17 Highlights:

- 18 • Four grass-clover-chicory mixtures were grown on three contrasting sites.
- 19 • Chicory and clovers had higher micronutrient concentrations than grasses.
- 20 • Mixture micronutrient concentrations increased with red clover proportion.

- 21       • Site properties affected overall micronutrient levels in species and mixtures.

22

23   Keywords: grass, legume, ley, trace element, soil, herb

24

25   **Abstract**

26   Forage crops provide micronutrients as well as energy, protein and fiber to ruminants.

27   However, the micronutrient concentrations of forage plant species differ, legumes generally

28   having higher concentrations than grasses. In addition to that there are also strong effects of

29   soil type. Typically, the concentrations of one or several micronutrients in forage are too low

30   to meet the nutritional requirement of dairy cows. We hypothesized that the overall

31   micronutrient (Co, Cu, Fe, Mn, Mo, Zn) concentrations of forage mixtures are affected by the

32   red clover dry matter (DM) proportion and site effects. This hypothesis was tested at three

33   contrasting sites. The results showed that increased red clover proportion increased the overall

34   concentrations of several micronutrients in the mixtures at all sites. At the site with the widest

35   range of red clover proportion (0-70%) in the mixture, the Co, Cu and Fe concentrations more

36   than doubled between the lowest and highest red clover DM proportion. At the other two sites

37   a smaller increase in red clover proportion (from 10% to 25% or from 25% to 50%) also

38   increased the overall concentrations of Co by up to 80% but less for other micronutrients. One

39   of the sites generally had higher micronutrient concentrations in the crop and removed larger

40   amounts of micronutrients with the harvested biomass compared to the other two sites. This

41   could be explained by differences in pH and micronutrient concentrations of the soils at the

42   sites. We conclude that increased red clover proportion in the sward has the potential to

43   increase the overall micronutrient concentrations but that the effect of the soil is also a

44   controlling factor.

## 45 **1 Introduction**

46 Forages are important in ruminant production. In addition to energy, fiber and protein, the  
47 forages provide macro- and micronutrients required for sustainable animal production and  
48 health (*Suttle*, 2010). Thus, in livestock production systems which mainly rely on forage the  
49 plants are the main source of the essential micronutrients such as cobalt (Co), copper (Cu),  
50 iron (Fe), manganese (Mn) and zinc (Zn) as well as the beneficial molybdenum (Mo).  
51 However, the micronutrient concentrations of forage vary with site (*Hopkins et al.*, 1994),  
52 largely due to the influence of differences in soil properties such as texture, organic matter,  
53 pH, total and available micronutrient concentrations of the soil (e.g. *Kähäri and Nissinen*,  
54 1978; *Paasikallio*, 1978). Thus farms who base feed on locally produced forage, for example  
55 organic farms, depend on the soil properties of the farm.

56 To ensure that feed rations meet livestock requirements, as specified by e.g. *National*  
57 *Research Council* (2001), mineral supplementations are allowed in both conventional and  
58 organic livestock systems. Such supplementation may lead to a relatively rapid increase in  
59 micronutrient concentrations in the soils of livestock farms (*Andersson*, 1992; *Knutson*, 2011)  
60 which in the long term may lead to excessive concentrations affecting important microbial  
61 processes on some soils (*Giller et al.*, 1998). However, the use and dependency of mineral  
62 supplementation may be reduced by altering the species mixture of the sward. Studies on  
63 different species mixtures have shown that grass-legume mixtures have higher micronutrient  
64 concentrations (*Govasmark et al.*, 2005; *Kunelius et al.*, 2006) and higher micronutrient  
65 removals in the harvested biomass (*Høgh-Jensen and Søegaard*, 2012) than pure grass  
66 swards. This is because of the generally higher micronutrient concentrations found in legumes  
67 compared to grasses (e.g. *Lindström et al.*, 2012; *Pirhofer-Walzl et al.*, 2011). However, the  
68 relationship between the legume proportion and the overall micronutrient concentrations of  
69 the mixed sward has rarely been evaluated. Furthermore, the strong link between plant

70 micronutrient concentrations and soil properties needs to be taken into account in studies  
71 regarding micronutrient concentrations in forage. A field experiment with a range of timothy-  
72 red clover dominated mixtures established at three contrasting sites provided an excellent  
73 opportunity to explore this. The hypothesis tested was that the overall micronutrient  
74 concentrations of forage mixtures are affected by the red clover dry matter (DM) proportion  
75 and by site effects.

## 76 **2 Materials and methods**

77 A field experiment was established in 2010 at three sites with contrasting soils in Sweden:  
78 Rådde (57°36'N, 13°15'E), Lillerud (59°38'N, 13°23'E) and Ås (63°14'N, 14°33'E). The soil at  
79 Rådde is a till with sandy loam texture developed from mainly granitic parent material, at  
80 Lillerud the soil is a postglacial silty loam originating from mainly granitic and sandstone  
81 bedrock, and at Ås a loamy till developed from alum shales. A composite soil sample, taken  
82 along a transect of each field before the trials were sown, was analysed for pH, total C and N,  
83 pseudo-total macro- and micronutrient concentrations and of “plant available” micronutrient  
84 concentrations (Tab. 1). Soil pH was first analysed in deionized water and then in 0.01 M  
85 calcium chloride solution according to *Sumner* (1994). Total N and C concentrations in soil  
86 samples were analysed by high temperature (1250°C) induction furnace combustion using  
87 LECO CN2000 (LECO Corporation, St Joseph, MI, USA). Pseudo-total macro- and  
88 micronutrient concentrations were extracted with concentrated nitric acid and hydrogen  
89 peroxide and analysed on ICP-SFMS at ALS Scandinavia AB in Luleå, Sweden (same  
90 laboratory and method as the Swedish arable soil monitoring program). “Plant available” soil  
91 micronutrients were extracted with 0.05 M EDTA (pH 7) and analysed by ICP-MS (*Ure and*  
92 *Berrow*, 1970).

93

94 The experiment included five species: timothy (*Phleum pratense* L., cv. Grindstad), meadow  
95 fescue (*Festuca pratensis* Huds., cv. Sigmund at Rådde and Lillerud, cv. Kasper at Ås), red  
96 clover (*Trifolium pratense* L., cv. Ares at Rådde and Lillerud, cv. Torun at Ås), white clover  
97 (*Trifolium repens* L., cv. Ramona at Rådde and Lillerud, Undrom at Ås) and chicory  
98 (*Cichorium intybus* L., cv. Grassland's Puna). All species except chicory have the bulk of  
99 their root system in the upper 25 cm of the soil profile. These species were sown in four  
100 different mixtures; i) timothy and red clover (15 and 5 kg ha<sup>-1</sup>, respectively); ii) timothy, red  
101 clover and meadow fescue (4.2, 10.8 and 5 kg ha<sup>-1</sup>, respectively); iii) timothy, red clover and  
102 white clover (2, 15, 3 kg ha<sup>-1</sup>, respectively); and iv) timothy, red clover and chicory (3, 15, 5  
103 kg ha<sup>-1</sup>, respectively). The experimental design was a randomized block design with three  
104 replicates. Plot size harvested was 12.0, 14.0 and 13.5 m<sup>2</sup> at Rådde, Lillerud and Ås,  
105 respectively.

106 The forage species were under-sown in spring barley (*Hordeum vulgare* L.) (sown at rates of  
107 120-200 kg seed per ha) on 7 May 2010 at Rådde, 24 May 2010 at Lillerud and 2 July at Ås.  
108 Corresponding harvest dates of barley were 6 July, 10 August and 6 September 2010. The  
109 barley crop was fertilized with 70 kg N ha<sup>-1</sup>, 10 kg P ha<sup>-1</sup>, 33 kg K ha<sup>-1</sup> at Rådde, 60 kg N ha<sup>-1</sup>,  
110 12 kg P ha<sup>-1</sup> and 15 kg K ha<sup>-1</sup> at Lillerud and 40 kg N ha<sup>-1</sup>, 50 kg P ha<sup>-1</sup> and 95 kg K ha<sup>-1</sup> at Ås.  
111 Weed ingression was controlled at Rådde by topping on 26 August.

112 In the spring of 2011 the crops at all sites received 60 kg N ha<sup>-1</sup> and another 50 kg N ha<sup>-1</sup> was  
113 applied after each cut except the last. In addition, the crop at Rådde was fertilized with 14 kg  
114 P ha<sup>-1</sup>, 75 kg K ha<sup>-1</sup> and 7 kg S ha<sup>-1</sup> in the spring and 27 kg K ha<sup>-1</sup> after each cut except the last.  
115 The crop at Lillerud was fertilized with 12 kg P ha<sup>-1</sup> and 21 kg K ha<sup>-1</sup> in the spring and 10 kg P  
116 ha<sup>-1</sup> and 18 kg K ha<sup>-1</sup> after each cut except the last. The amounts of P, K and S fertilizer  
117 applied were based on previous soil analyses. Different products with different combinations  
118 of N:P:K:S from Yara International ASA were used as fertilizers. With the exception of

119 YaraMila 22:0:12, which has 0.1% Zn and were used after first cut at Rådde (227 kg ha<sup>-1</sup>),  
120 none explicitly contains micronutrients. Data from *Eriksson* (2001) have been used to  
121 estimate amounts of micronutrients found as unlabelled traces in mineral fertilizers. The year  
122 before ley establishment (2009) cereals were grown on all sites, hence any carry over effect  
123 can be considered to have affected the soil and nutrients similarly at all sites.

124 In the spring and summer of 2010, the mean air temperatures at all sites were close to the 30  
125 year average but all sites received more precipitation than normal (Tab. 2). The following  
126 autumn and winter were dry, in particular at Rådde, and November-December was colder than  
127 usual at all three sites. The mean air temperature and amount of precipitation was close to the  
128 30 years mean during the spring and summer of 2011.

129 In 2011, the plots were harvested three times at Rådde (8 June, 20 July and 14 September) and  
130 Lillerud (7 June, 19 July and 4 October) and twice at Ås (16 June and 30 August). The first  
131 harvest was carried out at the ear emergence stage of timothy, and subsequent harvests  
132 according to farming practise at the respective sites. Plots were harvested with a Haldrup  
133 (Løgstør, Denmark) plot harvester to a stubble height of approximately 5 cm.

134 Two composite plant samples of forage species were taken from each plot on all harvest  
135 occasions. One sample was dried at 105 °C for at least 48 hours for DM determination. The  
136 other sample was stored cool in a perforated plastic bag (hole diameter 0.4 mm; Cryovac®,  
137 Duncan, S.C.) and sorted fresh within 48 hours into sown components and unsown species,  
138 which were dried in a forced-draught oven (55°C, minimum 48 h). Micronutrient analyses  
139 were made on each of the sown species from the first two harvests. To this end, these samples  
140 were milled (particle size <1 mm) in a cutting mill (Grindomix GM 200, Retsch GmbH,  
141 Haan, Germany) with a titanium knife and a plastic container which ensured minimal  
142 micronutrient contamination of the samples (*Dahlin et al., 2012*). The milled samples were

143 wet digested with 7 M ultrapure nitric acid and concentrated hydrogen fluoride at increasing  
144 temperature until boiling, then filtered and analysed for Co, Cu, Fe, Mn, Mo and Zn by ICP-  
145 SFMS at ALS Scandinavia AB in Luleå, Sweden.

146

### 147 **3 Statistics**

148 Micronutrient concentration and off-take (species proportion of DM yield  $\times$  concentration)  
149 differences between species at all sites were analysed for each harvest with a linear mixed  
150 model with species and site as fixed factors and block as a random factor, followed by  
151 Tukey's HSD test, using JMP 8.0.1 (SAS Institute Inc., 2009). The overall micronutrient  
152 concentrations of the mixtures were calculated by taking the botanical proportion of each  
153 species in each mixture into account. Within each harvest, total DM yield and average  
154 micronutrient concentrations for each mixture were analysed with a linear mixed model with  
155 mixture and site as fixed factors and block as a random factor, followed by Tukey's HSD test.  
156 The effect of red clover proportion (of sown species) on the average micronutrient  
157 concentration was analysed per site in SAS (Institute Inc., Cary, NC, USA) with the  
158 procedure MIXED where site, mixture and the interaction between site and red clover  
159 proportion were set as fixed factors and block as a random factor. Where the residuals showed  
160 a non-normal distribution the data were ln-transformed and results are presented as back-  
161 transformed least square means.

## 162 **4 Results**

### 163 **4.1 Dry matter yield and botanical composition**

164 Rådde and Lillerud had similar DM yields at the first two harvests in 2011 but Lillerud had a  
165 larger DM yield than Rådde at the third harvest (Tab. 3). The DM yields were smaller at Ås

166 than at Rådde and Lillerud at the first harvest but larger than at Rådde at the second harvest.  
167 The accumulated DM yields of the different mixtures were 11.5-13.4 t DM ha<sup>-1</sup> at Rådde,  
168 14.6-16.6 t DM ha<sup>-1</sup> at Lillerud and 7.4-10.8 t DM ha<sup>-1</sup> at Ås.  
169 Timothy and red clover dominated the mixtures at all three sites with similar proportions of  
170 red clover among the mixtures at Lillerud and Rådde whereas there was greater variation in  
171 red clover proportion between mixtures at Ås (Tab. 3). The mean red clover DM proportion at  
172 all harvests was 29% (min 17- max 37%) at Rådde, 34% (min 19- max 44%) at Lillerud and  
173 44% (min 0.1- max 73%) at Ås. The DM proportion of meadow fescue was between 10-30%  
174 at Rådde and Ås, but around 5% at Lillerud in the first two harvests. The DM proportion of  
175 white clover and chicory at all sites was well below 10%, with the exception of chicory (15%)  
176 in the second harvest at Ås.

#### 177 **4.2 Micronutrient concentrations and off-takes of species**

178 Generally, chicory had the highest micronutrient concentrations of all species whereas  
179 timothy had the lowest (Tab. 4). The exception was at Rådde and Lillerud where white clover  
180 had higher Mo concentrations than chicory and timothy which had similar concentrations.  
181 Red clover and white clover had higher micronutrient concentrations than timothy with the  
182 exception of Mn and Zn. The two clovers had similar micronutrient concentrations, although  
183 there was a tendency for the concentrations to be higher in white clover. There were few clear  
184 differences between species with regard to Mn concentrations although timothy had higher  
185 concentrations than red clover at Lillerud and Rådde. Meadow fescue generally had  
186 micronutrient concentrations between those of timothy and red clover.

187 Despite the higher micronutrient concentrations chicory had smaller micronutrient off-take  
188 (often < 10% of total mixture) compared to timothy (<80% of total mixture) (Tab. 5), when  
189 DM yield proportion were taken into account. Further, red clover and timothy generally had

190 similar micronutrient off-take. The exception was Rådde where timothy had larger off-take  
191 than red clover for all micronutrients but Co. In contrast, red clover had larger Co, Cu and Fe  
192 off-take than timothy in the second harvest at Ås.

### 193 **4.3 Effect of site and red clover proportion on mixture micronutrient concentrations and** 194 **off-takes**

195 The overall micronutrient concentrations of the mixtures were always significantly affected  
196 by site but there were few differences between mixture types. The mixtures at Lillerud  
197 generally had higher micronutrient concentrations than those at Rådde and Ås, in particular at  
198 the second harvest (Fig. 1). Average micronutrient off-take of mixtures also indicates that  
199 higher amounts were removed with both harvests from Lillerud compared with Rådde and Ås  
200 (Tab. 5). Molybdenum concentration showed the largest variation between sites and was  
201 always significantly higher in the mixtures grown at Ås compared to those at Rådde and  
202 Lillerud (Fig. 1). The Co concentration of the mixtures was always positively correlated with  
203 the red clover proportion in the harvested biomass. This was also the case for Cu  
204 concentrations in mixtures grown at Ås and Lillerud. With one exception, the mixtures at Ås  
205 always showed a positive correlation between the red clover DM proportion and  
206 micronutrient concentrations. However, this relationship did not hold for Zn where  
207 concentration was negatively correlated with red clover DM proportion at the first harvest and  
208 unrelated to red clover DM at the second harvest. Iron and Zn concentrations at Rådde and  
209 Mo concentrations at Lillerud were positively correlated with red clover DM proportion at the  
210 second harvest occasion.

## 211 **5 Discussion**

### 212 **5.1 Dry matter yield and botanical compositions**

213 The accumulated DM yields recorded at all three sites were within the range previously  
214 reported for grass/clover leys in Sweden (e.g *Frankow-Lindberg et al.*, 2009, *Halling et al.*,  
215 2002). The results can be considered representative for the sites, as the temperature was  
216 normal and the precipitation only slightly higher than normal compared to the long-term  
217 average (Tab. 2). The four seed mixtures produced stands of different botanical compositions  
218 at the three sites, with a wide range of red clover DM proportions at Ås and less variation at  
219 Rådde and Lillerud. The overall increase of red clover and meadow fescue DM proportion, at  
220 the expense of timothy, with each harvest is similar to the findings of *Jørgensen and Junttila*  
221 (1994) and *Mela* (2003). But, the overall grass proportion was similar irrespective of the  
222 mixture contained timothy only, or timothy and meadow fescue. White clover DM  
223 proportions were low at all sites and all harvests, in contrast to *Halling et al.*, (2002) who  
224 found increases of white clover with each subsequent harvest. Also, the DM proportion of  
225 chicory was much lower than those reported from other sites in northern Europe (*Høgh-*  
226 *Jensen et al.*, 2006; *Weller and Bowling*, 2002). This was due to the unexpectedly poor  
227 establishment of this species at all sites. Hence, the presence of chicory and white clover had  
228 little impact on the botanical composition and thus were less important with respect to  
229 micronutrient concentration of the whole mixture. This means that the proportions of red  
230 clover and timothy were the main components affecting the total micronutrient concentration  
231 of the crop.

## 232 **5.2 Micronutrient concentrations**

233 The micronutrient concentrations of the species were similar to the levels found in other  
234 studies (e.g. *Forbes and Gelman*, 1981; *Pirhofer-Walzl et al.*, 2011). Exceptions were the  
235 generally low Co concentrations in the species at all sites and unusually high Mo  
236 concentrations at Ås. Micronutrient concentrations in the different species was generally in  
237 the order chicory>clover>grass. Amongst the grass species timothy had the lowest

238 micronutrient concentrations. This is similar to the species rankings published by *Lindström et*  
239 *al.* (2012) and to conclusions regarding differences between forbs, legumes and grasses in  
240 previous studies (e.g. *Pirhofer-Walzl et al.*, 2011). Furthermore, our study confirms that  
241 chicory tends to have relatively low Mo concentrations compared to other species, which  
242 could be due to the fact that it can use ammonium as an N source (*Santamaria et al.*, 1998),  
243 and that there are few differences between species now studied with regard to Mn  
244 concentrations.

245 Red clover and timothy dominated the species mixtures and hence affected the overall  
246 micronutrient concentration and off-take of the mixtures most strongly. This was most  
247 obvious at Ås where the large variation in red clover DM proportion resulted in positive  
248 correlations between the red clover proportion and the overall concentrations of the mixtures  
249 of all micronutrients except Zn (Fig. 1). A similar pattern was observed at Rådde and Lillerud,  
250 in particular for Co where even a small increase of red clover DM proportion increased the  
251 overall Co concentration of the mixture. An increase in red clover DM proportion from 10%  
252 to 25% at Rådde or from 25% to 50% at Lillerud and Ås increased the average Co  
253 concentration of the mixture by more than 30% at the first harvest and more than 80% at the  
254 second harvest. Within the same range of red clover DM proportions, Cu and Fe  
255 concentrations increased by more than 15% and 40% at the first and second harvests,  
256 respectively, at Ås for both micronutrients, at Lillerud for Cu and at Rådde for Fe. Moreover,  
257 at Ås, the concentrations of Co, Cu and Fe more than doubled when comparing the lowest red  
258 clover DM proportion with the highest proportion. These findings support our hypothesis that  
259 the overall micronutrient concentrations of forage mixtures are affected by the red clover DM  
260 proportion and site effects. Our findings also increase the available information on the impact  
261 of clovers on the micronutrient concentration of grass-legume mixtures compared to pure

262 grass swards, as suggested by *Govasmark et al. (2005)*, *Høgh-Jensen and Sjøegaard (2012)*  
263 and *Kunelius et al. (2006)*.

264

### 265 **5.3 Site effects**

266 The three sites were deliberately chosen to have contrasting soil micronutrient concentrations,  
267 as analysed by nitric acid. The soil at Ås belongs to the 10% of Swedish soils with the highest  
268 Co, Mn and Zn concentrations and has above average Cu and Mo concentrations, according to  
269 the Swedish arable soils monitoring program (*Eriksson et al., 2010*). Lillerud has average (25-  
270 75 percentile) Co, Cu, Mn and Zn concentrations in the soil. Rådde has Co, Cu and Zn  
271 concentrations within the lowest 25% but more average concentrations of the other  
272 micronutrients studied. However, plant micronutrient concentrations are also affected by a  
273 range of other site factors including soil organic matter (*Adriano, 2001*), proportion of clay  
274 (*McBride, 1994*) and the weather during the experimental period (*Roche et al., 2009*).

275 The generally higher micronutrient concentrations in the forage species grown at Lillerud  
276 indicated that soil micronutrients were relatively available at this site compared to the other  
277 sites. The soil at Ås had higher micronutrient concentrations (pseudo-total concentrations  
278 extracted by nitric acid and EDTA used as a proxy for the plant available fraction) than  
279 Lillerud but the micronutrients were obviously less plant available. This might be explained  
280 by the high pH (above 7) of the Ås soil since this limits the availability of most micronutrients  
281 except Mo (*McBride, 1994*). The high plant Mo concentration at Ås is a further sign of this.  
282 However, we cannot exclude temperature effects (*Whitehead, 2000*). Another explanation of  
283 the relatively low micronutrient concentrations of the mixtures at the second harvest at Ås  
284 could, at least partly, be due to a dilution effect since the DM yield of this harvest was larger  
285 than at the other sites.

286 The Rådde soil had a similar pH to the Lillerud soil but a higher total C concentration, lower  
287 clay proportion and lower soil micronutrient concentrations. The DM yields at the two sites  
288 were similar but the micronutrient concentrations of the plants were lower at Rådde. The  
289 availability of micronutrients may be negatively or positively correlated with the organic C of  
290 a soil depending on the affinity of the respective micronutrient for the organic matter  
291 (*Adriano, 2001*) and whether there is a net immobilization into or mineralization from the soil  
292 organic matter pool. Further, a high clay proportion typically gives a high micronutrient  
293 availability (*McBride, 1994*). In addition to the higher micronutrient concentrations in the soil  
294 at Lillerud compared to that of Rådde, this could be the reason for the higher micronutrient  
295 concentrations in the biomass harvested at Lillerud than at Rådde.

296 Our results exemplify the difficulty in interpreting soil micronutrient analysis since the uptake  
297 by plants is a continuous biochemical process in contrast to soil analysis which is purely  
298 chemical processes and presents a snapshot of the soil micronutrient status (*Bussink and*  
299 *Temminghoff, 2004*). As seen in studies by *Jarvis and Whitehead (1981; 1983)* the variation in  
300 soil Cu concentrations between the twenty-one soils they studied was wider than between the  
301 Cu concentrations of the plants grown on them, in this case pure stands of perennial ryegrass  
302 and white clover. A similar comparison between species mixtures in this study (at a common  
303 red clover DM proportion of 25%) shows that the largest variations in EDTA-extracted soil  
304 occurred for Co and Mn concentrations which varied by a factor 10 – 20 between the three  
305 sites, while plant concentrations varied at most 2.5 times. The largest variation between  
306 mixtures due to red clover DM proportion was 8.5 times for Co concentration and 1.2 times  
307 for Mn concentrations, at Ås at the second harvest. This was due to the large differences in Co  
308 concentrations but small differences in Mn concentrations between red clover and timothy.  
309 On the other hand, Mo concentrations varied little between soils (the EDTA-extractable  
310 concentrations were below detection limit, but nitric acid extractable concentrations varied 4.2

311 times) while there was a 12-fold difference in plant Mo concentrations due to sites. In  
312 conclusion, the variation between species grown on the three study sites with regard to Co and  
313 Mn as well as Cu, Fe and Zn were smaller than the variation between the micronutrient  
314 concentrations extracted from the soil, whereas the opposite was true for Mo. A small  
315 variation in plant micronutrient concentrations was expected since plants can actively regulate  
316 their uptake of most micronutrients (*Marschner, 1995*).

317 Mineral N, P and K fertilizers may contain traces of micronutrients (*Eriksson, 2001*) which  
318 may affect the nutrient balance of the fields (e.g. *Bengtsson et al., 2003*). The current field  
319 experiments were N fertilized in a similar way at all sites. In contrast, the timing and amounts  
320 of P and K fertilizer differed between sites, partly due to soil status, which demanded products  
321 with different P:K ratios. One of the fertilizers contained a known, low concentration of Zn  
322 but traces of micronutrients may also have been present in all the used fertilisers. This might  
323 have affected the micronutrient uptake by the forage crop and resulted in site differences.  
324 However, the amounts of micronutrients estimated to have been added by the mineral  
325 fertilizers were small in comparison to the amounts of removed in the harvested crop.

#### 326 **5.4 Implications of the results**

327 The high DM yield proportion of timothy resulted in similar or higher micronutrient off-take  
328 despite its overall low concentration, compared to red clover. However, it is the concentration  
329 of micronutrients that determines the feed quality. Compared to the demands of lactating  
330 dairy cows (*National Research Council, 2001*), the requirements for Fe and Mn  
331 concentrations were met irrespective of red clover DM proportion and site whereas Co, Cu  
332 and Zn concentrations were generally too low. Despite the positive correlations between  
333 increased red clover DM proportions and increased Co concentrations of the mixtures at all  
334 sites, the concentrations were never more than half of the requirements of dairy cows (0.11

335 mg Co kg<sup>-1</sup> DM). However, plant material grown at Lillerud was close to the requirements of  
336 11 mg Cu kg<sup>-1</sup> DM and 43-55 mg Zn kg<sup>-1</sup> DM (low to high lactating cows). This was because  
337 Cu and Zn concentrations were higher in herbage at Lillerud than at the other sites. At  
338 Lillerud, the required Cu concentration of dairy cows was met where the red clover DM  
339 proportion at the second harvest exceeded 50%. The red clover DM proportion was also  
340 important for Fe and Mn concentrations at Ås at the second harvest. This was because  
341 decreased red clover DM proportion decreased the Fe and Mn concentrations close to the  
342 minimum requirement of 18 mg Fe kg<sup>-1</sup> DM and 14 mg Mn kg<sup>-1</sup> DM. In practise, other  
343 options are available to the farmer to provide animals with the required micronutrients where  
344 soils are deficient in some element, such as fertilization of the crop. Still, as the required  
345 concentrations in plants are frequently lower than those recommended for livestock feed  
346 supplements are generally given in conventional farming. However, in systems such as  
347 organic farming alternatives to dependency of external inputs are favoured. Furthermore, at  
348 farms with high soil concentrations of e.g. Cu and Zn, consideration of long-term soil health  
349 may call for other means of meeting animal micronutrient demands than fertilizing the soil or  
350 supplementing the feed and thereby generating Cu and Zn rich manure.

351 In order to favour the clover proportion in the sward, large applications of N fertilizer should  
352 be avoided or grasses will easily out-compete legumes. Even so, red clover proportion  
353 generally declines with sward age (*Mela, 2003*) which could result in a decline of  
354 micronutrient concentrations in the harvested plant material. However, white clover DM  
355 proportion tends to increase with time and is as rich in micronutrients as red clover.  
356 Consequently, a grass mixture with red and white clover gives a higher yield stability of  
357 clovers (*Frankow-Lindberg et al., 2009*), and such a mixture may also result in more stable  
358 micronutrient concentrations in the forage over time.

## 359 **6 Conclusions**

360 The generally high micronutrient concentrations of red clover compared to timothy resulted in  
361 a positive correlation between red clover DM proportion and the overall micronutrient  
362 concentration of the mixture. This was seen for several micronutrients at three contrasting  
363 sites. The micronutrient concentration levels in the harvested biomass also differed between  
364 the sites. Thus, our results suggest that increased red clover DM proportion in the sward have  
365 a potential to increase the overall micronutrient concentrations but that the effect of soil is  
366 also very important.

### 367 **Acknowledgements**

368 We thank SW Seed, Svalöv Sweden, for providing the seeds and everyone at the Rådde,  
369 Örebro and Ås research stations who helped out with the field experiments. This study was  
370 funded by Swedish Farmers' Foundation for Agricultural Research (SLF) project H0841014,  
371 the Swedish Research Council for Environment, Agricultural Sciences and Spatial Planning  
372 (FORMAS) project 2007-1636 and co-funded by the Swedish University of Agricultural  
373 Sciences (SLU).

504 **Figure 1:** Overall micronutrient concentration in relation to red clover proportion (% of DM  
 505 of the sown species) of species mixture at first (left row) and second (right row) harvest  
 506 occasions, in 2010, at Rådde (○-----), Lillerud (■——) and Ås (▲ ·····). Regression lines  
 507 indicate significant (\*:  $P < 0.05$ ; \*\*:  $P < 0.01-0.001$ ; \*\*\*:  $P < 0.001$ ) and near-significant (p-  
 508 values in figure) relationships. Horizontal dashed-dotted line indicate minimum dairy cow  
 509 requirement for low lactating cows; for Co this falls above the graph range ( $0.11 \text{ mg kg}^{-1}$   
 510 DM). With the exception of Co at the second harvest, all data were ln-transformed during  
 511 statistical analyses but the graph presents actual values, hence the lines are presented back-  
 512 transformed (n=12).
