plate 13).

As a very large number of readings were required at each point in the wake region, the recording mechanisms were automated as much as possible with the equipment available. The photomultiplier tube used was a Type 9592/A manufactured by EMI in the UK. The output from this photodetector was displayed using a Tectronix Type 561B, 10 MHz oscilloscope. The time base sweep rate was adjusted at each point to cope with the range of time intervals between peaks encountered. A Vinton 16 mm cine camera was focused onto the oscilloscope screen such that the image of the tube just filled a frame of the film. The camera was set to expose 8 frames/sec for the faster oscilloscope settings or 1 frame/sec using an Intervalometer for sweep rates longer than 2 msec/cm. (The intervalometer is an instrument that allows the Vinton camera to record single exposures of fixed duration at prechosen intervals between 1 second and 2 hours.)

As the shutter opened a microswitch built into the Vinton power supply along with the circuit in Figure 7.4, triggered the oscilloscope externally causing the recording of only one complete sweep on each consecutive frame. The film used was Ilford Micro Neg. Pan Type A403, a comparatively slow but high contrast emulsion, available in 2000 ft

lengths at extremely competitive cost. The camera is fitted with an internal frame counter which enabled a fixed number of sweeps to be recorded at each point. Calculation of the product of number of sweeps, times the sweep duration, resulted in the total time over which readings were taken at each point. The films were developed using a 100 ft Jobo Spiral in Kodak D19 developer for 7-8 minutes. They were analyzed frame by frame using PCD-X-Y Digit Reading Equipment, which incorporates the following features. The picture to be analyzed is projected onto a ground glass screen. An x-y shift arrangement is positioned at the point to be measured - in this case the centre of one of the peaks. Its precise position is displayed digitally and can, by pressing a button, be recorded onto paper roll as well as onto Olivetti computer terminal compatible punch tape, via a Data Dynamics 390 punch. Each group of three abscissae values corresponding to a series of peaks was recorded on a separate line equivalent on the paper tape. The CDC 6400 at the Imperial College Computer Centre was programmed using FORTRAN IV to calculate the velocities corresponding to the recorded intervals, plot velocity distribution histograms, calculate mean velocities and standard deviations at every point (see Appendix 2 & 3).

Chapter VIIISTATISTICAL ANALYSIS - CORRECTION 3D TO 2D CONVERSION

In the analysis of the velocity distribution one important factor has still to be taken into consideration, namely the fact that this, as most optical methods, gives measured quantities that are a result of integration along the optical path of the beam as it traverses the test region. Near the edge of the wake this presents no real problem as any interface giving rise to a recording must have been travelling near the outer circumference of the wake where the laser beam is tangential. A beam that passed through the cone of hot gases near its centre, however, was not only influenced by disturbances in the central, vertical plane of cross-section through the wake perpendicular to the beam. It also recorded events in front and behind this plane. In order to be able to map out a true velocity distribution in this central cross-section of the test region, it is therefore necessary to deduct these additional effects from the overall distributions of the signals as supplied by the photomultiplier.

In order to achieve this a basic assumption needs to be made, namely that the wake region is cylindrically symmetric about the axis through the cathode. As shown in Chapter III the burner was entirely axisymmetric with the exception of the gas inlets. The gases after entering the burner passed through two flow constrictions with a pressure drop across each of them inside the burner, as well as through the highly turbulent arc rotation region. It is therefore unlikely that they should have an intrinsic preferred direction, as long as they are not disturbed by external influences like forced convection. The likelihood of that occurring had been reduced by shielding and even switching off the laboratory extractor system while taking readings. The symmetry of the

wake cone is illustrated by the shadowgrams in Chapter V and confirmed by probe measurements discussed in Chapter VI. It is therefore thought that the axisymmetry of the wake region is not an entirely unreasonable assumption. Once we have accepted its validity the following model can be used for the correction of the integration along the optical path.

The cone making up the wake is cut by a number of equispaced horizontal planes. All readings at any one height above the plasma jet were taken along equispaced parallel beams in these planes. The readings of interest are those that originated from the region of intersection of these horizontal planes with the vertical plane containing the central cross-section through the plasma jet at right angles to the laser beam. In order to isolate these the circular disc, formed by the intersection of the horizontal plane with the cone of the wake, is divided into a number of concentric annuli of equal thickness leaving a small disc of radius equal to one and one half times that thickness in the centre, such that one and only one beam passes through each annulus tangentially to the inner boundary of the ring (Fig. 8.1). The central ray passes through the centre of the disc in the middle. This arrangement is preferable to allowing each beam to pass through the centre of one annulus as now each beam averages over a complete ring near its intersection with the central vertical plane. Every resulting mean value, however, corresponds to the middle of its ring. Therefore each, except the centre reading, needs to be assigned to a point one half of an annulus thickness closer to the outside of the wake than the position of intersection between the central vertical plane and the beam from which it resulted (Fig. 8.2).

The width of the annuli and therefore the separation between the beams is limited by theoretical as well as practical considerations.

Fig. 8.1 CONCENTRIC RING MODEL - VERTICAL VELOCITIES

Fig. 8.2 MEASURED VALUES AND THEIR ASSIGNED POSITIONS

As we shall attempt to obtain local average values for the physical properties of the wake region in each of these annuli, it is obviously desirable to keep them as small as possible for maximum accuracy. This does not only make the values obtained more truly localized, but also reduces the probability of errors due to averaging over a region of steep gradients of the physical quantities to be measured. On the other hand, it is of little use to make the thickness of these rings less than the length or total separation of the three slits, allowing for optical magnification, as the readings were naturally averaged over the area covered by the slit system. It is, however, important that this area size is selected such that it is meaningful to speak in terms of average values of quantities like velocity and density. In this case for a slit area of approximately 3 mm square an annulus thickness of 5 mm was chosen.

Vertical measurements were taken throughout the entire cross-section to check for the symmetry of the wake and to give a better average value for each annulus. Horizontal measurements were taken on one half of the wake only as just that part was visible with a vertical schlieren blind (the remainder of the wake had its schlieren markings deflected into the stop). As the conditions are different for horizontal and vertical velocity measurements, each case is treated separately.

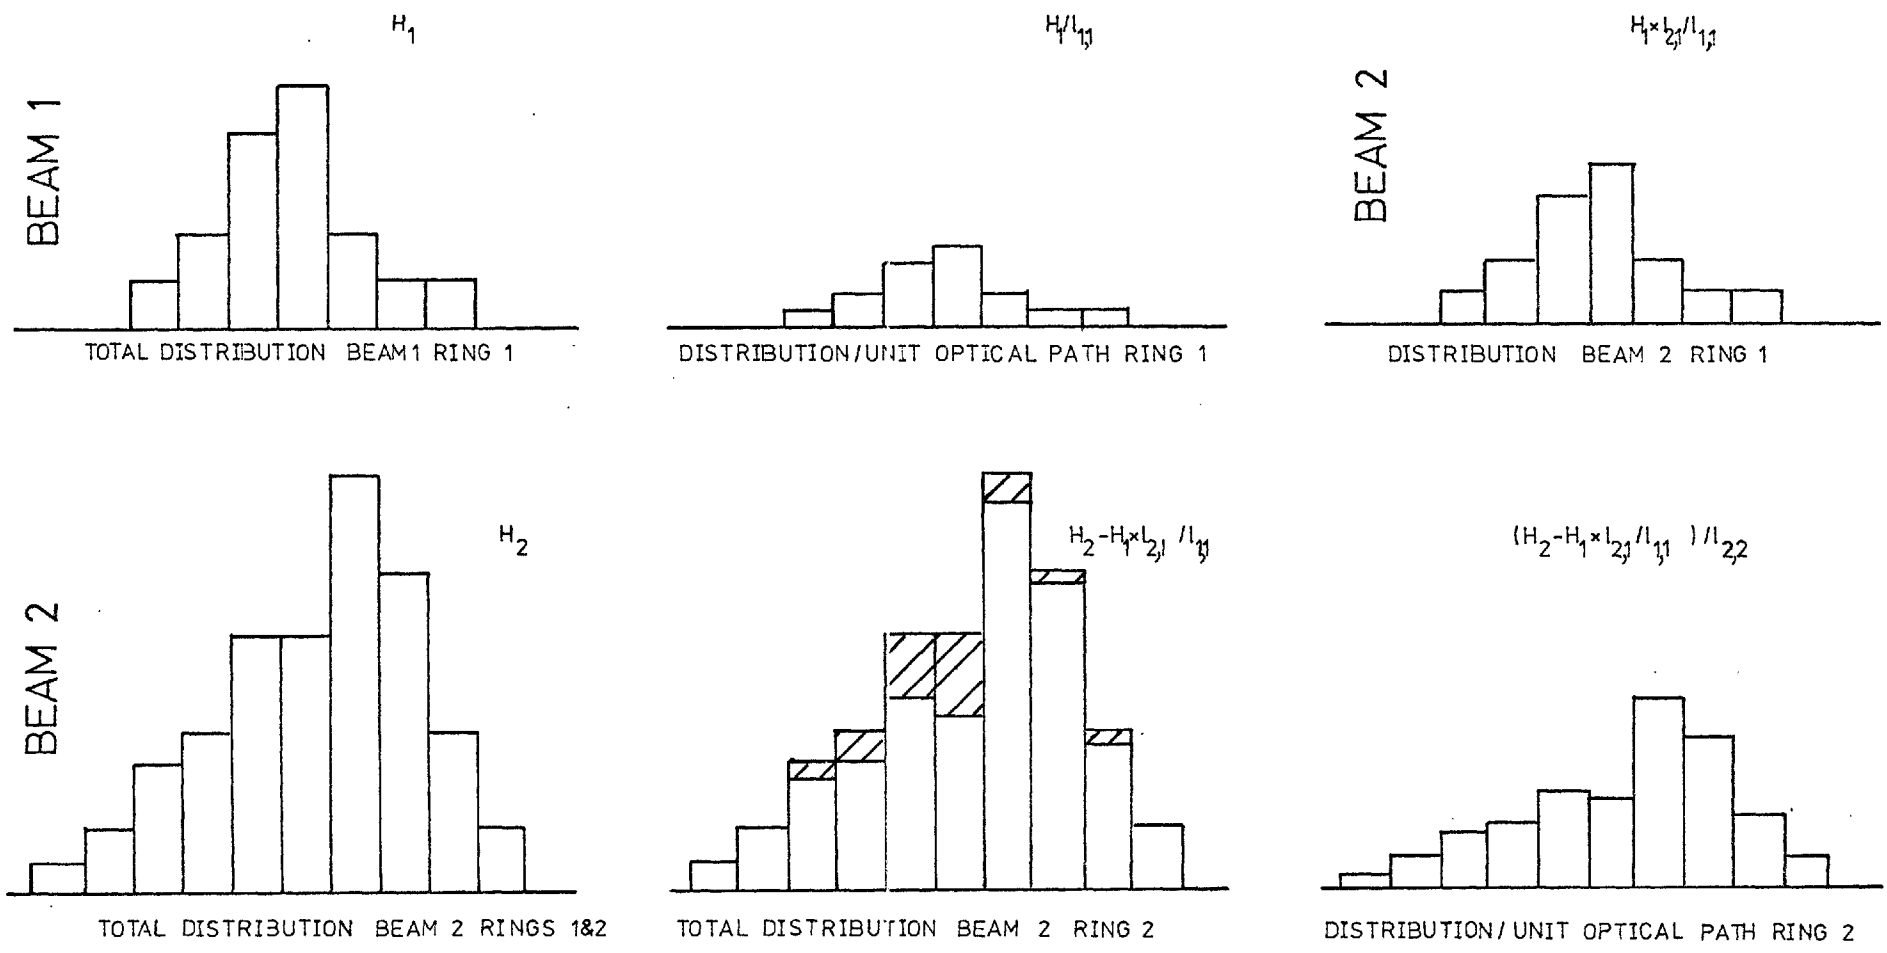

VIII.1 Vertical Velocity Analysis

Dealing first with vertical velocity components, these are all either in an upward or a downward direction and are at all stages perpendicular to the direction of the laser beam. The outermost part of the beam in each horizontal plane presents few problems, as shown by ray No.1 in Figure 8.1. That only passes through the outermost annulus and all signals in that part of the beam are due to that region representing a range of velocities encountered in that part of the wake.

They were recorded for a fixed duration of time and a histogram of a continuous series of small velocity intervals versus the number of times velocities in each interval occurred was plotted. In order to normalize this frequency distribution, each term of the histogram is divided by the relative length of the optical path of that beam in the annulus ($L_{1,1}$). A term in the histogram is defined in this context as the number of times velocities in a given interval occurred.

The next bundle of rays, shown in Figure 8.1 as number 2, passes through both the annuli 1 and 2. The distribution in this beam due to annulus 1 per unit length of optical path and measured over an equal period of time - keeping the selected velocity intervals the same as before - is known from the previous measurement. The contribution due to annulus 1 towards the total distribution of measurements in beam 2 is found by multiplying each term of the normalized histogram for region 1 by the total path length of beam 2 in annulus 1 ($L_{2,1}$). This distribution is then subtracted from the overall histogram obtained for beam 2 by subtracting each term in turn (Fig. 8.3). If the remaining histogram is then divided by the optical path of beam 2 in zone 2 ($L_{2,2}$), the normalized distribution of velocity in ring 2 is obtained.

A similar course of action is followed for all further parts of the laser beam. The overall distribution for each set of rays has all the normalized distributions due to rings outside the zone to which these rays are tangential, multiplied by the relevant optical path lengths in these areas, subtracted from itself. The resultant histogram is then divided by the optical path in the region to which that part of the beam is tangential. All these values can be calculated from the interval between consecutive photomultiplier output peaks and a number of calibration values like slit separation, magnification and the size of

FIRST SUBSCRIPT - BEAM, SECOND - RING

H - MEASURED DISTRIBUTIONS

l - OPTICAL PATH LENGTH

Fig. 8.3 SUBTRACTIONS OF HISTOGRAMS

the concentric annuli selected by program "Veloc", (Appendix 2). It should also now be clear why it was important to measure velocities for the same (or at least a known) time duration at each point in any one horizontal plane. It was necessary to obtain velocity distributions not only per unit length of optical path but also per unit time before carrying out the above-mentioned subtractions, in order to attach the correct weighting factors to the measurements due to every ring. This was ensured by measuring at each point for the same fixed amount of time as described in Chapter VII. As discussed in the same chapter the unequal slit separation provides a means of determining directions of velocities as well as their magnitudes. This enables one to draw up separate velocity distributions in the upward and downward directions. Alternatively, it is possible to consider both sets of velocities in one distribution by regarding all velocities in one direction as positive and in the other as negative. It is therefore possible to obtain average values as well as standard deviations and thus intensities of turbulence for either case. The directional sorting of velocities, their conversion into histograms and their correction in accordance with the annular model discussed above as well as the calculations of the statistical properties of the resultant distributions were carried out by program "Veloc". (Appendix 2). The program was written in Standard FORTRAN IV.

VIII.2 Horizontal Velocity Analysis

Turning now to the horizontal velocities, the treatment of these is somewhat more difficult as there are two different mutually perpendicular components of motion (Fig. 8.4). They are also not always perpendicular to the direction of the laser beam. One motion is in the radial direction. This carries pockets of gas across the ring boundaries towards or away from the centre of the wake. The other is a rotational motion - a result

Fig. 8.4 CONCENTRIC RING MODEL - HORIZONTAL VELOCITIES

of the swirl induced by the arc rotation. As this project is mainly concerned with the details of the distribution of the gases from the plasma jet and from the surrounding atmosphere within the test region, primary attention was focused on the radial motion, although the rotational velocities of the wake region are of interest also.

VIII.2.1 Radial velocities

The part of the beam that touches the outermost zone of the wake only presents no problems. Here the radial components of velocity are perpendicular to the direction of the beam, while the rotational ones are along it (Fig. 8.4). A pocket moving along the beam caused no signal and was therefore not recorded. The distribution obtained is therefore that of the radial velocities in that zone only. In order to normalize it the distribution is again divided by the optical path of the beam in that annulus. This is the case for all rings over the area in which they interact with their respective beams tangentially. However, when one comes to subtract the effects of the outer annuli, it becomes necessary to allow for the angles $\theta_{N,M}$ between the directions of radial velocity and the laser beam (Fig. 8.4). To do this the normalized velocity histogram for each outer ring ($H_{N,A}, H_{N,B}, \dots$) has its value intervals multiplied by the sine of that particular angle θ ($\theta_{N,A}, \theta_{N,B}, \dots$) that the beam makes with the radial direction in that particular zone. The first subscript denotes the beam and the second the ring being considered. The values from this distorted histogram are then fitted into a new distribution with intervals equal to those chosen in the first instance. Each of these new distributions is then multiplied by the relevant optical path length (l_{NA}, l_{NB}, \dots) and subtracted from the overall histogram obtained by measurement from that beam.

VIII.2.2 Rotational Velocities

It is important to note here that while the effects of the radial velocity components in the outer rings have now been removed, contributions from the rotational velocities have so far been entirely neglected. They are, however, present in each set of non-tangential interactions between beams and rings. To be precise each rotational velocity has been multiplied by a $\cos \theta$ before being recorded due to the geometry (Fig. 8.4). (Only the rotational velocity component perpendicular to the beam resulted in a reading.) Rotational components due to outer rings so far remain in the histograms belonging to all except the outermost ring, and as the distribution in each annulus is used in the calculation of all rings lying within it, the effect of the rotational velocities is cumulative. More exactly, each rotational velocity component from an outer beam has been multiplied by a $\sin \theta$ in the "distortion" of the histograms before being subtracted when the distributions for the outer rings were calculated as discussed in the last section.

On the removal of these rotational components the help of the symmetry of the wake region is again enlisted. The rotational velocity has the same sense about the axis and a uniform distribution within each ring. Each part of the beam traverses every non-tangential region twice, once nearer the point of entry into the test region and once nearer the points of exit. The velocity distributions due to these traverses - as can be seen on closer inspection of Figure 8.4 - are equal in magnitude but opposite in direction when resolved into a component perpendicular to the laser beam. The velocity component along the laser beam is again not measured. As both path lengths in any one zone, as well as the duration of measurement, are equal, the distributions of velocity in either direction due to the rotational motion can be

expected to be equal. If we now consider motion in an outward direction to be positive and motion towards the centre of the jet to be negative, then every histogram for horizontal velocities in each ring so far obtained is a distribution of radial velocities in each annulus with another histogram superimposed on it. The second distribution which is symmetric about the point of zero velocity is made up of the various rotational velocity components multiplied by their respective trigonometric functions. These distributions were accumulated by successive additions due to beams traversing the outer regions and subtractions due to connections for effects of radial velocities in the outer rings, as discussed above. It is important to note again that these additions and subtractions do not cancel out as in the case of the radial velocity, because here on each addition the distribution, (i.e. each of its intervals) is multiplied by the cosine of the angle $\theta_{N,M}$, while in the case of every subtraction this factor becomes $\cos \theta_{N-K,M} \times \sin \theta_{N,M}$ (Figure 8.4) leaving a symmetrical histogram formed by the rotational velocity distributions, times the trigonometrical factors.

If, however, the negative section of every histogram is subtracted from its positive counterpart, the symmetrical part is eliminated, and a distribution is obtained, that consists of radial velocity components only. In this process some of the radial velocity components are also cancelled out, and it is therefore not possible to assert the actual number of interfaces that have passed in each direction under the influence of radial motion. It is, however, possible to calculate a mean net velocity from each of the resulting histograms.

The subtraction was carried out by deducting each term on the negative side of the distribution from its respective positive term. It is therefore possible to have a negative number count for some velocity intervals. Physically this means that a net number of velocity measurements

in this interval equal to the absolute value of that term was measured in the negative direction.

The mean velocity of each net distribution can either be calculated by considering positive and negative frequency counts of positive velocity intervals only, or by allowing only positive frequencies for positive and negative velocities. As the mean is calculated by the summation of terms made up of products of number frequency times velocity intervals, both approaches result in equal average values. (Law of Commutation of Multiplication.)

However, it is not possible to compute a true standard deviation for the total horizontal velocity component in any of the rings, as the true total velocity distribution for radial plus rotational velocities is not known anywhere. Even in the outermost zone the standard deviation for radial components, in the innermost that for rotational components only can be calculated as the other components, are in both cases along the beam.

It is re-emphasized that the standard deviation in this case is not an indication of the uncertainty in the measurement, but rather a measure of the degree of turbulence for the system exhibiting a velocity distribution of the form:

$$V_J = \bar{V} + \Delta V_J$$

where V_J is the J th term of distribution, \bar{V} the mean velocity and ΔV the fluctuating velocity component.

Mean net horizontal radial velocities were calculated by program "Veloc 2" listed in Appendix 3.

Chapter IX

RESULTS AND DISCUSSION OF 'SCHLIEREN VELOCIMETER'

MEASUREMENTS

All measurements obtained using the 'Schlieren Velocimeter' as described in Chapter VII underwent the analysis as outlined in Chapter VIII. All values referred to in this chapter as velocities at a point are in fact mean velocity values computed from those corrected velocity distributions.

IX.1 The Effect of Two Peak Measurements

As previously mentioned, a number of oscilloscope traces exhibited only two rather than three peaks. These measurements could not give any indication about the direction of velocity. It was therefore necessary to determine what influence an omission of the two peak measurements would have on the overall measured mean velocity. Measurements were taken for a fixed flow rate at a number of points in the wake and average values were determined separately for two and three peak measurements. Directions of flow were disregarded as two peak readings could not yield an indication of directional preference. Both mean velocities were plotted for points at various distances above the nozzle and off axis in Figure 9.1.

This shows that the values obtained for two and three peak measurements are generally in good agreement with the possible exception of points near the boundary of the wake. Reasons for these discrepancies are suggested in Chapter VII. It was therefore decided that the consistent use of three peak readings only could be expected to yield acceptable results.

Fig. 9.1 COMPARISON OF 2 PEAK AND 3 PEAK RESULTS

IX.2 Measurements in the Complete Wake

Complete analyses were carried out throughout the wake for horizontal and vertical velocities with high and low carrier gas flow rates. For the high argon flow rate at 13 l/min and a cold flow Reynolds number of 2225, the region between 2 and 8 cm above the nozzle was measured at points 5 mm apart in the horizontal direction in rows 10 mm above each other. For the low flow of 4.4 l/min and cold flow Reynolds number of 750 measurements were taken at the same intervals from 1 to 7 cm above the plasma. High speed shadow cine records (Chapter IV) obtained at these flows show that for the higher carrier gas flow rate the entire central part of the wake region in the laser beam is made up of the "fast flow region" in which the effect of arc rotation predominates, as discussed in Chapter V. For the case of argon supplied at 4.4 l/min the test region contains the transition from the arc rotation controlled zone to the slower outer flow which had previously been found to be independent of the events in the nozzle.

Mean vertical velocities were computed from the average upward and downward velocities at each point, whereby, especially in the inner segments of the wake, the more prominent flow direction by far was found to be upward. The mean velocity values of all points in every row were fitted to a quadratic function of velocity in terms of radial distance from the centre of the wake, using the Method of Least Squares. The maximum of this velocity function was determined and the radial distance at which it occurred is plotted in Figure 9.2 for the high and Figure 9.3 for the slow flow rate. (It is not claimed that this quadratic is the best fit of velocity versus distance. It is used only to confirm the symmetry of the wake.) The same calculations were executed for the number of measurements obtained per unit time at all points at various

heights above the nozzle and the positions of their maxima are included in Figures 9.2 and 9.3. These frequency counts give an indication of the number of interfaces passing each point in the test region. Each of the four sets of maximum positions are seen to lie within 2 mm of the central axis of the wake. This emphasizes further the cylindrical symmetry of the test region, previously observed in Chapters V and VI.

The variations of the vertical velocities with radial distance in the wake for various heights above the nozzle are plotted for both carrier gas flow rates. Figure 9.4 shows this variation for the high carrier gas throughput, while Figure 9.5 gives the same information for the lower argon flow. In both cases the plots show an increase in vertical flow velocity as one moves away from the centre with a maximum mean flow velocity about 1 cm from the axis of symmetry of the wake. Past this maximum value the velocity falls almost linearly to zero at the outer limit of the wake. This is true up to a height of a few centimetres above the nozzle. Further downstream the central dip in the magnitude of the velocity is smoothed out, resulting in a velocity value plateau near the centre of the wake reducing to zero near its boundaries.

IX.3 Errors and their Corrections

Mean velocity measurements in the vertical as well as horizontal direction are liable to both statistical, i.e. random, and to systematic errors. These errors are relatively more important in the case of the horizontal results for a number of reasons. The horizontal velocity distributions actually measured have smaller mean values and larger relative standard deviations. It is, however, important to re-emphasize that because of the turbulence of the system, the standard deviations are

not direct measures of the error in determining velocities. Horizontal velocities, as the main flow is in the upward direction, also resulted in fewer measurements per unit time, because a smaller number of pockets passed the three horizontally spaced slits in every time interval. For the same reason relatively fewer interfaces actually completed their horizontal journey across all three slits within the time of their presence in the small test area defined by the slits. Last, but not least, the statistical analysis required to obtain the horizontal mean gas velocity at each point rather than only its component perpendicular to the laser beam is far more complex than that for the vertical motion which is entirely at right angles to the beam, as discussed in Chapter VIII. This is compounded by the fact that each horizontal velocity distribution obtained is made up of radial and rotational velocities of which the rotational components need to be cancelled out, which makes the calculation of only net mean velocities possible.

The horizontal mean velocities only are therefore corrected. The correction is made on the basis that for symmetric flow the net horizontal velocity at the centre of the wake is required to be zero. As the systematic error is expected to predominate, the error in the mean velocity obtained along each beam (E_n) is taken as fixed. (The condition of a mainly statistical error, i.e. E_n is a function of the number of readings per unit time, gives very similar results.) The error in mean velocity for the nth segment, ϵ_n , is calculated by the following formula:

$$\epsilon_n^2 = E_n^2 + \sum_{J=1}^{n-1} \epsilon_J^2$$

where n is the number of the ring counted from the outside and ϵ_J^2 is a function of the error in the Jth ring. This is because the mean velocity

value in each ring contains errors from that beam and all the outer rings. Even though the effects of the outer rings were subtracted (Chapter VIII) the resulting errors need to be computed by obtaining the square root of the sum of the squares of the contributing errors. As discussed in Chapter VIII in the case of the horizontal velocities each measurement contains only the radial velocity component perpendicular to that laser beam, i.e. the radial velocity times the sine of the angle (θ_J) between the velocity direction and the beam. Each error term in the summation due to the outer rings (ϵ'_J) therefore contains the relevant sine for that beam, i.e.

$$\epsilon'_J = \epsilon_J \sin \theta_J$$

For the central beam, for example, all θ_J 's are zero and $\sin \theta_J$'s therefore zero.

Given the boundary condition of no horizontal velocity at the centre and constant error (E_n) along all beams it is possible to obtain a value of the error of mean velocity in each segment (ϵ_n) from the above equations. The precise causes of the errors are contained in the term E. It is not necessary for them to be known for this analysis as long as they are systematic in nature.

All horizontal mean velocity values were corrected accordingly and these values are used in all further calculations and discussions.

IX.4 Velocity Distribution and Streamlines

The velocities assigned to each point were plotted throughout the test region in their vertical and horizontal components and were combined to yield resultant velocities at each point, using the rules of vector addition. As described in Chapter VIII mean velocity values obtained for each beam are assigned to the centre of the annulus to whose inner boundary that beam is tangential. Figures 9.6 and 9.7 show the velocity distributions obtained throughout the test regions for the fast and slow carrier gas flows respectively. The starting position of each arrow indicates the locality at which that mean velocity was determined, while the lengths and orientations of the arrows represent the magnitudes of the velocities in the indicated directions.

From an inspection of these flow vectors it can be seen that the main velocity occurs in an upward direction near the centre of the wake, and that it decays relatively slowly as one moves downstream. Near the wake boundaries the vertical velocities are much lower and no longer dominate. The horizontal flows, which result in the expansion of the wake and the entrainment of the surrounding air, become apparent in that region.

These velocity distributions are joined to give streamlines covering the test region in Figures 9.8 and 9.9. While the magnitudes of the velocities are not discernible from these flow lines an overall flow pattern is established for each wake region, showing the main central flows as well as the entrainment of the surrounding gases, the latter especially in the case of the lower carrier gas throughput rate.

The pattern for the larger argon flow (Fig. 9.8) shows a pronounced, slightly wavy central flow region, mainly upwards in direction, with a small amount of expanding flow and relatively little indication of recirculation and entrainment in the area covered by the laser beam

(from 2 cm to 8 cm downstream of the nozzle) except near its top end. In the case of the slower flow (Fig. 9.9) the pattern shows a more rapidly expanding jet counteracted by considerable entrainment flow 4 cm and further downstream of the burner nozzle, and the resulting recirculating eddies.

Eddies of a diameter of less than 1 cm - the vertical separations between positions of consecutive measurements - are not discernible. Also, because these are time averaged velocity measurements, laterally moving eddies cannot be resolved, although they were clearly visible on the high speed cine shadow records (Chapter IV).

IX.5 Estimation of Entrainment in the Immediate Vicinity of the Nozzle

A system of tight fitting concentric rings, similar to the one used to correct for the effects of the integration along the optical path of the laser beam in Chapter VIII, is again superimposed on each wake region. Each ring has a thickness of 5 mm, the central regions consist of cylinders of radii 7.5 mm and all heights are 10 mm. Six layers of such rings, each following immediately on the previous, are considered for the high and the low carrier gas throughput. The intersection between a plane containing one half of a central cross-section through the wake and the concentric ring system, results in a grid made up of rectangles of width 5 mm (7.5 mm nearest the centre of the wake) and height 10 mm, as shown in Figure 9.10. The grid is positioned such that the centre of each vertical segment coincides with an assigned position of velocity measurement.

From the horizontal and vertical velocity components of each point as measured and plotted in Figures 9.6 and 9.7, the average vertical mean for each horizontal grid section and the average horizontal mean

velocity for each vertical segment, were calculated and plotted for both argon flow rates (Figs. 9.10 and 9.11). Average vertical velocities were obtained by determining the mean of the four vertical velocities closest to the midpoint of each horizontal segment, while the horizontal velocities were computed by finding the mean horizontal velocity at each corner of each grid area and then averaging that with the relevant velocity component measured at the grid centre (Fig. 9.12).

As long as there are no abrupt velocity changes away from the central section of any grid segment, the product of the mean velocity component perpendicular to a grid line, times the area of the concentric ring surface, whose intersection with the central cross section results in that line, determines the net volumetric flow through that surface. As the surfaces containing the outer annuli are much larger than those near the centre, any errors in velocity measurements introduced near the wake boundaries by the lower flow velocities and fewer measurements per unit time encountered there, are emphasized in determining these flow rates.

The total flows through the surfaces which limit the grid systems at the upstream end (1 cm downstream of the nozzle for the slow flow and 2 cm for the fast argon flow) are considered first. The total flow rates through these surfaces are determined by adding the products obtained from the multiplication of each surface element times the mean vertical velocity assigned to its midpoint.

$$\text{Flow Rate} = \sum_{n=1}^m \pi (R_n^2 - R_{n-1}^2) \times V_n$$

where R_n is the outer limit of the nth ring, V_n the vertical velocity assigned to its centre, and m the number of sections contained in the surface considered. This flow is compared for both throughput rates

with the volumetric argon flow rates out of the nozzle. The volumetric flow rates at the nozzle at room temperature are known from the rotameter and gas temperature measurements. The energy transferred from the arc to the gas was calculated as the difference between the electrical energy supplied to the arc and the heat losses to the cooling water of the plasma jet burner, which were constantly monitored. Radiative losses were neglected. Dividing the heat transfer rate to the gas by the mass flow rate of the argon, results in the mean heat input per unit mass. From this and the specific heat at constant pressure c_p - a quantity constant up to temperatures of 8000 °K of 0.127 cal/l °K in the case of argon (Ref. 35) - the mean temperature of the gas leaving the plasma was calculated. Using the Ideal Gas Laws the volumetric flow rate (V_o) at the exit of the plasma jet is given as

$$V_o = V_R \times T_o/T_R$$

where V_R is the volumetric flow rate at room temperature (T_R) and T_o the nozzle exit gas temperature. It is, however, not necessary to assume a uniform distribution of energy from the arc to the gas. It has been shown (Appendix 1) that the volumetric expansion is the same whether the externally supplied energy is equally distributed to heat all the gas to a uniform final temperature or is concentrated into a fraction of the gas raising that part to a higher temperature and leaving the remaining argon at room conditions, as long as the pressure remains constant and the Ideal Gas Laws are observed.

In the case of the high argon flow rate 39% by volume of the gas passing the first surface, i.e. the first line of measuring stations, is entrained gas; similarly 46% for the slower flow rate. By mass the ratios of entrained air to total gas are even higher, 85% for the first

case and 93% for the second, because of the much higher temperature of the argon compared to the entrained air. If heat transfer from the hot argon to the colder air is allowed for, the proportion of entrained gas increased yet further because the specific heat of air is nearly twice that of argon and a given quantity of energy therefore causes less expansion of air than of argon.

This indicates a very high level of entrainment of surrounding air into the plasma jet wake in the immediate vicinity of the nozzle for both high and low flow rates. There is, however, no reason to believe that this entrainment was uniform across the wake. Most of the entrained gas must have passed near its boundaries, as determined in Section V.4 dealing with high speed cine records. As these entrainments took place upstream of the test regions they are not indicated in Figures 9.8 and 9.9.

IX.6 Relative Densities in the Wake

Every ring in the system is now considered to contain a gas mixture of mean density ζ_j . As there is no source or sink of gas in any of the rings the Law of Conservation of Mass can be expressed in the form of an integral around the total surface surrounding each ring:

$$\oint \zeta_x v \, dA = 0$$

where ζ_x is the density of gas flowing into or out of the surface and v the velocity perpendicular to the surface dA . In practice, the products of all surfaces times the mean velocities perpendicular to them were added for each ring. Applying this to every section of the wake gives a set of simultaneous equations equal to the number of rings present. Solving these equations results in a value for the mean density for each

segment in terms of the densities at the various positions from which the gases enter the test space. These density distributions were computed for all segments and plotted for both flow rates in Figures 9.13 and 9.14. The densities of the gases entering the test volumes are denoted as DA to DZ. It is important to note that the computed values are only relative densities with respect to the specific gravities at the boundaries of the test volume considered.

As the density in each grid section is expressed in terms of the density of the various parts of the inflowing gases, it is possible to determine the source and the relative quantity of each part of the gas mixture in every ring. Conversely a "sphere of influence" for each section of the inflowing gases can be mapped out throughout the test region. Figures 9.17 and 9.18 show this for fast and slow argon flow rates respectively. Comparisons of these two figures show the difference in entrainment pattern in the wakes for the two cases. There is comparatively little sideways entrainment in the test region for the case of the fast flow. The two innermost columns are not at all affected by the flow in the outer columns throughout the portion of the wake investigated. At lower flow rates, however, there is considerably more entrainment in this region and after a distance of 4 cm downstream of the nozzle the influence of the outer gas flows extends throughout the entire horizontal cross-section.

These conclusions confirm earlier qualitative observations made with the use of high speed shadow cinephotography and described in Chapter IV. The entire innermost two columns for the high argon flow (Fig. 9.13) and the same columns up to 4 cm downstream of the rotating arc for the slow flow (Fig. 9.14) correspond to the regions of high flow velocities in which the flow regimes are governed by the rotation of the arc in the nozzle as discussed in Chapter V. The absence of horizontal inwards

flow into the central wake core observed in that chapter is confirmed here by the measurement of zero entrainment into the inner columns in the sections of the wake region under observation.

IX.7 Discussion of Density Anomalies in the Wake

Considering the parts of the two innermost columns showing no entrainment, a closer inspection reveals an apparent decrease in density in the downstream direction if DA is assumed equal to DB. If no such assumption is made a density decrease is nevertheless observed in some innermost grid squares containing terms in DA only (Figs. 9.13 and 9.14). The rise in temperature that would account for this behaviour could have been a result of thermal eddy diffusion into the centre. The thermal gradient required for this to occur could have been caused by a deviation from the condition of uniform heating of the gas by the entire length of the arc as postulated by Chen and Lawton (Ref. 23), because the cathode acts as a heat sink. Alternatively, the centrifugal force resulting from the gas swirl induced by the arc rotation forces pockets of cooler, heavier argon away from the centre of the wake. These two possibilities are not mutually exclusive. As it is only possible to determine net horizontal flow rates these flow regimes could be masked by motion in the outward direction.

In order to establish an indication of the effects of eddy diffusion in the various parts of the wake the relative turbulence energy for the vertical velocities was plotted point for point for both flow rates throughout the wake. Horizontal standard deviations are not known (Chapter VIII) and their RTEs can therefore not be obtained. The relative turbulence energy (RTE) is defined as

$$\text{RTE} = s^2 / (s^2 + \bar{v}^2)$$

Fig. 9.19 RELATIVE TURBULENCE ENERGY
13 l/min ARGON, 1.1 kHz ARC ROTATION

Fig. 9.20 RELATIVE TURBULENCE ENERGY
4.4 l/min ARGON, 1.1 kHz ARC ROTATION

where s is the standard deviation of vertical velocity and \bar{v} its mean value. Lines of equal fractional energy in turbulent motion were drawn as shown for the high flow velocities in Figure 9.19 and for the low flows in Figure 9.20. On a time scale the region up to 4 cm downstream of the nozzle in Figure 9.20 corresponds to the entire test region for the fast flow. The patterns are quite complex but a comparison of equivalent wake sections on a time scale shows some similarity in layout including two separate loops in the inner part of the wake.

Even casual inspection of Figures 9.19 and 9.20, however, shows that in the inner zones of the test regions lower relative turbulence energies at least for the vertical velocities predominate. These values are more substantial in the outer regions and downstream where hot argon from the nozzle encounters and mixes with the surrounding or entrained air. It is in these areas that large shear forces between hot and cold gas flows as well as overshooting gas pockets can be expected. As larger gas pockets also predominate in these regions it is here that thermal eddy diffusion may be expected to play a more important part in the distribution of physical properties in the wake.

The density distribution in the centre of the test region, however, appears more like that, which one would expect in an area in which heat is released by a reaction. This behaviour could be caused by pockets of excited and ionized argon carried downstream, for example in the form of fragments of the arc channel. This supposition is supported by the presence of pockets of ionized gas in this region, detected by the corona probe (Chapter VI). Traces of dissociated air entrained in the vicinity of the arc may also contribute. These species would act as a carrier of energy in a non-translational mode which is transferred into translational energy in the wake. This change in the number of degrees of freedom has not been accounted for in the above analysis, which allowed for heat

transfer by normal convection only.

In order to check the plausibility of this explanation the "rate of heat release" is calculated that would be required to raise the gas flow in the innermost columns to the temperature needed to attain the measured density distributions. This release rate is compared with the energy supplied per unit time by the arc.

Each central grid cylinder was combined with the first ring at the same height above the nozzle and the new mean density for every one of the resulting cylinders of 1.25 cm radius and 1 cm height computed. $DA = DB = D_0$ is assumed. The translational mean temperature (T_t) in terms of the temperature of the gas entering the grid system (T_0) for each cylinder was calculated using the Ideal Gas Law:

$$\zeta_M \times T_t = \zeta_0 \times T_0$$

where ζ_M is the measured density and ζ_0 the density of the gas entering the column ($= DA = DB$). From this the rate of heat release (R) required in each cylinder to maintain this temperature was calculated using the formula:

$$R = \zeta_M \times A \times v_J \times c_p \times \Delta T_t$$

where A is the cross sectional area through the cylinder ($= 1.25^2 \times \pi$), v_J the mean upward velocity in this segment, c_p the specific heat of argon taken as constant (Ref. 35) and ΔT_t the change in translational temperature from one segment to the next (Tables 9.1 and 9.2). The heat release rate is plotted for both argon throughput rates considered versus distance downstream in Figure 9.15. Each curve contains a maximum within the test region. The total "heat release" in the wake region

determined from the area underneath each graph can be compared with the rate of heat supplied from the arc to the gas, heat losses to the burner having been deducted. In both cases the energy carried downstream in a non-translational form within the innermost two columns would amount to 25% or slightly less of the heat absorbed by the gas from the plasma, radiation losses being neglected. As can be seen from Figures 9.6 and 9.7 these innermost columns contain the largest flow velocities and the highest carrier gas throughput. This along with the tendency of hotter pockets to move towards the centre of the wake makes a figure of less than 25% of energy in a non-linear form in this region quite possible.

When the "heat release" rate is plotted versus time, rather than distance downstream, the positions of maxima for the high and low argon flow rates are found to coincide within experimental limits (Fig. 9.16). This suggests that the rate of energy conversion into a translational mode occurs on a constant time scale, independent of concentration, which is characteristic of a zero order rate law. From the present data no conclusions can be drawn about the temperature dependence of the above mentioned conversion rate. Although in terms of average values the heat transfer per unit volume to the faster gas flow is less than that to the slower flow, the energy transition is likely to occur in pockets of high temperature (including possible remains of the arc column) present under both flow conditions. The coincidence of the two "heat release" maxima gives support to this theory.

In practice both thermal eddy diffusion and energy transfer between different degrees of freedom may cause the density anomalies obtained from the analysis that takes account of ordinary convective heat transfer only. Eddy diffusion effects, however, appear to be most important in the outer wake regions, while the energy transfer into a translational mode predominates in the wake core.

Fig. 9.16 APPARENT HEAT RELEASE RATE VS. TIME

The presence of excited, ionized and possibly dissociated species in the core of the wake extending far into the downstream direction has important effects on the analysis of the distribution of physical properties in the wake as well as on the application of plasma jets to chemical and physical processing.

Any mathematical treatment of the plasma jet wake is not complete unless its equations contain terms allowing for the transfer of energy from non-translational to translational degrees of freedom. Simple fluid-dynamic considerations appear not to be sufficient at least in the inner core of the wake. Pockets of ionized and excited species far downstream would also explain the rapid reaction rates observed in the wake of plasma jets. Harrison and Weinberg (Ref. 14), for example, detected the formation of acetylene at the interface between the hot argon and methane-air mixture in electrically augmented flames. This indicates the presence of pockets of sufficiently excited argon to supply the energy required to facilitate this reaction. Alternatively, if the carrier gas is to take an active part in the reaction the reaction rate is further increased by the existence of species other than in their ground state of one or more of the reactants.

Heat transfer to particles or to solid surfaces is also greatly increased by the neutralisation of ionized species, by de-excitation and possible reassociation far downstream in the wake region. Simple heat transfer coefficient can therefore not be used in the modelling of systems incorporating plasma jets.

Chapter XCONCLUSIONS

A promising plasma reactor configuration utilizes an arc spinning in an annulus under the influence of the interaction between the current in the plasma and an applied magnetic field. A carrier gas is pumped through the annulus to transfer the thermal power, dissociated, excited or ionized species from the arc to the downstream wake region. Because of the high by-pass ratio and the relatively slow mixing in the downstream region, the rotation rate of the arc must be tuned to the flow rate of the gas if the effects of the arc are to be distributed uniformly throughout the wake.

Theoretically, unless the arc is set to rotate through one revolution in the time required for the gas to pass a distance of 1 arc diameter down the nozzle, a rotating spiral staircase of hot gas in an atmosphere of cooler gas results in the region downstream of the electrodes. In practice this pattern is quickly broken up by the intense turbulence in the wake and only indications of some fragments of the spiral remain a few centimetres downstream of the nozzle.

This plasma jet configuration permits a variety of modes of introduction of reactants into its wake. They can either be mixed in with the carrier gas, which usually results in high electrical power dissipation in the arc, or they can be injected at the upper end of the nozzle, or allowed to be entrained into the wake from the surrounding atmosphere, depending on the aerodynamic configuration and use of the reactor.

The wake region was investigated using shadow and schlieren methods with the help of short duration photography (single and double exposure) and high speed cinephotography. A novel probe applying the phenomena of the corona discharge was used to map out regions of equal mixedness in

the test space. A schlieren velocimeter was devised and used to obtain time averaged localized velocity distributions throughout the wake in both the horizontal and vertical directions. Effects of averaging along the optical path were corrected for by using a concentric ring model.

The wake consists of a cylindrically symmetric cone whose spread is inversely proportional to the gas flow rate through the nozzle. The cone is made up of a large number of small pockets of gas of different temperatures and compositions. Each pocket consists of a gas mixture of uniform properties at its centre with slight refractive index and therefore density gradients towards its edge. At the pocket boundary itself these refractive index changes become abrupt.

The wake cone consists of two separate zones. The inner one is made up of predominantly small pockets of gas present in very large numbers and moving at very high turbulent velocities. The flow properties in this region are dependent on the rotation rate of the arc in the nozzle and its extent in the downstream direction is a function of the flow velocity of the gas through the plasma jet. The pattern in this inner region is relatively stable to induced draughts and little entrainment appears to take place into this zone. It also contains segments of remnants of arc columns in the form of excited and ionized argon.

The region surrounding the inner core in the outside layers of the wake cone and downstream of the fast flow regime consists of larger pockets of lower number densities moving with much lower velocities. The general flow pattern in this zone depends on the flow rate of the gas through the plasma jet and is independent of events in the nozzle. While the velocities in the inner regime are almost exclusively in the upward direction, the slow moving region contains horizontal velocity

components as well as recirculating eddies. It is more susceptible to outside influences and seems to be instrumental in most of the entrainment of the surrounding gases into the wake.

As the onset of the outer region in the downstream direction is a function of the carrier gas flow rate, the downstream distance after which the outer gas is distributed throughout the wake region depends on the gas velocity in the nozzle. A considerable amount of surrounding stationary atmosphere is entrained in the immediate vicinity of the nozzle into, probably, the outer layers of the wake cone. These outer flows do not spread throughout the wake until reaching the zone past the inner flow regime, when they are distributed with further entrained gases throughout the wake. The relative entrainment rate in general is inversely proportional to the volumetric flow rate through the plasma jet.

The velocity vector distribution and the flow lines in the test region were plotted for argon flow rates of 13 l/min and 4.4 l/min and localized relative density distributions throughout the wake region from 1 cm to 8 cm downstream of the nozzle were calculated for both these cases.

A falling off in density in the fast moving inner regions with distance from the nozzle, followed by a rise in density further downstream, was observed. Calculations show that this dip occurred at a constant time interval of the order of a few milliseconds after the argon left the plasma jet. This density distribution could be due to a variety of reasons. It could be caused by a motion of cooler, heavier gas pockets away from the wake centre (because of the centrifugal forces due to the swirl of the gas introduced by the rotating arc) or by thermal eddy diffusion resulting from a cooler centre of the wake of the plasma jet immediately downstream of the nozzle, resulting from a cooling effect

of the cathode. Alternatively, pockets of gas containing non-translational energy in the form of excited or ionized argon or traces of entrained, dissociated air convert this energy into a translational form resulting in an apparent rise in gas temperature and reduction in density.

In order to assign areas of relative importance to these alternatives, values of relative turbulence energy for the vertical velocities were plotted throughout the wake region for both high and low flow rates. These distributions show that the fractional energy in turbulent motion, and therefore the eddy diffusion, is most important in the outer regions containing the shear layers between hot and cold gas flows. In the core of the wake which exhibits a density distribution reminiscent of that found in exothermic reactions "heat release" by energy transfer between different degrees of freedom seems to predominate.

This indicates the presence of ionized, excited and possibly dissociated species up to a distance of many centimetres downstream in the core of the wake, the extent of which depends on the carrier gas flow rate. This has important consequences on any analysis of the wake of the magnetically rotated arc as well as on the various uses of plasma jet in physical and chemical processing.

DEPENDENCE OF AN EXPANDED VOLUME OF GAS ON THE DISTRIBUTION
OF THE ENERGY CAUSING THE EXPANSION

Consider a volume V of gas at temperature T_0 . A quantity of energy E is passed onto a part of the volume of gas x , heating it to a temperature T_f . The remaining gas $(V - x)$ stays at temperature T_0 . Energy balance on volume x :

$$E = x \times \zeta \times \sigma \times (T_f - T_0)$$

where ζ is the density and σ the specific heat of the gas. Therefore:

$$T_f = E/x \times \zeta \times \sigma + T_0$$

If volume x after expansion becomes volume y and T_0 and T_f are in [$^{\circ}$ Abs.] then from the Ideal Gas Laws:

$$x/T_0 = y/T_f = y/(E/x \times \zeta \times \sigma + T_0)$$

The final Total volume after expansion VH is:

$$VH = y + (V - x) = [x/T_0 \times E/(x \times \zeta \times \sigma) + T_0] + (V - x)$$

$$VH = [E/\zeta \times \sigma \times T_0 + x] + (V - x)$$

$$VH = E/\zeta \times \sigma \times T_0 + V$$

The expression for VH is independent of x . This shows that the final volume after expansion of a gas is independent of the fact whether the energy causing the expansion is distributed uniformly throughout the gas or whether it is concentrated on a fraction of the original volume as long as the Ideal Gas Laws are observed and specific heat of the gas remains constant over the temperature range considered.
