Energy-based evaluation of liquefaction potential under non-uniform cyclic loading

Ricardo J.N. Azeiteiro, Paulo A.L.F. Coelho, David M.G. Taborda and José C.D. Grazina

Abstract

Uniform cyclic loading is commonly used in laboratory tests to evaluate soil resistance to earthquake-induced liquefaction, even if the cyclic stresses induced by earthquakes in the field are highly irregular. This paper discusses the use of stress and energy-based approaches to evaluate the liquefaction resistance of sand under irregular loading. Results of undrained cyclic triaxial tests including a large-amplitude singular peak loading cycle are presented and compared to those obtained using uniform loading. Although samples are subjected to loading patterns which would have been deemed equivalent by conventional stress-based methods, the number of cycles required to trigger liquefaction strongly depends on the amplitude and location of the peak within the loading history. Conversely, a unique relationship exists between the accumulation of dissipated energy per unit volume, computed using stress and strain measurements, and the observed residual pore water pressure build-up for all tests, throughout the entire cyclic loading application. This demonstrates that conventional laboratory tests using uniform loading conditions can be employed to determine liquefaction resistance if their interpretation is carried out based on energy principles.

1. Introduction

Earthquake-induced soil liquefaction has been a subject of intensive research during the last decades. This phenomenon involves significant loss of the soil's strength and stiffness due to excess pore water pressure build-up, as well as a concurrent dissipation of energy mainly by frictional mechanisms (Okada and Nemat-Nasser 1994). Based on the assumption made by Nemat-Nasser and Shokooh (1979) that pore water pressure generation can be uniquely related to the cumulative energy dissipated per unit volume of soil up to the onset of liquefaction, several energy-based procedures for the evaluation of liquefaction potential of sand have been developed (e.g. Davis and Berrill 1982; Berrill and Davis 1985; Law *et al.* 1990; Figueroa *et al.* 1994; Dief and Figueroa 2007; Kokusho 2013). According to Liang *et al.* (1995), when compared to alternative stress-based (e.g. Seed and Idriss 1971; Seed *et al.* 1975; Idriss and Boulanger 2006) and strain-based (e.g. Dobry *et al.* 1982) approaches, energy-based methods have the strong advantage of accounting for both induced shear stress and strain, thus avoiding the need to decompose the irregular shear stress (or strain) time histories to find an equivalent uniform loading.

In order to verify the suitability of the energy concept for liquefaction evaluation, several laboratory testing programmes were designed to verify the uniqueness of the relationship between pore water pressure build-up and dissipated energy per unit volume. In particular, a series of undrained cyclic triaxial tests in which the energy content of the specimens was continuously monitored were performed by Simcock *et al.* (1983). A greater energy dissipation was observed as excess pore water pressure increased. Further evidence on the satisfactory relationship between these quantities was presented by Towhata and Ishihara (1985). Indeed, based on results of torsional shear tests using different loading patterns, the authors concluded that the relationship between excess pore water pressure generation and dissipated energy per unit volume is unique throughout the entire test, being independent of the shear stress path

followed in each test. A similar conclusion was drawn by Baziar and Sharafi (2011) and Kokusho (2013) when analysing results of undrained hollow cylinder torsional tests and undrained cyclic triaxial tests, respectively.

The laboratory testing programme performed by Figueroa and his co-workers (Figueroa *et al.* 1994; Liang *et al.* 1995; Dief and Figueroa 2007) is also noteworthy. These authors concluded that the energy required for the onset of liquefaction – known as capacity energy – was practically independent of the loading pattern used (uniform and non-uniform) and type of test performed (torsional cyclic shearing and centrifuge experiments). These results seem to be confirmed by the recent study of Polito *et al.* (2013), where cyclic triaxial tests using three different uniform loading shapes (sinusoidal, triangular and rectangular), as well as two irregular patterns where performed.

In this paper, a laboratory testing programme was carried out using a non-uniform loading pattern absent from previous research, characterising shock-type earthquakes – i.e. ground motions where the maximum induced shear stress is clearly higher than the remaining shear stress history (Ishihara and Yasuda 1975). This experimental programme aimed at comprehensively investigating the applicability of stress- and energy-based approaches to the prediction of the effect of a singular large-amplitude peak load on the liquefaction resistance of sand. Indeed, the study of a large number of earthquake records has shown that the location and magnitude of the peak acceleration varies widely between seismic events. As a result, in this paper, undrained cyclic triaxial tests in which a singular peak loading cycle of larger amplitude was applied within an otherwise uniform loading pattern were performed. Both the location and magnitude of the peak loading cycle were systematically varied in each test, highlighting the influence of an earlier or later crossing of the phase transformation line (Ishihara et al. 1975) on the liquefaction resistance of sand. Moreover, conventional undrained cyclic triaxial tests using uniform loading were also carried out in order to assess whether

4

stress-based methods can adequately deal with the irregularity of loading. The stress oscillations imposed in these conventional tests were chosen to be equivalent to those imposed in the non-uniform triaxial tests in accordance with the methodology proposed by Seed and Idriss (1971) and Idriss and Boulanger (2006). Based on the obtained results, it is discussed whether or not conventional laboratory tests using uniform loading can be reliably used for the evaluation of liquefaction resistance. The complete set of experimental results are subsequently interpreted using an energy-based approach. The relationships between the excess pore water pressure generation, the observed double amplitude axial strain and the accumulation of dissipated energy per unit volume are examined throughout the entire test. Conclusions are drawn about the ability of energy-based methods to accommodate the loading irregularity observed in real earthquake motions.

2. Laboratory testing programme

2.1. Material and equipment used

All tests in this experimental programme were performed on reconstituted samples of Coimbra sand, which characterises the deposits located along the banks of the Mondego River, Portugal. Analyses of the major seismic events occurred in Portugal show that these deposits are susceptible to liquefaction (Jorge and Vieira 1997).

Coimbra sand is a fine-grained sand, with sub-rounded to sub-angular particles. In order to avoid segregation, only the fraction between the no. 40 (0.425 mm) and no. 100 (0.150 mm) sieves of the ASTM series was used, resulting in a uniformly graded material. The mean particle diameter, D_{50}, and the uniformity coefficient, C_u, are approximately 0.28 mm and 1.6, respectively. The density of soil particles, G_s, is 2.65 and the minimum and maximum void ratios, e_{min} and e_{max}, determined according to ASTM D4253-00 (2006) and ASTM D4254-00 (2006), are close to 0.48 and 0.81, respectively. The behaviour of this sand has been extensively

studied within the small to large strain range and under different type of solicitations as part of a collaborative research project (e.g. Santos *et al.* 2012).

A fully computer-controlled hydraulic triaxial apparatus of the Bishop and Wesley (1975) type, designed for 38 mm diameter specimens, was used to perform the cyclic triaxial tests. In order to apply extension loading, a flexible sleeve connecting a top cap to a reaction head was used.

2.2. Experimental procedures

Air-pluviation of dry sand was used to prepare samples with a height/diameter ratio close to 2 and a void ratio of about 0.67, i.e. with a relative density close to 40 %. The desired density was controlled by the rate of pouring, which depended on the size and number of openings of a miniature container. The height of pouring, which also affects the resulting relative density, was kept approximately constant during sample preparation by raising the container while pouring the sand, ensuring the uniformity of the specimens in height. The pouring technique was methodically tested to guarantee accuracy and repeatability, with the density of the produced samples being confirmed from mass and volume measurements after preparation. A small suction of about 5 kPa was used to sustain the sample after dismounting the mould used during sand pouring.

All samples were saturated by flowing de-aired water through the sample, always at very low effective confining stresses, until a Skempton's B-value above 0.98 was measured in all tests. Subsequently, samples were isotropically consolidated to an effective pressure of 100 kPa. A back-pressure of 400 kPa, used during the saturation stage, was kept during this consolidation stage, to ensure that the sample remained saturated. Undrained cyclic shear loading was applied afterwards, until large strains and excess pore water pressures were measured.

2.3. Location and magnitude of the singular peak

Undrained cyclic triaxial (UCT) tests having a singular peak loading cycle of much larger amplitude than the remaining constant amplitude loading were conducted on samples of

Coimbra sand to study the effect of the largest earthquake-induced stress cycle on the liquefaction resistance of sand. In order to define realistic amplitudes and locations of the peak loading cycle to be used in the laboratory tests, real earthquake records were analysed. Specifically, bedrock horizontal acceleration time series of 132 earthquakes, which occurred around the world, ranging from the 1935 Helena earthquake to the 2015 Nepal earthquake, were collected (Appendix). For each horizontal motion, the maximum and average accelerations, a_{max} and a_{av}, respectively, the cycle at which the maximum acceleration was registered, $N(a_{max})$, and the total number of loading cycles, N_{tot}, were assessed. While a_{max} was directly obtained from each accelerogram data, representative values of each ground motion were selected to determine a_{av}, $N(a_{max})$ and N_{tot}. In particular, a low-amplitude cut-off level was used to prevent many cycles of small amplitude from inappropriately influencing the obtained results (Hancock and Boomer 2005). According to Seed *et al.* (1995), loading cycles having amplitudes less than about 30 % of the maximum amplitude do not have a significant contribution to the onset of liquefaction and, therefore, a cut-off level of 0.30 a_{max} was adopted in the present study. All peak accelerations having an amplitude greater than 0.30 a_{max} were then selected and used to estimate a_{av}, $N(a_{max})$ and N_{tot}. Fig. 1 illustrates the application of this methodology to the 1989 Loma Prieta earthquake.
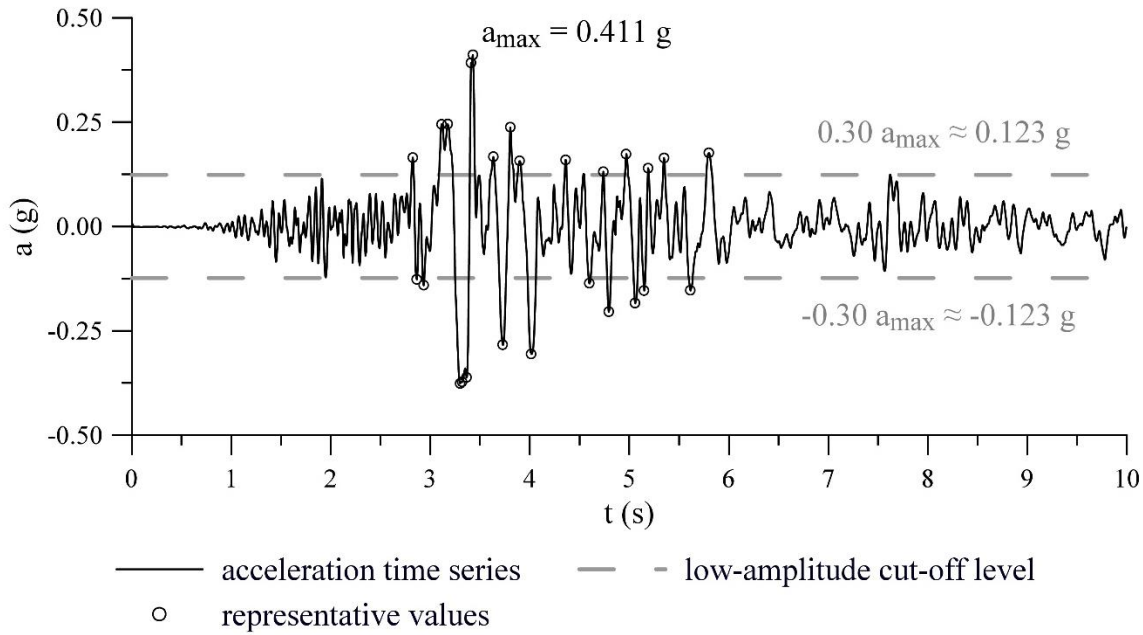

Fig. 1. Representative horizontal acceleration peak values for the 1989 Loma Prieta earthquake recorded at Gilroy Array Station 1 in the North-South direction

Possible correlations between a_{max} and a_{av}, as well as $N(a_{max})$ and N_{tot} were examined. Fig. 2 shows that a_{max} and a_{av} are approximately directly proportional, with a ratio close to 1.87 being obtained. Regarding the correlation between the representative cycle at which the maximum acceleration was registered, $N(a_{max})$, and the total number of cycles, N_{tot}, Fig. 3 suggests that the location of the largest peaks within the earthquake's time history may vary significantly from earthquake to earthquake, with a tendency for this peak to occur between the first loading cycle, $N(a_{max}) = 1$, and $N(a_{max}) = 0.80\, N_{tot}$.

Based on these findings, and assuming, as a first approach, that shear stresses induced in a soil element at a certain depth from ground surface are proportional to the ground acceleration (e.g. Seed and Idriss 1971; Ishihara and Yasuda 1975; Idriss and Boulanger 2006), a singular peak loading cycle with twice the amplitude of the remaining uniform loading cycles was considered. The location of the higher amplitude peak within the overall loading pattern, defined by the specific value of mean effective stress at which the loading regime is changed, p'_p, was varied in each test, in order to assess its influence on the liquefaction resistance of sand.

8

**Fig. 2.** Relationship between the maximum and average acceleration of real earthquake time histories

Fig. 3. Relationship between the cycle corresponding to the maximum peak acceleration and the total number of cycles of real earthquakes

As detailed in Table 1, in three of the tests – UCT 30/60/100, UCT 30/60/80 and UCT 30/60/50 – a peak loading cycle characterised by a peak value of deviatoric stress, q_p, of 60 kPa was applied when the mean effective stress, p'_p, reached 100, 80 and 50 kPa, respectively, with the remaining undrained loading consisting of cycles with a uniform deviatoric stress amplitude, q_u, of 30 kPa. Additionally, a test using uniform loading of 40 kPa, corresponding approximately to 0.65 q_p, as suggested by the methodology proposed by Seed and Idriss (1971) and Idriss and Boulanger (2006), – UCT 40 test – was performed.

As detailed later, in all of the aforementioned non-uniform loading tests, it was observed that the phase transformation (PT) line (Ishihara *et al.* 1975) (i.e. the line defining the transitory state at which the behaviour of sand changes from plastic contraction to plastic dilation) was initially crossed when the singular peak loading cycle was applied, leading to a very fast reduction of the mean effective stress in the subsequent loading cycles and, therefore, to the onset of liquefaction after few additional cycles. Consequently, in those tests, the early occurrence of the peak load was found to be unfavourable to the liquefaction resistance of sand. In order to investigate whether or not the peak loading cycle also presents a drastic influence on the liquefaction resistance of sand in situations where its application would not result in a premature crossing of the PT line, two additional tests were carried out, using smaller values of $q_p = 45$ kPa and $q_u = 23$ kPa – UCT 23/45/50 and UCT 23/45/80 tests. A test using a uniform loading of 30 kPa (≈ 0.65 q_p of UCT 23/45/50 and UCT 23/45/80 tests) was also carried out – UCT 30 test.

3.   Experimental results and analysis

3.1. Sample response under similar loading conditions

Since a single method of sample preparation was used to produce samples with similar initial density and samples were consolidated to the same isotropic stress level, a similar undrained cyclic shear response is expected in all tests under similar loading conditions.

Fig. 4a show the accumulation of residual excess pore water pressure ratio, $(r_u)_{res}$, i.e. the ratio of excess pore water pressure corresponding to a null deviatoric stress, with the number of loading cycles, N, while Fig. 4b depicts the observed variation of double amplitude axial strain, ε_{DA}, with N. Except for the UCT 30/60/100 test, where the peak loading cycle was applied at the beginning of the test, and for UCT 30 and UCT 40 tests, where only uniform loading was used, the moment at which the peak loading cycle was applied in each test is clearly identified in this figure by a large filled square. It can be observed that the results obtained for the UCT 30 sample present a similar accumulation of residual pore water pressure and of axial strain with

number of loading cycles to those registered for the UCT 30/60/50 and UCT 30/60/80 tests, prior to the application of the peak load. Naturally, such similarity was suddenly interrupted by the occurrence of the peak loading cycle, as this triggered a very rapid increase of excess pore water pressure and axial strain accumulation.
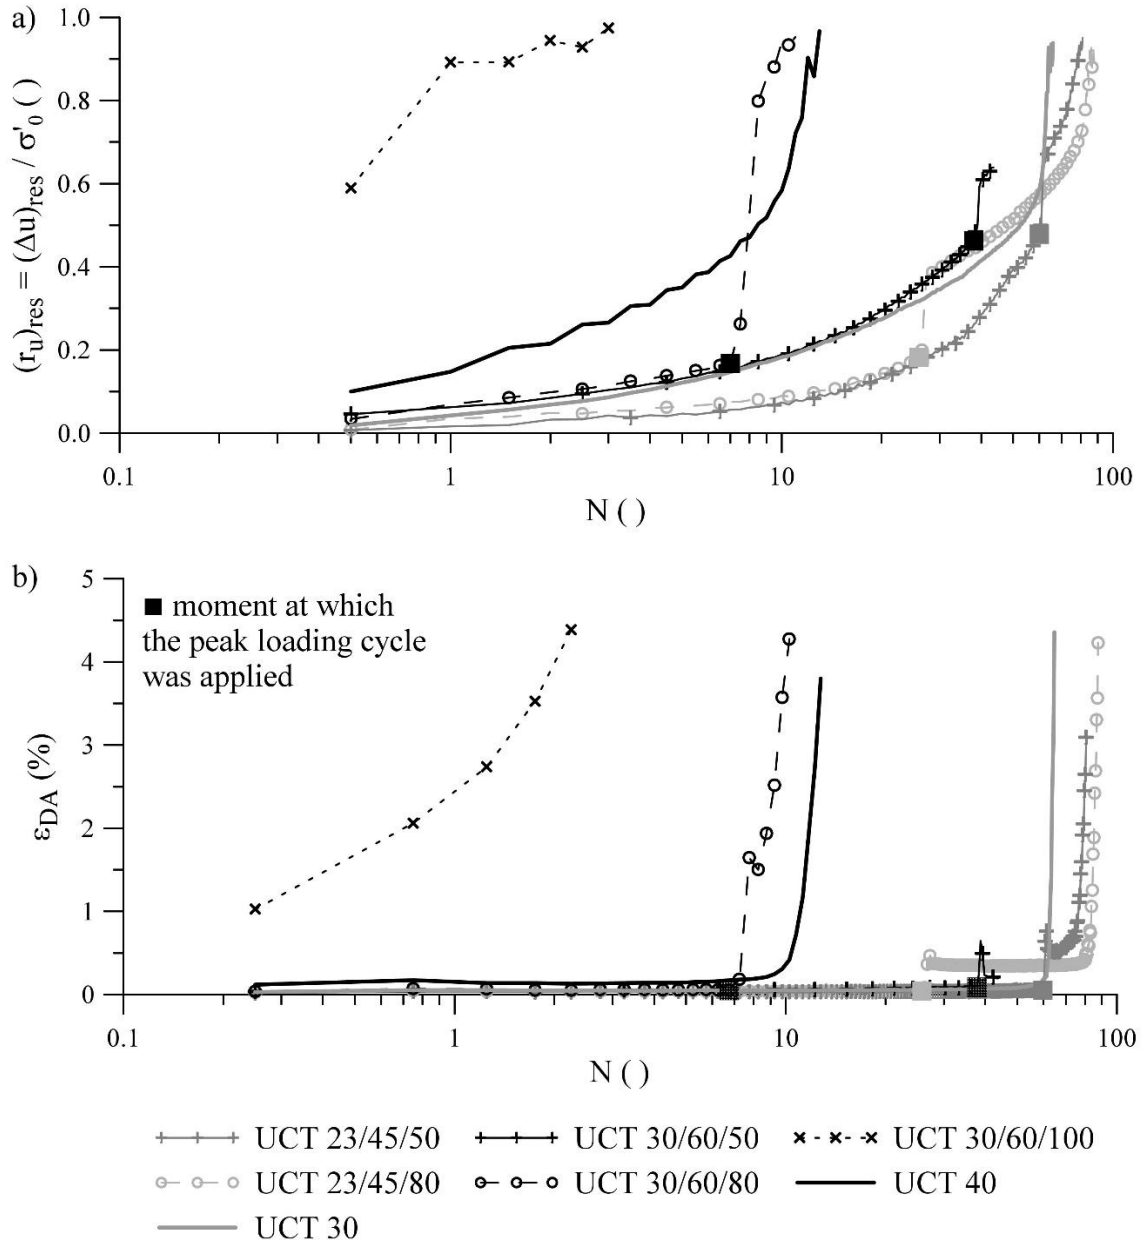

Fig. 4. Comparison of observed (a) residual pore water pressure build-up and (b) double amplitude axial strain with the number of cycles of loading

As expected, a different response was obtained for the UCT 30/60/100 test, since the peak load was applied in the first loading cycle, with the residual excess pore water pressure ratio being close to 0.90 just after that first cycle. Moreover, in the UCT 40 test, the larger deviatoric stress

amplitude led to higher rates of residual excess pore water pressure generation and of axial strain accumulation than those observed in the UCT 30, UCT 30/60/50 and UCT 30/60/80 tests, before any peak loading cycle was applied.

Likewise, the UCT 23/45/50 and UCT 23/45/80 tests presented a remarkably similar behaviour until the application of the peak loading cycle in the UCT 23/45/80 test (27th loading cycle). As expected, these tests showed the lowest rate of accumulation of residual pore water pressure and double amplitude axial strain before peak load was applied, due to the smaller uniform deviatoric stress amplitude used (q_u = 23 kPa).

3.1.1. Number of loading cycles to the onset of liquefaction

It is usual to consider either the development of unit excess pore water pressure ratio (r_u = 1.0) or the observation of 5 % double amplitude axial strain (ε_{DA} = 5 %) as a condition to define the onset of liquefaction (also known as initial liquefaction) in laboratory testing (Ishihara 1996). As demonstrated later in this paper, when test results are interpreted using energy principles, a criterion based on the former quantity appears to be more adequate and, therefore, was adopted in the present study. Fig. 4 shows that, for the tests performed, the onset of liquefaction depends not only on the magnitude of loading (as inferred, for example, from the comparison between the results obtained for tests UCT 40 and UCT 30), but also on the loading pattern adopted in each test. More specifically, in the case of UCT 30/60/50, UCT 30/60/80 and UCT 30/60/100 tests, it can be observed that the later the singular peak loading cycle was applied, the greater the number of loading cycles required to trigger initial liquefaction, N_{liq}, as previously observed by Azeiteiro *et al.* (2012). Conversely, in the case of the UCT 23/45/50 and UCT 23/45/80 tests, a smaller difference between the number of loading cycles needed to reach initial liquefaction was observed, with the latter test requiring slightly more cycles (N_{liq} = 81 against 88, as indicated in Table 1), despite the earlier application of the peak load (N_p = 61 and 27, respectively, as also shown in Table 1). Indeed, it seems that the different impact of the location

of the peak loading cycle is related to whether or not the Phase Transformation (PT) line is crossed during its occurrence. As depicted in Fig. 5, while in the UCT 23/45/50, UCT 30/60/50 and UCT 30/60/80 tests, a reverse in the stress path can be observed during the extension part of the peak loading cycle, suggesting that the PT line has been crossed (Ishihara *et al.* 1975), this does not seem to occur in the UCT 23/45/80 test (Fig. 5a). Consequently, even if the larger shear stress oscillation imposed in the peak loading cycle results in a large increment of residual pore water pressure (Fig. 4a) and double amplitude axial strain (Fig. 4b), the reduction in mean effective stress upon load reversal is not as drastic in the UCT 23/45/80 test as it is in the UCT 23/45/50, UCT 30/60/50 and UCT 30/60/80 tests.

Moreover, Fig. 4 shows that the number of loading cycles needed to trigger liquefaction in the UCT 40 test ($N_{liq} = 14$) is smaller than that required in the UCT 30/60/50 test (more than 63 cycles), but larger than those needed in the UCT 30/60/80 and UCT 30/60/100 tests (11 and 3 cycles, respectively). This indicates that there is a substantial impact of the location of the peak loading cycle on the measured liquefaction strength, meaning that the laboratory evaluation of field liquefaction potential may need to take into account the irregularity of earthquake-induced shear stresses when stress-based analyses are performed.

3.2. Dissipated energy during undrained cyclic triaxial loading

In undrained triaxial shearing, the dissipated energy per unit volume (also known as unit energy, energy density or shear work per unit volume) per cycle, δW, can be determined using the area of the stress-strain hysteresis loop corresponding to that loading cycle. Since the stress-strain loops measured in each cycle of the conducted tests were not closed (Fig. 6a), the following methodology, outlined by Taborda *et al.* (2016), was adopted to estimate δW:

1) isolate each half-cycle stress-strain loop;

2) create a symmetric image of each half-cycle stress-strain loop about its centre;

15

3) centre each half-cycle stress-strain loop and its corresponding mirror image at the origin of the stress-strain space (i.e. move each half-loop in a way that its two tips are located at equal horizontal and vertical distances to the origin); an entire and closed stress-strain loop is defined by the original and the mirrored half-loop (Fig. 6b);

4) estimate the area enclosed by each closed loop using a trapezoidal approximation – Equation 1; and divide the obtained value by two in order to account only for the dissipated energy per unit volume in a half cycle.

[1] $\qquad \delta W = \int \sigma \, d\varepsilon = \int_k q \, d\varepsilon_a \approx \sum_{i=1}^{k-1} \frac{1}{2} \left(q^{(i)} + q^{(i+1)} \right) \left(\varepsilon_a^{(i+1)} - \varepsilon_a^{(i)} \right)$

where q is the deviatoric stress, ε_a is the axial strain and k is the total number of points in which the stress-strain loop is discretised.

For each of the performed tests, the accumulation of dissipated energy per unit volume, i.e. $\Delta W = \sum_{i=1}^{N} \delta W$, with the number of loading cycles, N, was determined (Fig. 7). It can be observed that a small amount of dissipated energy is accumulated during the earlier stages of loading, with a sharp increase of this quantity being measured as sand approaches liquefaction. It is also interesting to point out that, as expected, the accumulation of dissipated energy with the number of loading cycles (Fig. 7) follows a similar pattern to that described by the observed double amplitude axial strain (Fig. 4). Moreover, a clear jump in ΔW – N curves can be seen at the moment the peak loading cycle occurs.
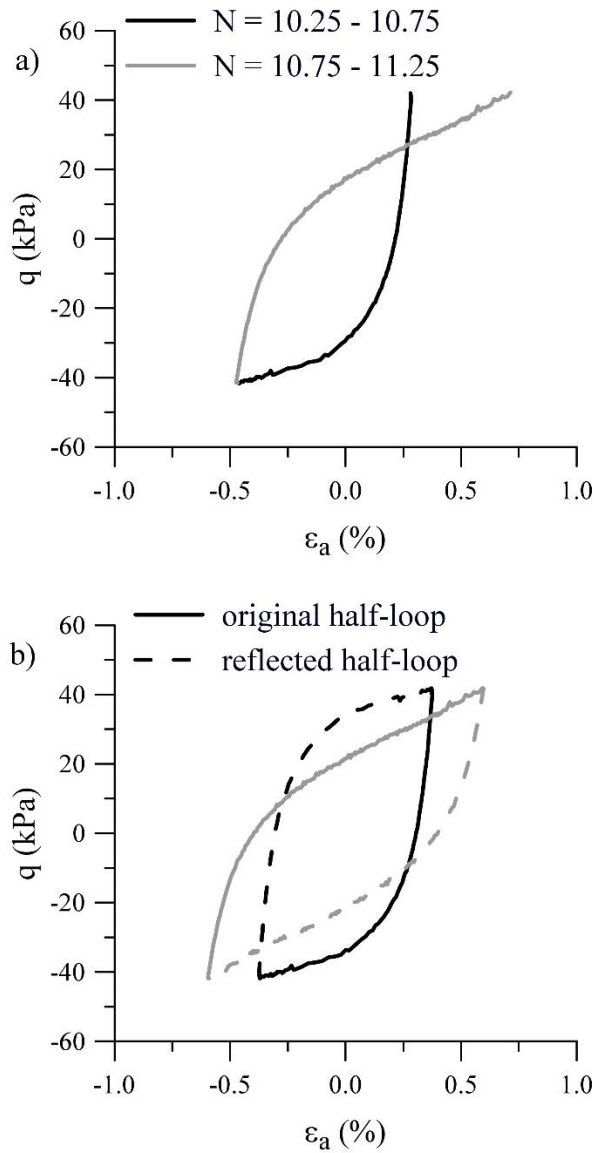

Fig. 6. Example of application of the methodology used to estimate the dissipated energy per unit volume (UCT 40 test): (a) original half-loops and (b) construction of closed loops using mirror images
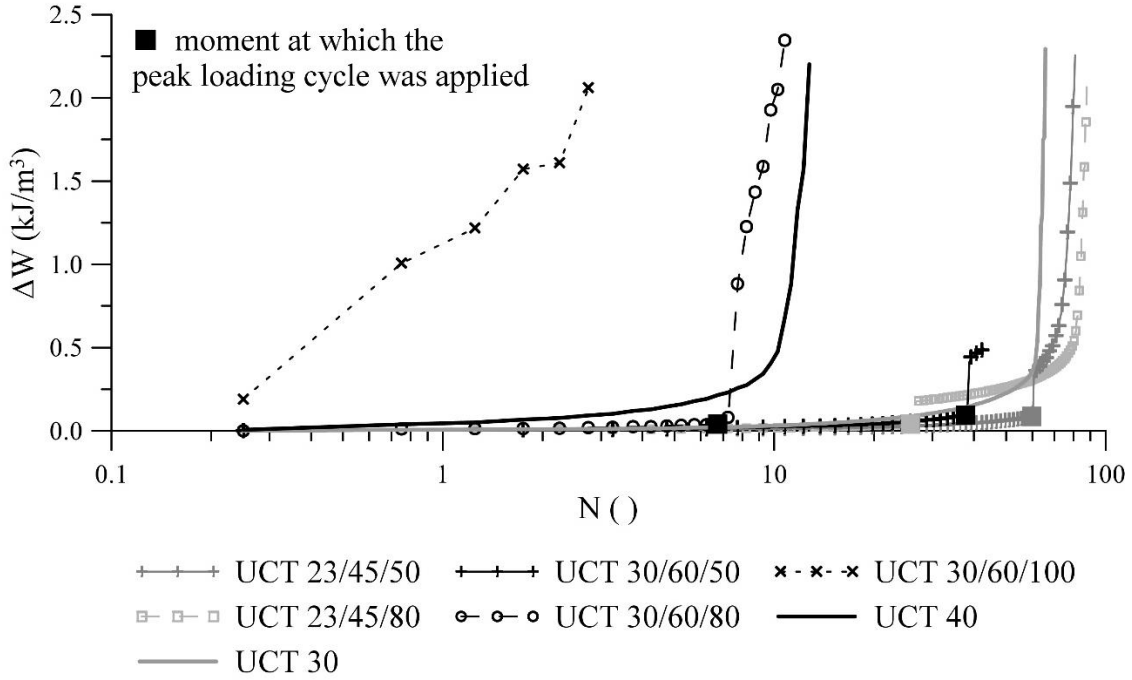

Fig. 7. Accumulation of dissipated energy per unit volume with the number of loading cycles

3.3. Excess pore water pressure generation as a function of dissipated energy

Fig. 8 presents the relationship between the dissipated energy per unit volume, ΔW, normalised by the post-consolidation isotropic effective stress ($\sigma'_0 = 100$ kPa), and the ratio of residual excess pore water pressure build-up, $(r_u)_{res} = (\Delta u)_{res} / \sigma'_0$. Although all samples have been consolidated to the same isotropic stress σ'_0, a normalisation of ΔW by σ'_0 was used to facilitate the comparison with other results published in the literature (see Table 2). Moreover, while $(\Delta u)_{res}$ was measured at the beginning and middle of each loading cycle (where the deviatoric stress is null), ΔW was estimated per each half-cycle and, therefore, between points corresponding to the maximum and minimum deviatoric stress. Thus, in order to compare these quantities, average values of residual pore water pressure were used – a procedure similar to that followed by Simcock *et al.* (1983). As shown in Fig. 8, similar curves were obtained for all conducted tests, which suggests that $(r_u)_{res} - \Delta W / \sigma'_0$ relationship is practically independent of the loading pattern imposed in each test. These results seem to confirm those previously obtained by Towhata and Ishihara (1985), who observed that $(r_u)_{res} - \Delta W / \sigma'_0$ relationship is

18

independent of the loading pattern applied in a torsional shear device (torsional shear, triaxial shear, a combination of both, etc.). Indeed, the obtained results also extend those obtained by Liang *et al.* (1995) and Polito *et al.* (2013). Based on regression analyses of element laboratory test results, both groups of authors concluded that the capacity energy, ΔW_{liq}, seems to be independent of using a uniform or an earthquake-type time series loading. The present experimental results suggest that not only ΔW_{liq} appears to be independent of the loading pattern used in each test (see Table 1), but also that a unique relationship between $(r_u)_{res}$ and $\Delta W / \sigma'_0$ is obtained for the entire loading history (i.e. from the earlier stages of loading to the moment liquefaction is triggered).
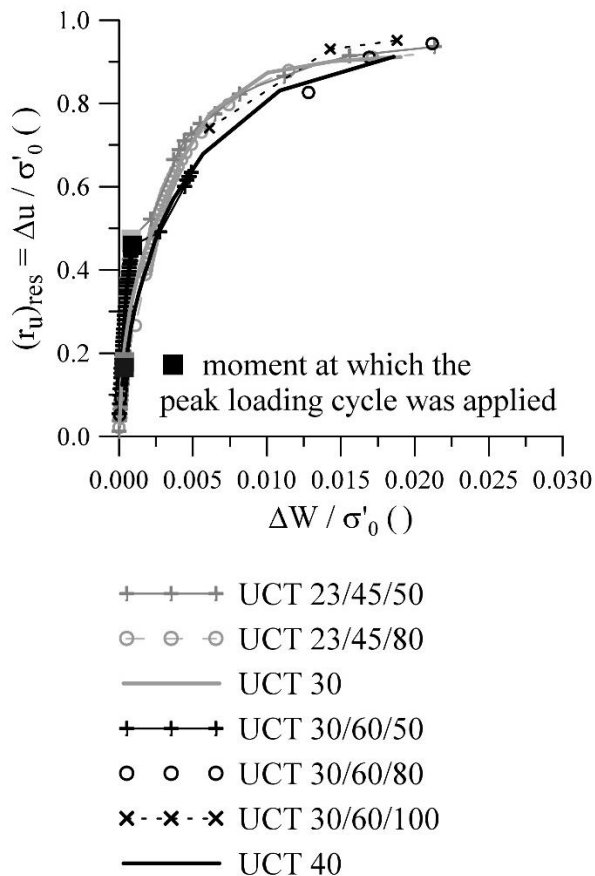

Fig. 8. Ratio of residual pore water pressure build-up as a function of the accumulation of dissipated energy per unit volume

As suggested by Liang *et al.* (1995), this may indicate that the laboratory evaluation of field liquefaction based on an energy-based method can be performed using uniform loading, rather

than using a complex earthquake-loading pattern. More specifically, if the seismic wave energy dissipated by a given layer of a soil deposit during a representative earthquake is adequately estimated, either by a wave propagation analysis or using a simplified procedure (see, for example, Davis and Berrill (1998), Dief and Figueroa (2007), Jafarian *et al.* (2011) or Kokusho and Suzuki (2012) for further details), then liquefaction susceptibility can be evaluated by comparing this value with the energy required to the onset of liquefaction, i.e. the capacity energy. This latter quantity can be obtained by performing laboratory tests on representative samples subjected to the *in situ* stress state and using, for simplicity, uniform cyclic loading, since its value has been shown to be independent from the adopted loading history (see Fig. 4). As discussed by Seed et al. (1975), the use of uniform cyclic loading for the laboratory evaluation of liquefaction potential presents two great advantages: 1) the testing equipment requirements to carry out the laboratory tests are reduced and 2) the obtained laboratory data can be used to assess the liquefaction potential of that soil layer for several design earthquakes. The unique $(r_u)_{res} - \Delta W / \sigma'_0$ relationship further suggests that if a random stress history of an earthquake motion is to be represented by an uniform cyclic stress history which causes similar effect on the soil, then an energy-based approach (e.g. Green and Terri 2005) for implementing the Palmgren–Miner cumulative damage hypothesis (Milner 1945) seems to be more appropriate than a stress-based approach (e.g. Seed *et al.* 1975).

It is also noteworthy that, for a given material, a good correlation between $(r_u)_{res}$ and $\Delta W / \sigma'_0$ exists. This conclusion applies not only to clean sands, but also to silty-sand mixtures (Polito *et al.* 2008; Baziar and Jafarian 2007; Baziar and Sharafi 2011) and clays (Cao and Law 1992), with each of the materials having its specific relationship. This further expands the applicability of energy-based approaches for the evaluation of liquefaction potential.

The present experimental data was subsequently compared with laboratory test results obtained for other sands reported in the literature (Table 2). In accordance with the conclusions drawn

by Law *et al.* (1990) and Dief and Figueroa (2007), Fig. 9 suggests that the $(r_u)_{res} - \Delta W / \sigma'_0$

relationship depends on soil type and/or test conditions. Therefore, if an energy-based method

is to be employed to evaluate the liquefaction potential of a specific site, representative samples

of that soil deposit should be tested in laboratory to evaluate its particular $(r_u)_{res} - \Delta W / \sigma'_0$

relationship.

3.4. Observed double amplitude axial strain as a function of dissipated energy

In contrast to the unique relationship between $(r_u)_{res}$ and $\Delta W / \sigma'_0$, the results shown in Fig. 10 suggest that the loading pattern has substantial influence on the relationship between $\Delta W / \sigma'_0$ and the double amplitude axial strain, ε_{DA}, observed during undrained cyclic triaxial loading. Moreover, it can be observed that, in general, as the number of loading cycles required to achieve a given level of ε_{DA} decreases (Fig. 4b), a higher average slope is obtained for the

$\Delta W / \sigma'_0 - \varepsilon_{DA}$ curve (Fig. 10), when comparing tests where a similar amplitude of loading was used – for example, UCT 30/60/80 and UCT 30/60/100 tests.

4. Summary and conclusions

Undrained cyclic triaxial tests having a singular peak loading cycle of larger amplitude were carried out on similarly prepared air-pluviated samples of Coimbra sand to evaluate the effect of the location and magnitude of the largest peaks of earthquake-induced shear stresses on the liquefaction potential of sand. In order to use realistic loading in the experiments, the characteristics of real earthquakes were firstly examined. Based on the obtained results, three particular locations of the peak load were experimentally explored: at the beginning of shearing and when the mean effective stress reaches 80% and 50% of its initial value. Moreover, different shear stress amplitudes were used for both the peak loading cycle and uniform loading

pattern, in order to examine the influence of the crossing of the phase transformation line on the resistance of sand. Additionally, undrained cyclic triaxial tests using standard uniform loading were performed to evaluate the impact of using a simplified loading pattern in laboratory testing, rather than complex patterns more akin to those imposed during real earthquake motions.

The experimental results suggest that the number of cycles required to the onset of liquefaction depends not only on the magnitude of the imposed loading, but also on the loading pattern followed in that particular test. It was observed that the occurrence of an early peak load can either greatly reduce the liquefaction resistance or have only a minor effect, with the analysis of the registered stress paths suggesting that such substantial difference is related to whether or not the phase transformation line is crossed. Indeed, when the application of the peak loading cycle resulted in the crossing of the phase transformation line, a more detrimental effect on liquefaction resistance of sand was observed.

The results of these laboratory tests were further investigated using energy concepts, to examine whether or not energy-based evaluation of field liquefaction potential also need to incorporate the irregularity of loading. The accumulation of dissipated energy per unit volume, ΔW, was estimated using the recorded stress-strain responses. Possible correlations with the observed ratio of residual excess pore water pressure build-up, $(r_u)_{res}$, and double amplitude axial strain, ε_{DA}, were explored. It was found that a unique relationship between $\Delta W / \sigma'_0$ and $(r_u)_{res}$ appears to exist, being independent of both amplitude and location of peak loading cycle. Furthermore, similar results were obtained when using uniform or non-uniform loading. This suggests that standard cyclic tests using uniform loading can be used for realistic energy-based evaluation of field liquefaction potential.
