Abstract Radiotherapy is one of the principal modalities of rectal cancer treatment, and the ability to predict radioresistance could potentially improve survival through a targeted treatment approach. Cyclooxygenase-2 (COX-2) may protect against damage by irradiation that would justify the use of COX-2 inhibitors. The purpose of this study was to investigate the potential role of COX-2 in tumor response and outcome of patients with rectal cancer treated preoperatively with radiotherapy. Using immunohistochemistry, we examined COX-2 expression in 88 surgical specimens of rectal cancer treated preoperatively and in 26 pretherapeutic biopsies. We tested whether COX-2 expression was correlated with clinico-pathologic parameters and with survival and local recurrence. COX-2 was expressed in 50% of the pretherapeutic tumor biopsies and in 88.6% of post-irradiated surgical samples. COX-2 expression was correlated only with enhanced tumor

inflammation ($p=0.03$) and with tumor volume exceeding 30 cc ($p=0.05$). COX-2 was not significantly correlated with patient survival, but none of the patients with COX-2 negative tumors did recur locally, whereas 80% of patients with local recurrences have COX-2 positive tumors. We conclude that COX-2 expression is overexpressed in the majority of rectal cancers treated with radiotherapy and likely plays a role in local relapse.

Keywords Radiotherapy · Rectal cancer · Cyclooxygenase-2 · Survival · Recurrence

Introduction

Nowadays, many therapeutic procedures are available for locally advanced rectal cancer (LARC). However, except the fact that surgery with total mesorectal excision is the mainstay of treatment [11–13, 16, 30], there is no consensus amongst the published literature about what should be the “standard” treatment and the primary endpoint in rectal cancer. Studies with systemic treatment do not show an impact of chemotherapy on overall survival or progression-free survival [1, 10]. In Europe, in contrast to the United States and Canada, a preoperative radiotherapy has been considered as the preferred treatment option for LARC to reduce the incidence of local recurrence [17, 38].

In addition to the problem of the best choice of a standard treatment, the therapeutic efficacy is often hindered by tumor resistance and especially tumor radioresistance. Recent studies indicate that COX-2, an enzyme involved in the metabolic conversion of arachidonic acid to prostaglandins, plays an important role in tumor growth and spread of established tumors by affecting mitogenesis, cellular adhesion, immune surveillance, apoptosis, and

angiogenesis [6, 21, 24, 34, 44, 41, 46]. Several studies have shown that COX-2 expression is elevated in human colorectal neoplasia as compared to normal mucosa, thus making COX-2 a potential target for chemoprevention [7, 15, 42]. A possible relationship between COX-2 expression in colorectal cancer tumors and patient survival has been investigated but nowadays data are inconclusive [8, 20, 22, 28, 33, 40, 48]. Because COX-2 may also be involved in tumor radio resistance, targeting of COX-2 or downstream products (prostaglandins) may eventually improve tumor response to radiotherapy [25, 26]. In vitro and in vivo studies have shown that treatment with selective COX-2 inhibitors significantly enhances tumor response to radiation without appreciably affecting normal tissue radio response [19, 23, 26, 29]. However, evidence of enhanced tumor response to radiation is less obvious in human models.

The purpose of this study was to investigate the relationship between the radiation resistance and the level of COX-2 on a retrospective series of patients with locally advanced rectal cancer (LARC) treated exclusively with radiotherapy. We therefore investigated COX-2 expression in pretherapeutic biopsies and surgical specimens and we tried to correlate it with histological response and clinical outcome.

Materials and methods

Patients

Between 1993 and 2002, 279 patients with locally advanced rectal cancer were included in a multicenter phase II trial on preoperative hyperfractionated and accelerated radiotherapy approved by the Human Investigations Committee of the radiation oncology centers [5]. Only 104 patients treated in our institution and already selected for a previously reported study were considered for this analysis [2].

Patients were eligible if they presented at preoperative work-up with cT3–cT4, whatever the N-stage, or cT1–cT2 with radiological evidence of positive lymph nodes. All patients were treated on protocol after obtaining informed consent for treatment. The age of the patients ranged from 28 to 85 (median, 63 years) and the sex ratio was 1.2 (female/male). Before initiation of the treatment, all patients underwent complete clinical examination, endoscopic biopsy, blood count, assessment of renal and hepatic function, and CEA determination. Distant metastatic disease was excluded by chest X-ray and abdominal ultrasound or computed tomography (CT scan). Assessment of the local extension of the tumor was done by digital rectal examination, rectal ultrasound, and/or CT scan. All patients were irradiated according to the same protocol [5]. The decision concerning the surgical technique, mainly abdominoperineal resection (APR) or low anterior resection, is left to the individual surgeons. The protocol

stipulates that a total mesorectal excision with a sharp dissection is “the surgical standard” for those rectal tumors.

Biopsy specimens

Only 26 patients had pretherapeutic biopsies that were available for immunohistochemistry. Biopsies had been fixed in 10% neutral formalin for 12–24 h at room temperature. In the remainder cases, the tumor samples had been exhausted during previous studies and were no more present in the paraffin blocks or immunostaining failed because the material had been fixed in sublimated formol.

Macroscopical assessment of surgical specimens

The surgical specimens were fixed in 10% buffered neutral formalin for 24 h. The whole tumor and attached mesorectum were serially sliced at 3- to 4-mm intervals perpendicular to the longitudinal axis of the rectum, which allowed macroscopical identification of the areas of deepest invasion.

Histological assessment of surgical specimens

All irradiated rectal tumors were retrospectively reanalyzed (H.B). The tumors were classified according to the WHO classification of tumors of the digestive system [47] and staged according to the TNM classification [35]. Tumor downstaging was obtained by comparison of the clinical preoperative and postoperative pathological tumor staging. Tumor volume was calculated on the length and width evaluated on the macroscopical examination and on the tumor thickness assessed on slides. Tumor inflammation, tumor necrosis, and tumor regression were graded as previously described [2]. Tumor inflammatory reaction (mononuclear and granular cells) was graded as 1 when absent or mild, 2 when moderate, and 3 when extensive. Tumor necrosis was graded as 1 when absent or less than 25% of the tumor mass, 2 when it represented 25–50% of the tumor mass, 3 when it represented 50–75% of the tumor mass, and 4 when it represented 75% of the tumor mass. Tumor regression was graded in five grades, based on the presence of residual tumor cells and the extent of fibrosis. Grade 1 was defined as sterilization of the tumor, grade 2 by the presence of rare residual cancer cells scattered through the fibrosis, grade 3 by more residual tumor cells but fibrosis still predominates, grade 4 by more residual cancer cells than fibrosis, and grade 5 when the tumor shows no signs of regression. Vascular invasion was also recorded.

COX-2 immunohistochemistry

Four-micrometer-thick tissue sections were deparaffinized in xylene, rehydrated, treated with 0.3% H₂O₂ in methanol

for 30 min to block endogenous peroxidase activity. The antigen retrieval was done using a pressure cooker. After preheating 1 l of 0.01 M sodium citrate buffer, pH6.0 until boiling in a stainless steel pressure cooker, the sections were heated for 2 min, during which the pressure cooker reached operating temperature. Subsequently, the pressure cooker was removed from the heat source and placed under running cold water with the lid on to cool it down. The slides were placed in a container with running cold water and cooling continued for another 10 min. The sections were subsequently rinsed in phosphate-buffered saline (PBS) and conditioned with 10% normal goat serum for 30 min at room temperature (RT) and incubated with anti-COX-2 monoclonal antibody (Cayman Chemical, Ann Arbor, MI, USA) diluted at 1:200 in PBS with 0.1 M NaCl at RT for 2 h. After rinsing in PBS, the slides were incubated with DAKO EnVision™ (mouse) for 30 min at RT. After the slides were rinsed in PBS, peroxidase was revealed by immersion in diaminobenzidine (DAB; DAKO, Carpinteria, CA, USA) according to the manufacturer's instructions and the sections were counterstained with hematoxylin and mounted for microscopic examination. The negative control was performed by using COX-2 blocking peptide diluted at 1:50 according to the manufacturer's instructions (Cayman Chemical). Immunohistochemical expression of COX-2 was evaluated semiquantitatively by two observers using a double-headed microscope (H.B, P.Y) on blinded sections. There was no staining on the negative control slide. Staining for COX-2 in the normal rectal mucosa was used as a positive control. Absorptive epithelial cells bordering the luminal surface and especially basal part of the crypts showed COX-2 positivity, generally localized in the paranuclear region and cell membranes, less frequently in the nuclei. If no crypt staining was obtained after two attempts, the case was eliminated from the study on technical grounds. In tumor cells, COX-2 immunoreactivity was observed in the cytoplasm and/or in the nuclei (Fig. 1). The spindle-shaped stromal cells, intermingled with neoplastic glands, sometimes showed staining for COX-2. All cases were scored as following: score 0: <5% of positive cells; score 1: 5–30% of positive cells; score 2: 30–60% of positive cells; score 3: >60% of positive cells. Tumor cases with COX-2 score 0 were considered as negative.

Statistical analysis and follow-up

All patients were followed for local recurrence and distant metastasis every 6 months for the first 2 years and every year thereafter. A physical examination, serum carcinoembryonic antigen (CEA) assay, chest X-ray, abdominal ultrasound or CT scan, and a CT scan of the pelvis were included in the follow-up procedure. The events were death

(all causes of death included) for overall survival (OS), distant metastases or locoregional relapse or death for disease-free survival (DFS), and local or locoregional relapse for local control (patients who died without local or locoregional relapse were censored at time of death), respectively.

All statistical analyses were conducted using the JUMP software (SAS, Cary, NC). A *p* value <0.05 was considered statistically significant. In univariate and multivariate analysis, OS, DFS, and local control were used as the end points. In univariate analysis survival curves were estimated according to the Kaplan–Meier method for the following variables: age, sex, pT, pN, tumor differentiation, tumor inflammation, tumor necrosis, tumor regression, tumor volume, and vascular invasion. The significance of their difference was estimated by the log-rank test. To increase the number of patients per group, the categories of the different pathological variables were also combined for these analyses, i.e., pT1–2 vs pT3–4; well and moderately differentiated adenocarcinomas vs poorly differentiated and mucinous carcinomas; absence or mild necrosis (score 1) vs moderate to extensive necrosis (scores 2–4); absence or mild inflammation (score 1) vs moderate to marked inflammation (scores 2 and 3); responder group (tumor regression grades 2–4) vs non-responder group (tumor regression grade 5).

Multivariate survival analysis according to the Cox's proportional hazards models was constructed by backward elimination of the following variables: age, sex, pT, pN, tumor differentiation, tumor inflammation, tumor necrosis, tumor regression, and vascular invasion.

Results

Pathological findings

Eighty-eight out of 104 patients with rectal cancer were selected for the COX-2 study. The remainder cases were excluded because the tumour was sterilized (tumor regression grade 1) or for technical reasons. There were 20 pT2 tumors (23%), 57 pT3 (65%), and 11 pT4 (12%). Tumor downstaging obtained after comparison of the clinical and pathological stages was observed in 44% of the cases. Regional lymph node metastases were found in 59% of patients. Of the tumors, 25% were well-differentiated adenocarcinomas, 42% were moderately differentiated adenocarcinomas, 10% were poorly differentiated adenocarcinomas, and 25% were mucinous carcinomas. Partial tumor regression (G2–4) was noted in 80% (G2=16%; G3=39%; G4=25%) and absence of regression (G5) was noted in 20% of the tumors. Tumor necrosis was absent or mild (score 1) in 66% of the tumors, moderate to extensive

Fig. 1 Low (a) and high magnification (b) of COX-2 expression in a rectal adenocarcinoma treated preoperatively with radiotherapy

in 34% (scores 2–4) of the tumors. Tumors showed a mild or no inflammation (score 1) in 30% of cases, a moderate to marked inflammation in 70% (score 2 and 3) of cases. Vascular invasion was present in 29 patients.

Survival and local control

During follow-up (median=42 months), 24 patients developed distant metastasis and eight patients a local recurrence. Thirty-nine patients died, 29 of whom from rectal cancer.

The median OS was 53 months. The median actuarial OS was significantly lower in patients with lymph node metastases ($p=0.005$, log rank test) and for those patients presenting tumors with vascular invasion ($p=0.003$). There was no difference in OS between responders (G2–4) compared to non-responders (G5).

The median DFS was 46 months. The median actuarial DFS was significantly lower in patients with advanced pT stages (pT3–4) ($p=0.03$, log rank test) and with lymph node metastases ($p=0.0008$, log rank test). The DFS was longer in responders than in non responders ($p=0.03$, log rank test). Moreover, a significant correlation was found between the different grades of tumor regression and DFS ($p=0.04$, log rank test).

The actuarial locoregional recurrence rates at 2 and 5 years were 7.5% and 11.4%, respectively. There was a trend for a better local control in responders as compared to non-responders ($p=0.10$, log rank test).

Cyclooxygenase-2 immunostaining and pathologic analysis

By immunohistochemistry COX-2 was found to be absent in 13 (50%) out of 26 tumor biopsies taken before treatment (score 0). In tumor biopsies expressing COX-2, four cases were scored 1, four cases were scored 2, and five cases were scored 3.

In 88 surgical specimens, ten tumors (11%) did not express COX-2 (score 0). Of 78 COX-2 positive tumors (89%), 38 (44%) had a mild (score 1), 25 (28%) a moderate

(score 2), and 15 (17%) a marked (score 3) COX-2 expression. The distribution of COX-2 expression and pathologic parameters is summarized in the Table 1. When comparing COX-2 expression in biopsies and surgical specimens we found that among 13 patients with negative tumor biopsies, ten (78%) became COX-2 positive in the surgical specimens with a scoring of expression varying from 1 to 3, whereas only three cases remained negative after irradiation. Among the cases with positive COX-2 in tumor biopsies, two had a higher score of expression, seven had the same score of expression, whereas four cases had a lower score of expression in the irradiated tumors.

COX-2 expression was not correlated with any of the following parameters: sex, age, tumor downstaging, pT, pN, tumor regression, tumor necrosis, vascular invasion. We found a trend of correlation between COX-2 and tumor differentiation ($p=0.087$). COX-2 was correlated with moderate and marked tumor inflammation ($p=0.03$) and with tumor volume exceeding 30 cc ($p=0.05$). Grouping according to level of expression of COX-2 with any of the tested pathological variables did not modify the conclusions of the present analysis.

We were not able to demonstrate any significant correlation between the expression level of COX-2 and OS and DFS. However, it is noteworthy that none of the patients having tumor without COX-2 expression did recur locally (0/10), in contrast to eight out of ten recurrences (80%) in 78 patients with tumor characterized by a COX-2 expression. It might well be that the number of local events is too small in the present series to allow us to highlight a significant difference.

Discussion

Colorectal cancer is a significant cause of morbidity and mortality in Western populations. Rectal cancer if treated by surgery alone is characterized by a high incidence of local recurrence (20 to 70%), regional lymph node and distant metastases [17, 38]. Until now, there is no consensus

Table 1 Correlations between COX-2 expression and histological parameters in 88 surgical specimens of rectal cancer treated with preoperative radiotherapy

NS non significant

among the published literature about what should be the “standard” treatment and the primary endpoint in rectal cancer (survival, disease-free survival, local control, sphincter sparing surgery or quality of life). However, neoadjuvant preoperative radiotherapy has been shown to induce tumor regression significantly, improving local control and overall survival [2, 5, 32]. Nevertheless, the tumor response, which is different from one patient to another, is probably limited by many genetic factors. Among those factors, the COX-2 appears to play an important role. Cyclooxygenase is a key enzyme that catalyses the conversion of prostaglandins and other eicosanoids from arachidonic acid. COX-2 is induced during pathologic conditions and is often overexpressed in premalignant lesions and malignant tumors [3, 6, 24, 43, 44]. This enzyme is linked to carcinogenesis, maintenance of progressive tumor growth, and facilitation of metastatic spread [4, 41]. Several studies have shown that COX-2 expression is elevated in human adenomas and colon cancers [7, 31, 33].

Data about the relationship between COX-2 expression and patient survival in colorectal cancer are inconclusive [8, 15, 20, 22, 28, 33, 36, 40, 48]. However, COX-2 protein

expression has become the focus of active investigation because of its possible implication in tumor radio resistance. Indeed, it was reported that COX2 is upregulated by radiation, inducing radio resistance [25, 26, 29]. Preclinical studies have shown that treatment with selective COX-2 inhibitors significantly enhances tumor response to radiation without appreciably affecting normal tissue radio response [19, 26]. However, if in vitro and in vivo results support this hypothesis, the data available from human studies are scarce. In oral squamous cell carcinoma [39] and in laryngeal cancer [27] elevated COX-2 expression has been associated with radio resistance and diminished survival. Expression of COX-2 was also correlated with poor prognosis in squamous cell carcinoma of the uterine cervix treated with radiation therapy [9, 18].

In the present study, we investigated by immunohistochemistry the expression of COX-2 in 88 surgical specimens from a cohort of patients with rectal cancer treated preoperatively with radiotherapy and attempted to correlate this with pathologic parameters and clinical outcome. We also investigated the expression of COX-2 before neoadjuvant radiotherapy in a subset of rectal cancers with available tumor biopsies. COX-2 expression was present in

50% of pretherapeutic tumor biopsies and 89% of irradiated tumors. We found also that the large majority of negative tumor biopsies expressed COX-2 protein after radiotherapy and that a subset of positive tumor biopsies has an increased expression. This finding support the fact that, at least in a subgroup of rectal cancer, COX-2 is upregulated by radiation as already reported in some cancer cell lines [37]. However, this is in partial contradiction with a recent study that compared COX-2 expression in pretherapeutic rectal carcinoma biopsies and posttherapeutic surgical specimen and which found that COX-2 expression is present in nearly all pretherapeutic biopsies although there is an increase of the intensity of COX-2 expression in one third of posttherapeutic rectal cancer [45].

In the present analysis, COX-2 expression in post irradiated tumors was not correlated with any of the tested pathologic parameters in particular with tumor regression and tumor downstaging. We found that COX-2 was correlated with tumor inflammation which is in accordance with the fact that COX-2 is known to be induced by proinflammatory cytokines and that COX-2 is upregulated at sites of inflammation [14]. We also found that COX2 was more frequently expressed when tumor volume exceeds 30 cc. We were not able to provide an explanation for this finding especially as we did not find any correlation with tumor regression or tumor downstaging.

More importantly, we found that COX-2 expression is not a significant prognostic factor neither for overall patient survival nor for DFS in irradiated rectal carcinomas. These data are in line with one published study on human rectal cancer pretreated with chemoradiotherapy [45] but are not in accordance with the results reported in studies on squamous cell carcinoma of head and neck and cervix treated with radiotherapy alone or radiochemotherapy [39, 27, 9, 18].

Nevertheless, we found that there was a trend toward increased local failure in patients with treated tumors expressing COX-2. In contrast, all the patients with COX-2 negative tumors were free of local recurrence. The difference was not statistically significant, probably due to the small number of recurrences overall. However, testing of this hypothesis within the frame of a randomized trial could be interesting.

Conclusion

This study shows that radiotherapy induces an expression of COX-2 in the majority of rectal cancer patients and is correlated with tumor inflammation. COX-2 expression is not associated with rectal cancer survival and tumor response, but a possible association with local recurrence remains to be evaluated in a larger cohort of patients with rectal cancer treated by preoperative radiotherapy.
