#### Abstract:

In model predictive control (MPC), an optimization problem is solved every sampling instant to determine an optimal control for a physical system. We aim to accelerate this procedure for fast systems applications and address the challenge of implementing the resulting MPC scheme on an embedded system with limited computing power. We present the sensitivity-based multistep MPC, a strategy which considerably reduces the computing requirements in terms of floating point operations (FLOPs), compared to a standard MPC formulation, while fulfilling closed-loop performance expectations. We illustrate by applying the method to a DC-DC converter model and show how a designer can optimally trade off closed-loop performance considerations with computing requirements in order to fit the controller into a resource-constrained embedded system.

*Keywords:* model predictive control, suboptimality, robustness, sensitivity analysis, reducing computational expense

# 1. INTRODUCTION

Over the recent decades, MPC has garnered increased attention as it has proven to be an important tool in control of nonlinear systems in modern technological applications. The optimization problem needed to be solved at each time step results in a high computational expense and computational latency. Computationally costly MPC algorithms used to be implemented using highly powerful computing systems (i.e., server, desktop, industrial PCs) in order to meet real-time requirements. Nowadays, researchers are addressing the challenge to make MPC algorithms less computationally demanding without sacrificing the control performance to cater to systems with fast dynamics.

One approach to reduce the computational complexity is by using obtained controls for extended period of time. For instance, the move blocking strategy (Cagienard et al. (2007)) fixes the control inputs as constant over several time steps while the *multistep MPC* (Grüne (2009)) uses an open-loop control for several time steps thus reducing the number of optimizations performed. However, these approaches come with the disadvantage of reduced robustness of the closed-loop solution against perturbations. An update strategy to the multistep MPC based on reoptimizations on shrinking horizons, referred to as updated multistep MPC, is proposed and analyzed in Grüne and Palma (2015) giving a straightforward approach to provide a coping mechanism to counteract the perturbations and enhance controller performance. Robust performance improvements due to re-optimization are rigorously quantified in Grüne and Palma (2015) based on Grüne and Palma (2014). Now in this paper, we consider the sensitivity-based multistep MPC which is a particular MPC variant which

allows further savings in terms of the computational load that uses sensitivity analysis in a specific way (see Palma and Grüne (2012) and compare with other MPC strategies that also use the sensitivity approach, e.g., Zavala and Biegler (2009), Yang and Biegler (2013) and Pannek et al. (2013)). We show that this sensitivity-based control is a linear approximation of the re-optimization-based control and therefore, the analysis of the updated multistep MPC carries over to the sensitivity-based multistep MPC.

Along with the development of sophisticated algorithms, digital electronics have advanced during the last ten years. Nowadays, modern embedded systems feature high numerical computing power (e.g. 1GFlops for each core on an ARM Cortex-A9) with low power consumption (<1Watt) and cost. This allows the implementation of computationally heavy control schemes for fast dynamical systems at low cost. This provides high performance control techniques to new application domains demanding tight real-time requirements. Still, for a fixed price and/or size of an embedded hardware, which determine/s its capability and limitation, a researcher-designer faces yet a trade-off decision between low computing cost and high performance.

The paper aims to present an MPC controller that fulfills both control performance and low computing complexity requirements and highlight its potential for controller design on embedded computing systems. Based on the setting and basic concepts in Section 2, we present various MPC algorithms in Section 3. As a case study, the MPC schemes are tested to control a DC-DC converter in Section 4. We show not only is the sensitivity-based control a less costly alternative to re-optimization, we also show how matrix structures can be exploited to obtain the sensitivities much more efficiently. Numerical results and a trade-off analysis on cost and performance are presented in Section 5.

# 2. PRELIMINARY SETUP

Consider the nonlinear discrete time control system

$$x(k+1) = f(x(k), u(k)),$$
(1)

where x is the state and u is the control value. The state space X and the control space U are vector spaces and for a given state constraint set X and control constraint sets  $\mathbb{U}(x), x \in \mathbb{X}$ , we require  $x \in \mathbb{X} \subseteq X$  and  $u \in \mathbb{U}(x) \subseteq U$ . Let the notation  $x_u(\cdot, x_0)$  (or briefly  $x_u(\cdot)$ ) denote the state trajectory steered by control sequence  $u(\cdot)$  having initial state  $x_0$ . We refer to (1) as the nominal system. Given a time-dependent feedback law  $\mu : \mathbb{X} \times \mathbb{N} \to \mathbb{U}$ , we obtain the feedback-controlled system

$$x(k+1) = f(x(k), \mu(x(\tilde{k}), k)),$$
(2)

where the state at time instant k + 1 relies on the state at k and the feedback depending on a certain state at  $\tilde{k} \leq k$ , where the feedback plays the role of a control for the system. We refer to (2) as the nominal closed-loop system.

Consider the following finite-horizon minimization problem

$$\min_{u(\cdot)\in\mathbb{U}^N(x_0)} J_N(x_0, u(\cdot)) \qquad \qquad \mathcal{P}_N(x_0)$$

for an objective function  $_{N-1}$ 

$$J_N(x_0, u(\cdot)) := \sum_{k=0}^{\infty} \ell(x_u(k, x_0), u(k))$$

representing a sum of stage costs  $\ell : \mathbb{X} \times \mathbb{U} \to \mathbb{R}^+_0$ associated with an initial state  $x_0$ , a control sequence  $u(\cdot)$  and optimization horizon N. We minimize over all finite control sequences  $u(\cdot) \in \mathbb{U}^N(x_0)$  with N elements. We define the optimal value function associated with the initial state value  $x_0$  by

$$V_N(x_0) := \inf_{u(\cdot) \in \mathbb{U}^N(x_0)} J_N(x_0, u(\cdot))$$

In our discussion, we assume there exists a control sequence  $u^*(\cdot) \in \mathbb{U}^N(x_0)$  for which  $V_N(x_0) = J_N(x_0, u^*(\cdot))$ where  $u^*(\cdot)$  is called the optimal control sequence.

# 3. MPC ALGORITHMS

To form a feedback law  $\mu,$  we consider the following receding horizon strategies:

# Algorithm 3.1 Multistep or *m*-step MPC

- (1) Measure the state  $x(k) \in \mathbb{X}$  of the system at time instant k.
- (2) Set  $x_0 := x(k)$  and solve the finite horizon problem  $\mathcal{P}_N(x_0)$ . Let  $u^*(\cdot) \in \mathbb{U}^N(x_0)$  denote the optimal control sequence and define the time-dependent *m*-step MPC feedback

$$u_{N,m}(x(k), k+j) := u^*(j), \quad j = 0, \dots, m-1.$$
 (3)

(3) Apply the control values  $\mu_{N,m}(x(k), k+j)$ ,  $j = 0, \ldots, m-1$ , to the system, set k := k+m and go to (1).

If m = 1, we recover the standard MPC scheme and by increasing m, optimization is performed less often resulting in a lower computational cost. Algorithm 3.1 gives rise to a feedback law  $\mu_{N,m}$  that, under appropriate conditions (see, e.g., Grüne (2009) or Grüne and Palma (2015)), gives a suboptimal solution to the infinite horizon problem  $\mathcal{P}_{\infty}(x_0)$  and renders the system asymptotically stable.

We may also consider the updated multistep feedback MPC. This approach is similar to the standard MPC as it entails performing optimization every time step. However, unlike the standard MPC wherein we perform optimization over the full horizon N, we re-optimize here over shrinking horizons.

Algorithm 3.2 Updated *m*-step MPC

- (1) Measure the state  $x(k) \in \mathbb{X}$  of the system at time instant k.
- (2) Set  $j := k \lfloor k \rfloor_m$  where  $\lfloor k \rfloor_m$  denotes the largest integer multiple of m less than or equal to  $k, x_j := x(k)$  and solve the finite horizon problem  $\mathcal{P}_{N-j}(x_j)$ . Let  $u^*(\cdot) \in \mathbb{U}^N(x_0)$  denote the optimal control sequence and define the updated MPC feedback

$$\hat{\mu}_{N,m}(x(k),k) := u^*(0).$$
 (4)

(3) Apply the control value  $\hat{\mu}_{N,m}(x(k),k)$  to the system, set k := k + 1 and go to (1).

Remark 3.1. Due to the dynamic programming principle (Bertsekas (2001)), the nominal feedback-controlled systems (2) generated by  $\mu_{N,m}(x(k),k)$  and  $\hat{\mu}_{N,m}(x(k),k)$ , respectively, coincide. Hence, comparison of both schemes will only be meaningful in the perturbed setting.

We consider the evolution described by the perturbed closed-loop system

$$\tilde{x}_{\mu}(k+1) = f(\tilde{x}_{\mu}(k), \mu(\tilde{x}_{\mu}(k), k)) + w(k)$$

where w(k) represents external perturbations. The presence of disturbance acting on the system brings adverse effects on the performance of Algorithm 3.1 since the measured states deviate from the predicted states  $x_{\mu_{N,m}}(j, x_0), j = 1, \ldots, m - 1$ , as the controller is not able to counteract this deviation for an extended time duration. The use of Algorithm 3.2 addresses this issue as the updates serve as a coping mechanism against the perturbations.

It is shown in Grüne and Palma (2015) that the worsening of the suboptimality performance caused by the perturbations is less prominent when using Algorithm 3.2 compared to the non-updated case in Algorithm 3.1. Furthermore, a significant improvement in suboptimality performance and stability brought about by the updates through reoptimization becomes more pronounced for systems that are unstable and controllable even for larger perturbations. We refer the readers to Grüne and Palma (2015) or Grüne and Palma (2014) for the technical details of the comparison between the *m*-step and the updated *m*-step MPC schemes.

Updated *m*-step MPC is less computationally expensive than the standard MPC. However, even if costs are gradually reduced at each step via Algorithm 3.2, optimization still nevertheless needs to be carried out at each iteration. To further save costs, for small perturbations, the updates may also be replaced by approximative updates in which re-optimizations are approximated through sensitivity approach.

Remark 3.1 implies that by performing the re-optimization on a shrunken horizon using the current state of the nominal system as the initial value, the solution is a tail of the optimal solution obtained from full horizon optimization. The current measured state coincides with the predicted state generated by the full horizon optimal control. In the perturbed setting, using the updated *m*step MPC, the current measured state we use as the initial value in the re-optimization on a shrunken horizon can be viewed as a perturbation of the predicted value that would have been the initial value had there been no perturbations.

This setting allows for an alternative to re-optimization through the use of sensitivity analysis. This enables the approximation of the solution of the updated m-step MPC with the avoidance of solving all optimization problems on shrunken horizon and hence reducing computational cost. We now consider the MPC variant called **sensitivity-based** *m*-**step MPC** (**SBM MPC**) proposed in Palma and Grüne (2012) (based on the sensitivity theorem of Fiacco (1976), motivated by sensitivity-based strategies in Büskens and Maurer (2001); Maurer and Pesch (1995); Pesch (1979); Zavala and Biegler (2009); Yang and Biegler (2013)) for which the only optimizations performed are full-horizon optimizations done only every m steps.

# Algorithm 3.3 SBM MPC

- (1) Measure the state  $x(k) \in \mathbb{X}$  of the system at time instant k.
- (2) Set  $j := k \lfloor k \rfloor_m$ ,  $x_j^m := x(k)$ . If j = 0, solve  $\mathcal{P}_N(x_0^m)$ . Store  $u_0^*, \dots, u_{N-1}^*$ and  $x_0^*, \ldots, x_N^*$  representing the optimal control sequence and the optimal trajectory, respectively.Define the time-dependent MPC feedback

$$\overline{\mu}_{N,m}(x(k),k) := u_j^* + \frac{\partial u_j}{\partial p_j}(x_j^*)(x_j^m - x_j^*). \quad (5)$$

(3) Apply the control values  $\overline{\mu}_{N,m}(\tilde{x}(k),k)$  to the system, set k := k + 1 and go to (1).

In using Algorithm 3.3, we first apply the obtained  $u_0^*$  and then we apply corrections on  $u_1^*, u_2^*, \ldots, u_{m-1}^*$ . Hence, at time instants 1, 2, ..., m-1, instead of optimizing again (e.g., using SQP active-set strategy) as in the standard MPC, or instead of re-optimizing using shrinking horizons as in the updated *m*-step MPC, in the hopes of reducing the operation costs, we compute the sensitivities

$$\frac{\partial u_1}{\partial p_1}(x_1^*), \frac{\partial u_2}{\partial p_2}(x_2^*), \dots, \frac{\partial u_{m-1}}{\partial p_{m-1}}(x_{m-1}^*)$$

from appropriate linear systems to be detailed shortly and use them as corrective updates.

Note that the problem  $\mathcal{P}_N(x_0^m)$  includes an initial condition constraint  $x_0 = x_0^m$ . Now for  $j = 1, \ldots, N-1$ , by the Dynamic Programming Principle, the tail  $u_j^*, \ldots, u_{N-1}^*$ gives the optimal control sequence for  $\mathcal{P}_{N-j}(x_j^*)$  which includes an initial condition constraint  $x_j = x_j^*$ . Let us consider the general problem  $\mathcal{P}_{N-j}(p_j), \ j = 0, \dots, N-1$ which includes an initial condition constraint  $x_j = p_j$ and let the parameter  $p_j$  take the value of measured state  $x_j^{\mathrm{m}}$ . Taking  $\mathcal{P}_{N-j}(x_j^{\mathrm{m}})$ , let us denote the resulting optimal control sequence as  $u_{j,0}^*, \ldots, u_{j,N-j-1}^*$ . Then for  $j = 1, \ldots, N-1$ , the already available information  $u_j^*$  from the nominal solution of the problem  $\mathcal{P}_{N-j}(x_j^*)$  and the sensitivity differentials  $\frac{\partial u_j}{\partial p_j}(x_j^*)$  provide  $u_{j,0}^*$ , i.e., the first element of the optimal control sequence of the *perturbed* problem  $\mathcal{P}_{N-j}(x_j^{\mathrm{m}})$  through

$$u_{j,0}^{*} = u_{j}^{*} + \frac{\partial u_{j}}{\partial p_{j}}(x_{j}^{*})(x_{j}^{m} - x_{j}^{*}) + \mathcal{O}\left(\|x_{j}^{m} - x_{j}^{*}\|^{2}\right)$$
(6)

 $j = 0, \ldots, m - 1$ . From this we observe that the feedback  $\overline{\mu}_{N,m}(x(k), k)$  defined in (5) is a first-order approximation of  $\hat{\mu}_{N,m}(x(k),k)$  defined in (4) with an error having an order of magnitude of at most  $||x_j^{\rm m} - x_j^*||^2$ . The analysis on the suboptimality performance and stability of the updated *m*-step MPC carries over to the SBM MPC as presented in great details in (Palma, 2015, Section

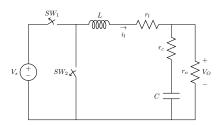

Fig. 1. a DC-DC converter

6.3) showing that the enhanced robustness induced by performing the shrinking horizon updates (reported in Grüne and Palma (2015)), under certain assumptions, is well-approximated by the sensitivity-based updates.

### 4. CASE STUDY: DC-DC CONVERTER

A synchronous step-down converter, also referred to as a DC-DC converter, (see Suardi et al. (2013) and Geyer et al. (2008) for model details) is a switching electronic circuit (Figure 1) that converts an input voltage level  $V_s$  to satisfy a desired voltage requirement  $V_o$ . The setup is comprised of two switches  $SW_1$  and  $SW_2$  cascaded by a second order LC low-pass filter and by an output ohmic load  $r_0$  along with the capacitor C and inductor L internal  $\widetilde{\text{ESR}}(r_c)$ and  $(r_l)$ , respectively. In this setting, feedback control is used in order to stabilize the output voltage with respect to load, input voltage and component variations. At each switching period  $T_{SW}$ , the output voltage and the current flowing in the inductor  $i_l$  are measured and used to control the opening and closing time of the two switches. When  $SW_1$  is closed (i.e., at time  $d(t) \cdot T_{SW}$ , where  $d(t) \in [0, 1]$ is the duty cycle),  $SW_2$  is opened and the input power is transferred to the output through the inductor. For the remaining time  $(1 - d(t)) \cdot T_{SW}$  of the switching period, the status of the switch are swapped providing a path for the inductor current  $i_l$ . This procedure is then repeated.

The described process leads to a set of affine time-invariant continuous-time state-space equations representing the two operating conditions. Defining the state vector as  $x(t) := [i_l(t) V_o(t)]^{\top}$ , the system behavior is modeled by

$$\dot{x}(t) = \begin{cases} A_c x(t) + b_c, \ kT_s \le t \le (k + d(t))T_s \\ (SW_1 \text{ is closed}) \\ A_c x(t), \qquad (k + d(t))T_s \le t \le (k + 1)T_s \\ (SW_2 \text{ is closed}) \end{cases}$$
(7)

with output voltage given by  $V_o(t) := c_c^T x(t)$  and  $A_c, b_c$ and  $c_c$  given by

$$A_c := \begin{bmatrix} -\frac{r_l}{L} & -\frac{1}{L} \\ \frac{1}{C} \frac{r_o}{r_o + r_c} \left(1 - Cr_c \frac{r_l}{L}\right) & -\frac{1}{C} \frac{1}{r_o + r_c} \left(1 + Cr_c \frac{r_o}{L}\right) \end{bmatrix}$$
$$b_c := \begin{bmatrix} \frac{1}{L} \\ \frac{r_o}{r_o + r_c} \frac{C}{L} \end{bmatrix}, \quad c_c := \begin{bmatrix} 0 \ 1 \end{bmatrix}^\top$$

As reported in Suardi et al. (2013), this hybrid model may not be suitable for control purposes. To address this, a standard state-space averaging method (Maksimovic and Cuk (1991)) is used resulting in an average continuoustime model that merges the laws of the hybrid model and uses the duty cycle d(t) as an input variable. This gives a nonlinear mathematical model to which linearization around an operating point can be carried out for further simplification of the controller design. This then leads to the state-space average model of the step-down converter (7) given by

$$\dot{x}(t) = A_c x(t) + b_c \cdot d(t)$$
  

$$V_o(t) = c_c^T x(t)$$
(8)

which is a linear system for which the states can be measured straightforwardly. Here, the input is the duty cycle d(t) and the output is the output voltage  $V_o(t)$ . In addition, constraints arise from the converter topology, e.g., the duty cycle has to be between 0 and 1, and for safety reasons, the inductor current  $i_l$  must be less than its saturation value  $i_{lmax}$ . This therefore implies the need for a controller that can handle constraints.

#### 4.1 Design of the controller

We consider the continuous-time finite horizon LQ problem defined by the cost function

$$J_{c} = x(T)^{\top} P_{c} x(T)$$

$$+ \int_{0}^{T} \begin{bmatrix} x(t) \\ u(t) \end{bmatrix}^{\top} \begin{bmatrix} Q_{c} & 0 \\ 0 & R_{c} \end{bmatrix} \begin{bmatrix} x(t) \\ u(t) \end{bmatrix} dt$$
(9)

where  $Q_c = I$  and  $R_c = 1$  have been chosen arbitrarily and  $P_c$  is the solution of continuous Ricatti equation and  $T = 40 \ \mu s$  is the prediction horizon. We assume a zeroorder hold. The function (9) represents the nominal closedloop performance of the continuous-time model (8).

### 4.2 Discretization

We discretize the continuous-time model (8) and the continuous weighting matrices  $\begin{bmatrix} Q_c & 0\\ 0 & R_c \end{bmatrix}$  in (9) using the sample time  $T_s$  and zero-order hold approximation on the input. Let  $u_k$  denote the discrete domain counterpart of the input d(t) in (8). Due to sampling, (8) is transformed into

$$x_{k+1} = Ax_k + bu_k$$

where  $A := e^{A_c T_s}$ ,  $b := \left(\int_0^{T_s} e^{A_c \tau} d\tau\right) b_c$  and  $u_k$  is a constant control between sampling instants. The corresponding sampled-data cost function is given by

$$J_{T_s} = x_N^{\top} P x_N + \sum_{k=0}^{N-1} \begin{bmatrix} x_k \\ u_k \end{bmatrix}^{\top} \begin{bmatrix} Q & M \\ M^{\top} & R \end{bmatrix} \begin{bmatrix} x_k \\ u_k \end{bmatrix}$$

where  $N = \lceil T/T_s \rceil$  is the number of samples for the prediction horizon T.

# 4.3 MPC problem formulation

The MPC problem is defined by the core optimization problem solved at each time instant given by

$$\min_{x_k,u_k} \quad x_N^{\top} P x_N + \sum_{k=0}^{N-1} \begin{bmatrix} x_k \\ u_k \end{bmatrix}^{\top} \begin{bmatrix} Q & M \\ M^{\top} & R \end{bmatrix} \begin{bmatrix} x_k \\ u_k \end{bmatrix}$$
  
s.t. 
$$\begin{array}{c} x_0 = \begin{bmatrix} \alpha, \beta \end{bmatrix}^{\top} \\ x_{j+1} = A x_j + b u_j \\ \begin{bmatrix} 0, 0 \end{bmatrix}^{\top} \leq x_{j+1} \leq \begin{bmatrix} i_{\max}, V_s \end{bmatrix}^{\top} \\ 0 \leq u_j \leq 1 \\ j = 0, 1, \dots, N-1 \end{array}$$
(10)

We gauge the performance of the algorithm through the closed-loop cost function

$$J_{cl} = x_{N_T}^{\dagger} P x_{N_T}$$

$$+ \sum_{k=0}^{N_T - 1} \begin{bmatrix} x_k \\ \mu(x_k) \end{bmatrix}^{\top} \begin{bmatrix} Q & M \\ M^{\top} & R \end{bmatrix} \begin{bmatrix} x_k \\ \mu(x_k) \end{bmatrix}$$
(11)

)

for simulation time  $N_T = \lceil T_T/T_s \rceil$  where  $T_T$  is the simulation time and  $\mu$  is the MPC feedback (namely,  $\mu_{N,m}$  and  $\overline{\mu}_{N,m}$ .)

# 4.4 Matrix structures

Defining the optimization variable

$$z := \begin{bmatrix} x_0^{(1)} \ x_0^{(2)} \ u_0 \ | \ x_1^{(1)} \ x_1^{(2)} \ u_1 \ | \ x_2^{(1)} \ x_2^{(2)} \ u_2 \ | \ \dots \\ \dots \ | \ x_{N-1}^{(1)} \ x_{N-1}^{(2)} \ u_{N-1} \ | \ x_N^{(1)} \ x_N^{(2)} \ \end{bmatrix}^\top$$

the objective function has the form  $\min_{z} \frac{1}{2}z^{\top}Hz$  where H is block diagonal with N blocks of  $\begin{bmatrix} Q & M \\ M^{\top} & R \end{bmatrix}$  and a block of P. The equality constraints composed of  $2 \cdot (N+1)$  equations can be written as

$$\begin{bmatrix} I_2 \\ -A & -b & I_2 \\ & \ddots & \\ & & -A & -b & I_2 \end{bmatrix} z = \begin{bmatrix} \alpha \\ \beta \\ 0 \\ \vdots \\ 0 \end{bmatrix}$$

which is of the form  $C_{eq}z = d_{eq}$ . The  $(2+1)\cdot 2\cdot N$  inequality constraints can be written as

$$\begin{bmatrix} 0 & 0 & 1 & & \\ & 1 & & \\ & \ddots & & \\ \hline 0 & 0 & -1 & & \\ & & -1 & & \\ & & & -1 \end{bmatrix} z + \begin{bmatrix} 0 & & & \\ u_{ub} & & \\ x_{ub}^{(1)} & & \\ \frac{x_{ub}^{(2)}}{u_{ub}} \\ \vdots \\ \frac{u_{ub}}{x_{ub}^{(1)}} \\ x_{ub}^{(2)} \end{bmatrix} \ge 0$$

which we can write in the form  $Cz \leq \bar{d}$ . This shows that the problem (10) can be written in the form

$$\min_{z} \frac{1}{2} z^{\top} H z$$
(12)  
s.t.  $C_{eq} z - d_{eq} = 0$   
 $-Cz + \bar{d} \ge 0$ 

which is a QP wherein the constant matrix H happens to be the exact Hessian of the Lagrangian function of (10). Solving the optimization problem (12) is straightforward using quadprog in Matlab where an active-set method can be chosen to solve the problem.

# 4.5 Implementing m-step and SBM MPC

In using SBM MPC, updates are performed on the entries of the m-step feedback. To solve the required updating/correcting sensitivities, we need to construct and solve the systems

$$\begin{bmatrix} \nabla_{z^{j}z^{j}}^{2} \mathcal{L}^{j}(z^{j^{*}}, \eta^{*}, x_{j}^{*}) & \nabla_{z^{j}} C_{\mathcal{A}^{j}}(z^{j^{*}}, x_{j}^{*}) \\ \nabla_{z^{j}} C_{\mathcal{A}^{j}}(z^{j^{*}}, x_{j}^{*})^{\top} & 0 \end{bmatrix} \begin{bmatrix} \frac{\partial z^{j}}{\partial p_{j}}(x_{j}^{*}) \\ \frac{\partial \eta_{\mathcal{A}^{j}}}{\partial p_{j}}(x_{j}^{*}) \end{bmatrix}$$
$$= -\begin{bmatrix} \nabla_{z^{j}p_{j}}^{2} \mathcal{L}^{j}(z^{j^{*}}, \eta^{*}, x_{j}^{*})^{\top} \\ \nabla_{p_{j}} C_{\mathcal{A}^{j}}(z^{j^{*}}, x_{j}^{*})^{\top} \end{bmatrix}$$
(13)

for  $j = 1, \ldots, m-1$ . See the derivation from Palma (2015, Equation (6.10) as a consequence of the Sensitivity Theorem, Theorem 5.5.1). Consequently, by computing the sensitivities  $\frac{\partial z^j}{\partial p_j}(x_j^*), j = 1, \ldots, m-1$ , we obtain  $\frac{\partial u^j}{\partial p_j}(x_j^*), j = 1, \ldots, m-1$ . If we denote the problem

formulation (10) (or (12)) by  $\mathcal{P}_N(p_0)$  where  $p_0 = [\alpha, \beta]^{\top}$ , computing the sensitivities  $\frac{\partial u^j}{\partial p_j}(x_j^*), j = 1, \ldots, m-1$ by (13) requires solving a sequence of systems for  $j = 1, \ldots, m-1$  corresponding to the OCPs  $\mathcal{P}_{N-j}(p_j)$  of decreasing horizon and adjusting parametric value.

Due to the nice structure of the matrices resulting from the OCP (10) (i.e., the involved Hessian and Jacobian matrices), adding the fact that these resulting matrices are constant matrices, the sequence of systems (13) can easily and immediately be constructed.

The exact Hessian  $\nabla_{z^j z^j}^2 \mathcal{L}^j(z^{j^*}, \eta^*, x_j^*)$  of the Lagrangian function of  $\mathcal{P}_{N-j}(p_j)$  evaluated at  $p_j = x_j^*$  has the same form but smaller in size as H (i.e., the corresponding Hessian for  $\mathcal{P}_N(p_0)$  with  $p_0 = [\alpha, \beta]^\top$ ). It has N - j blocks of  $\begin{bmatrix} Q & M \\ M^\top & R \end{bmatrix}$  and a block of P. The submatrix  $\nabla_{z^j} C_{\mathcal{A}^j}(z^{j^*}, x_j^*)^\top$  denoting the Jacobian of the active constraints are obtained appropriately from the active constraints of  $\mathcal{P}_N(p_0)$  with  $p_0 = [\alpha, \beta]^\top$ . This shows that the coefficient matrix of the linear system corresponding to the OCP  $\mathcal{P}_{N-j}(p_j)$  at  $p_j = x_j^*$  can be constructed through the submatrices of the coefficient matrix solved for  $P_N(p_0)$  at  $p_0 = [\alpha, \beta]^\top$  which is already available. Finally, the right-hand side is a zero matrix except for the identity  $I_2$  appearing in  $\nabla_{p_j} C_{\mathcal{A}^j}(z^{j^*}, x_j^*)^\top$  corresponding to  $x_j - p_j$ .

Lastly, we note that one has to take care so as not to violate constraints or create changes in the active constraints when updating by sensitivities. See techniques used in Palma (2015, Sections 6.2 and 7.2).

#### 5. CASE STUDY NUMERICAL RESULTS

We consider a low-power (2 Watt) step-down converter setup with the following design parameters:  $V_s = 6$  V,  $r_l = 15.5 \text{ m}\Omega$ ,  $V_o = 1$  V,  $i_{lmax} = 4$  A,  $r_o = 500$ m $\Omega$ ,  $C = 68 \ \mu\text{F}$ ,  $L = 1.5 \ \mu\text{H}$  and  $r_c = 1.5 \ \text{m}\Omega$ . We formulate different *m*-step and SBM MPC controllers by varying the sampling frequency  $f_s \in [300\text{kHz}, 400\text{kHz}]$ (where  $f_s := 1/T_s$ ) and  $m \in \{1, 2, ...10, 11\}$ . Closed-loop simulations are performed in Matlab in order to measure the controller closed-loop performance and the required average computing power in terms of FLOPs.

#### 5.1 Closed-loop performance

For each *m*-step or SBM MPC scheme, we perform  $10^3$  simulations of the plant evolution of different initial values (using a set of random and uniformly distributed feasible initial state values) and evaluate the closed-loop function (11). These values are then averaged and assigned to the scheme. Figure 2 shows the trend of the performance of the algorithm along increasing sampling frequency  $f_s$  for varying multistep *m* both for *m*-step and SBM MPC. Due to fast sampling, the entries of the submatrices M, P, Q, R in (11) have a magnitude of  $10^{-6}$ . Thus, we expect  $J_{cl}$  to be around a magnitude of  $10^{-5}$ . The scheme with m = 1 gives the standard MPC where we solve an OCP at every sampling instant. As expected, this gives the best performance where the feedback is able to react to the disturbance at each time step. Also shown is that higher sampling frequency yields better closed-loop performance since faster reaction implies faster disturbance rejection. Furthermore, the closed-loop performance worsens upon

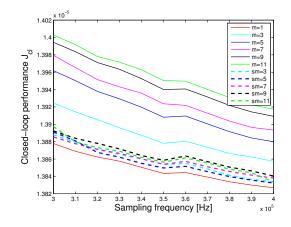

Fig. 2. Performance  $J_{cl}$  for varying sampling frequency  $f_s$ . The symbol m stands for the number of steps of the m-step MPC while sm for the SBM MPC.

using higher value of m (in solid lines). This is as expected since the system runs in open loop for a longer time causing further propagation of the deviation between the measured and the predicted states. However, improvement is achieved through the use of the sensitivity updates. Unlike the m-step feedback law, SBM MPC uses the perturbation magnitude and the sensitivity information to allow the controller to react to this measured and predicted state deviation. As seen in Figure 2 (in dashed lines), the performance profiles get closer to that of the standard MPC although it is not clear which of the SBM schemes performs the best.

#### 5.2 Computing Power

Figure 3 shows the trend in the average FLOPs of the algorithm along increasing sampling frequency for varying multistep m both for MF and SBM MPC. The standard MPC (m = 1) requires the most number of iterations. The number is divided by m as m increases and additional amount is added if sensitivity updates are performed. Note that Figure 3 shows the worst-case scenario FLOPs requirement, i.e., with maximum number of active inequality constraints. In the reality, the number of active constraints is significantly much less than the maximum possible. This means that the FLOPs represented in the dashed lines must be significantly much lower than those represented in the red plot. The SBM MPC requires significantly less computing power compared to standard MPC, but requires more compared to an *m*-step approach when m > 1. In addition, by increasing the sampling frequency  $f_s$ , the measured FLOPs increase for any controller. This is related to the discretization step (see Section 4.2) in the sense that increasing  $f_s$  means increasing the prediction horizon N and therefore the problem size and computational complexity.

Lastly, note that using m-step MPC, the peak computational load is the same as that of the standard MPC because an optimization problem has to be solved every m steps. However, since the average computing power is reduced, the multistep approach requires less energy and results to be more suitable for embedded systems.

#### 5.3 Pareto Optimality Analysis

As shown in Figures 2 and 3, the closed-loop performance and computing power requirements are strongly correlated: (i) increasing the sampling frequency  $f_s$  and decreasing the number of multistep m lead to controllers with lower  $J_{\rm cl}$  (i.e., better closed-loop performance) and

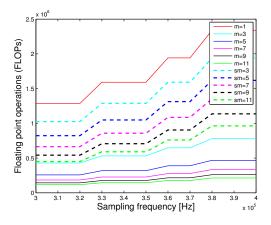

Fig. 3. FLOPs for varying sampling frequency  $f_s$  and various *m*-step MPC and *sm* for SBM MPC

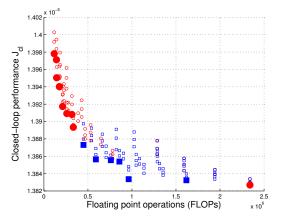

Fig. 4. A Pareto efficiency plot (solid circles and squares forming the Pareto frontier) on a set of feasible options for *m*-step (red circles) and SBM MPC (blue squares)

higher computing power requirement; (ii) similarly, decreasing  $f_s$  and using higher multistep m yield controllers with worse closed-loop performance and limited computing power. This results in the design trade-off between closed-loop performance and computing power. We analyze these trade-offs and present them in terms of Pareto optimality and efficiency (for a single point solution) or compromise solutions (see tutorial in Marler and Arora (2004)). Figure 4 shows the Pareto frontier, thus the design trade-off between closed-loop performance  $J_{cl}$  and computing power in terms of FLOPs. On one extreme, the points in red represent the *m*-step schemes with higher value of m which we observe to be less computationally demanding algorithms, while on the other extreme is the MPC scheme with m = 1 which is the one with the highest computing requirements but with the best closed-loop performance (indicated by the lowest  $J_{cl}$ ). Moreover, the points in blue represent the SBM MPC schemes which we observe to be the algorithms compromising a 'balance' between the two opposing objectives of having a good algorithm performance and being computationally less demanding. This suggests a great potential for the suitability of the scheme for embedded systems with limited computing power.

#### 6. CONCLUSION

The SBM MPC, viewed as a less costly approximation of the updated m-step feedback MPC is examined and implemented to control a DC-DC converter. Comparing the standard MPC, *m*-step (m > 1) MPC and SBM MPC schemes, a trade-off analysis, essential for designing and implementing controller on embedded system, is conducted. SBM MPC maintains a compromise between fulfilling control performance and low computational cost requirements.
